Henry’s law states that ‘at constant temperature, the amount of gas which dissolves in a liquid with which it is in contact is proportional to the partial pressure of that gas’. Hence, while the amount or mass of gas which dissolves in a liquid is also dependent on that gas’s solubility, an increase in partial pressure of the gas will increase the amount that goes into solution.

The effects of these laws can be seen in Table 50.2.

The constituent gases of the diver’s breathing mixture have important pathophysiological effects. Oxygen is critical to metabolic processes and a reduced partial pressure of oxygen will result in hypoxaemia. However, the increase in oxygen partial pressure may also be toxic. Oxygen toxicity is more likely with increasing \( p_{O_2} \) and with duration of exposure. The lung may be affected with prolonged exposure to a \( p_{O_2} \) above 0.6 ata\(^{-1}\) and, in the central nervous system (CNS), prolonged exposure often manifests as convulsions with relatively short duration exposure to \( p_{O_2} \) above 1.6 ata.\(^4\) CNS toxicity is enhanced by exertion,\(^5\) so a diver at rest in a chamber can tolerate a \( p_{O_2} \) of 2.8 ata which would result in convulsions if the diver was active in the water. Oxygen tolerance can be extended if exposure is intermittent.\(^6\) Nitrogen which is normally an inert component of the air we breath has narcotic and anaesthetic effects\(^7\) at high partial pressures, which limits the depth at which air can be used as a breathing mixture and represents a distinct safety hazard. The narcotic effects begin to be noticeable at a depth of about 30 msw (\( p_{N_2} \) approximately

for explosive gas mixtures. It has high thermal conductivity and introduces the potential for thermal control problems and produces speech distortions caused by gas density. However, it diffuses very easily, so also overcomes some of the respiratory problems. Argon is used as a shielding gas in welding operations. It is breathable but more narcotic than nitrogen. Argon has the advantages of having no narcotic effect and being very light, so also overcomes some of the respiratory problems caused by gas density. However, it diffuses very easily, has high thermal conductivity, and so introduces significant thermal control problems and produces speech distortion which affects vocal communications. Other gases may also be encountered. Argon is used as a shielding gas in welding operations. It is breathable but more narcotic than nitrogen and hence a hazard. Hydrogen has been used in some experimental deep dives for its minimal density. It has high thermal conductivity and introduces the potential for explosive gas mixtures.

## PRESSURE–RELATED PHYSIOLOGY AND PATHOPHYSIOLOGY

### MIDDLE EAR BAROTRAUMA

The most immediately recognized effect of change in environmental pressure is the result on the middle ear cavity. The Eustachian tube is normally closed and hence the middle ear cavity is a closed gas space with one flexible side, the tympanic membrane. The body tissues behave like a fluid and transmit pressure so any change in environmental pressure is transmitted to gas-containing spaces in the body. An increase in pressure results in a reduction in middle ear gas volume and causes movement of the tympanic membrane. This is readily sensed and can cause pain if the membrane is stretched enough. If the diver opens the Eustachian tube, air at ambient pressure passes up into the middle ear and the tympanic membrane moves back to the normal position. As a diver descends in the water or in a tunnel, the Eustachian tube is compressed in a gas environment, this action of ‘equalizing’ ear pressures is required recurrently until the diver reaches stable depth. If equalization is not performed, the differential pressure across the Eustachian tube may effectively prevent the diver from opening the tube and result in pain and trauma to the tympanic membrane or inner ear organs. The tympanic membrane may be bruised and haemorrhagic or may rupture, an event, which although painful, equalizes pressure. In most cases, middle ear barotrauma resolves within two weeks with complete healing of the ear drum. It is important to ensure Eustachian function has returned to normal before returning to diving or other pressure exposure. However, the transmitted pressure effects may also damage the organ of Corti and produce a permanent hearing loss. Vigorous attempts to equalize pressure by holding the nose and doing aValsalva manoeuvre increase intracerebral pressure and hence the pressure difference across the round window. Rupture of this membrane results in leak of endolymph into the middle ear and a gradual onset of vertigo, nausea and hearing loss. This is an emergency and requires urgent otological assessment.

### SINUS BAROTRAUMA

Other gas-containing spaces in the body may also cause problems. Sinus cavities should normally communicate with the nasal airways and hence not behave as closed spaces. However, minor inflammatory change in the nasal mucosa may readily close sinus ostia and so prevent free gas movement. These spaces are of fixed volume in bony cavities so cannot change volume. In the event of the gas content reducing in volume interstitial fluid and blood is effectively sucked into the mucosa, a process which can generate some pain. On subsequent ascent, the trapped gas expands again and may force mucous and blood out of the ostia into the nasal cavity. Although the presentation can be dramatic, the injury is usually minor and resolves spontaneously. Persistent inflammatory change in the sinus mucosa may result in persistent obstruction of the ostia and long-term inability to dive. Rarely, the acute event may result in local nerve injury to the fifth or seventh cranial nerves.

### PULMONARY BAROTRAUMA

The lungs are the largest gas-containing space in the body. In normal breathing, the lungs communicate freely with the upper airways and mouth so changes in environments. The lungs are the largest gas-containing space in the body. In normal breathing, the lungs communicate freely with the upper airways and mouth so changes in

Volume column shows the lung volume changes during a breath–hold dive from total lung capacity at the surface. MVV (maximum voluntary ventilation) shows the restriction of ventilation imposed by increasing gas density. pO2 column shows how an inspired partial pressure of 1 ata can be achieved either by breathing 100% oxygen on the surface or by breathing air at a depth of 40 msw.
volume of gas in the lungs can be easily compensated for during normal breathing. Should the diver either stop breathing, hold their breath or change depth rapidly, gas volume may change enough to injure the lung. Compression of the lung (squeeze) is extremely rare in normal diving or compressed air work, but a common issue in extreme breath-hold diving. Overexpansion of the lung (burst lung) is a much more important problem in diving with potentially fatal results. If during a rapid ascent, the diver does not exhale adequately, the lung will expand beyond normal volume and may rupture allowing gas to escape through the interstitial tissue of the lung. This gas may track to the pleural cavity causing pneumothorax often with tension, or into the mediastinum, or it may rupture into the pulmonary venous system and pass directly into the left heart and result in arterial gas embolism. Rarely, gas may track through the retroperitoneal space and cause pneumoperitoneum. Both tension pneumothorax and gas embolism may be rapidly fatal. Pneumothorax presents in a similar manner to spontaneous pneumothorax in other situations with chest pain and breathlessness and is treated in the same way. Pneumomediastinum often presents slowly after the dive, often several hours later with crepitus over the anterior chest and neck, discomfort in the neck and hoarse voice (Figure 50.1).

There is no specific treatment available, but breathing 100 per cent oxygen accelerates the removal of air from the tissues. Arterial gas embolism usually presents with an acute cerebral event, convulsion, loss of consciousness, sudden blindness or hemiplegia and is usually almost immediately following surfacing from a dive. Treatment is required rapidly and includes administration of 100 per cent oxygen and therapeutic recompression using an appropriate treatment procedure.

The pathogenesis of these disorders is incompletely understood. Arterial gas embolism occurs when the lung ruptures as a result of pulmonary barotrauma and gas is released into the pulmonary venous system. Relatively low transpulmonary pressure can rupture the lung, but many external factors may provide support to the thorax and lung, allowing the lung to sustain higher pressures.9,10 When gas escapes into the pulmonary venous system, its main target organ is the brain. Gas enters the cerebral circulation and, although some will pass through, it triggers circulatory change with local hyperaemia and an increase in cerebral blood volume, systemic hypertension, a loss of cerebral autoregulation and rapid development of cerebral oedema.1,12 The latter is almost certainly related to the injury to vascular endothelium. In those who survive the acute injury, the progress of the illness may be significantly affected by the presence of inert gas already dissolved in brain tissue. Dissolved gas may enhance the volume of gas involved exacerbating the pathological impact. Hence, an episode of arterial gas embolism occurring in the presence of a significant dissolved gas load may have a worse prognosis than one occurring without. Much of the clinical information concerning prognosis is derived from submarine escape training where dissolved gas load is minimal and hence may not reflect outcomes after an incident occurring during other diving activity.

The risk of sudden change in pressure is much less in compressed air work where the working chamber pressure and compression and decompression rates are controlled by a pressure lock operator. However, there remains a risk of explosive decompression resulting from engineering or equipment failure.

Figure 50.1 Lateral radiograph of a diver’s neck showing extensive air in deep tissues, confirming the diagnosis of pneumomediastinum. The diver had presented with a sore throat after an uneventful air dive.
Decompression sickness 551

BAROTRAUMA TO OTHER ORGANS

The bowel usually contains gas, but is distensible and ultimately open ended. Hence while gas movement may be recognized by the diver or tunneller, it is rarely pathological. A small number of cases of gastrointestinal barotrauma have been reported, but mostly associated with explosive uncontrolled ascent.

Gas spaces around the body are also affected. The gas space between a diver’s breathing mask and face is affected by pressure change. A diver’s mask includes the nose, allowing the diver to exhale through the nose to equalize pressure. Without this action, the diver’s periorbital soft tissues are effectively sucked into the mask space producing oedema and haemorrhage. This results in a dramatic appearance, but is not a serious injury.

Divers wearing a dry suit have an enclosed gas space around them which will reduce in volume during descent. Eventually, the suit will be compressed around the diver and folds in the suit material may trap subcutaneous tissues of the diver and result in linear bruising (suit squeeze) which may be painful (Figure 50.2).

Many modern suits now have a gas injection system allowing the diver to introduce additional gas and release the pressure. This provides more comfort, but introduces an additional hazard due to buoyancy effects.

DECOMPRESSION SICKNESS

Decompression sickness is a spectrum of clinical syndromes which result from the effects of the formation of excessive amounts of gas microbubbles in the tissues and bloodstream, during or after a decompression, from gas which had previously been dissolved in body tissues according to Henry’s law.13

When a diver or compressed air worker is exposed to increased environmental pressure and breathes a gas mixture containing an inert gas (e.g. nitrogen or helium), body tissues are exposed to an increase in partial pressure of that gas. As a result, additional gas dissolves. Some gas may diffuse through the skin directly into subcutaneous tissues, but the majority of the gas will dissolve initially in the pulmonary blood flow and be distributed gradually to all body tissues. This process of solution, distribution and diffusion is gradual and will take six to eight hours at a constant pressure until complete equilibrium in all body tissues is established.

At this point, the diver is said to be saturated with the inert gas at that particular pressure. On return to the surface, the partial pressure of the gas reduces and so the tissues become effectively supersaturated with gas which is then released from solution. On slow ascent, this excess gas will mostly be transferred through the circulation to the lungs and exhaled. However, the difference in partial pressure between the diver’s tissues and the environment may be sufficient to cause gas to come out of solution and form bubbles. Bubbles are not inert and the bubble surface is capable of triggering a reaction in tissues and in blood involving the coagulation system and an inflammatory process.14

Bubbles can be identified in both tissues and the circulation using ultrasound methods15 and it is recognized that some bubble formation is commonly seen after apparently safe dives or compressed air exposures and not associated with any ill effects.16 It appears most likely that a pathological outcome is triggered by a critical volume of gas bubbles, in particular tissues or perhaps a critical rate of formation. These critical factors may be different in different tissues and vary between individuals.

Recognized risk factors for clinical episodes of decompression sickness fall into two major categories: (1) pressure exposure-related factors, such as the depth (pressure) and duration of the exposure, previous exposures over the preceding hours and days; and (2) the ascent/decompression rate, decompression methodology and individual diver’s predisposing clinical factors, such as intracardiac shunt17,18 or personal susceptibility.19 Many cases in divers are provoked by incautious ascent, omitting appropriate decompression stops or by rapid and uncontrolled ascent as a result of loss of buoyancy control. In civil engineering or tunnelling operations, the incidence of decompression illness is significantly higher than in commercial diving. This may reflect longer exposures often approaching or reaching saturation levels repeated daily with relatively inadequate decompression procedures.

Symptoms of decompression sickness are very variable, but fall into several main categories.20

Neurological

Neurological symptoms include paraesthesiae of any area, sensory loss, focal weakness and disturbance of balance.21 More pronounced spinal cord involvement may cause
marked weakness and paraplegia or even tetraplegia and be associated with sphincter disturbance. Low back pain or pain in a girdle distribution is often a precursor of spinal cord symptoms. Vestibular symptoms (staggers) of nausea, vertigo and loss of balance may occur either with or without other neurological symptoms. Disturbance of cerebral function is less common, but well documented, and may include behavioural change or even loss of consciousness. Although the ultimate prognosis for neurological disease is usually for considerable recovery, this is the main cause of permanent disability resulting from decompression illness.

Constitutional

Many patients also report constitutional symptoms of tiredness, nausea, feeling cold or weak. These symptoms are most likely a result of hypovolaemia resulting from loss of fluid through damaged capillary endothelium into interstitial tissues and often improve rapidly with rehydration and therapeutic recompression.

Pulmonary

Pulmonary involvement (chokes) results from massive bubble load in the venous circulation and obstruction of the pulmonary circulation. This results in cough, breathlessness and haemoptysis. The resulting high pulmonary arterial pressure results in intrapulmonary shunting and passage of bubbles to the arterial circulation and severe neurological symptoms usually follow. Individuals with significant pulmonary involvement are critically ill and there is a high mortality.

The underlying pathology results from the formation of gas within tissues from molecules previously dissolved in tissues and hence the mechanisms relate to the appearance of microbubbles. These may occur in many tissues, but have been most commonly identified in the bloodstream using Doppler methodology. Microbubbles in tissue may migrate into the vascular bed. It is recognized that some gas microbubbles occur commonly after symptom-free decompressions, so it appears that the onset of disease may relate to a threshold which may be volume, number or rate of microbubbles.
of appearance. It is clear that the passage of microbubbles results in damage to the endothelium which results in fluid leak into interstitial tissues. This is important within the cerebral circulation resulting in cerebral oedema, but also results in significant haemoconcentration. Correction of haemoconcentration with large volumes of intravenous fluid often results in peripheral oedema and pleural effusion. Within the bloodstream, microbubbles trigger the coagulation cascade and stimulate platelet aggregation, and activate the complement system contributing to haemoconcentration.

These effects are well established; however, how these effects relate to specific organ-related symptoms is less clear. There is evidence that pulmonary symptoms are associated with the venous vascular bubble load. Increasing obstruction to the pulmonary capillary bed results in hypoxia and increasing pulmonary arterial pressure with symptoms of breathlessness, haemoptysis and chest tightness. Endothelial leak results in the development of pulmonary oedema.

As pulmonary arterial pressure rises, bubbles begin to appear in the arterial circulation. This is associated with the development of neurological manifestation, particularly of spinal cord origin. Whether spinal cord injury occurs primarily as a result of arterial bubble embolization or as a result of bubble formation in situ or a combination of both or other mechanisms is uncertain. The close association between spinal cord injury and right to left intracardiac shunt supports the theory that bubble embolization plays a role. Conversely, animal experimental work has demonstrated that autochonous (in situ) bubble formation can occur. The end result is the appearance of punctuate haemorrhagic lesions scattered in spinal cord tissue most obvious in white matter associated with axonal swelling and subsequent myelin degeneration.

Other symptoms of decompression sickness are also difficult to explain in terms of pathogenesis. The characteristic musculoskeletal pain symptom has been explained on the basis of gas present within the joint, within soft tissues around the joint, within narrow cavities of adjacent bone and as referred pain of neurological origin. Constitutional symptoms have been explained on the basis of the proinflammatory processes associated with decompression sickness, but might readily be explained by the hypovolaemia. The classical cutaneous manifestation of cutis marmorata shows evidence of an acute vasculitis on biopsy, but its origin may relate to embolization of cutaneous vessels or the direct transcutaneous migration of gas. The close association of this rash with right to left intracardiac shunt suggests embolization is more relevant. Vestibular decompression illness may result from gas formation from endolymph with subsequent damage to the semicircular canal sensor cells.

Symptoms may develop at any time after the commencement of the ascent phase of a dive, but are most common in divers in the first one to two hours following surfacing. Over 90 per cent of cases present within 24 hours of completion of the last exposure in both divers and tunellers. However, the pattern is complicated by travel involving ascent to altitude after exposure either by road or in commercial aircraft. Such altitude exposure may provoke symptoms during a period of 24–48 hours following exposure that may prove to be slow to resolve even with appropriate hyperbaric oxygen therapy.

Immediate first aid treatment includes administration of 100 per cent oxygen and rehydration by the most effective means available. Patients presenting with decompression illness should receive specialist assessment and transfer to a recompression unit for further treatment with intravenous fluids and recompression. Those patients with severe neurological illness or paraplegia may also require the expertise of a specialist spinal injury unit in their continuing management.

A 32-year-old compressed air diver made an emergency rapid ascent from a 12 minute dive to a depth of 30 msw. This was followed immediately by an impairment of consciousness and hemiparesis which resolved spontaneously within minutes. Some 20 minutes later, he noticed wooliness in his feet which progressed into classic paraplegia. He was evacuated by air to a chamber, where some 24 hours later he was recompressed but with little response. While in the chamber, a surgeon conducted a laparotomy 'because of paralytic ileus' and after decompression the wound dehisced. The patient emerged still paraplegic, but six months later was able to walk with two sticks.

Comment
It may be speculated that after a relatively short dive with little nitrogen gas load, the rapid ascent resulted in pulmonary barotrauma and cerebral gas embolism. Although these symptoms resolved spontaneously, either the pulmonary injury, or diffuse endothelial injury interfered with normal nitrogen elimination and resulted in neurological decompression illness. Severe neurological illness does not always respond to recompression therapy and the delay in recompression may have contributed to the lack of response. Paralytic ileus is common after severe spinal injury and may complicate the decompression phase of treatment. Surgical intervention in a chamber is best avoided.

### Bone Necrosis

Both divers and compressed air workers are at risk of developing dysbaric osteonecrosis. This is a form of aseptic bone necrosis which occurs as a long-term health effect (Figure 50.4). It may occur after a single pressure exposure, but is more likely after deeper and longer pressure exposures and it is more likely to occur in individuals with a history of acute decompression illness. It is discussed in detail below.
When the human body is placed upright in water, the water pressure difference between the feet and the head forces fluid to move upwards. As a result, a number of physiological changes occur. The normal distribution of blood volume is affected with blood from the lower limb extremity moving upwards and mainly being accommodated within the chest. This results in an increase in pulmonary blood volume and a rise in right atrial pressure. The former results in a small reduction in vital capacity impeding ventilation and the latter results in production of atrial natriuretic hormone and a resultant diuresis. The pressure difference between the centre of the chest and the mouth introduces a resistance to breathing, as drawing air down into the chest against the pressure gradient increases the work of inspiration. Conversely, the work of expiration is aided. These changes disappear when the body is horizontal, for example when the diver is swimming and are reversed when the diver is head down. The changes may combine with gas density effects to result in a significant impairment of ventilatory capacity during exercise and a degree of carbon dioxide retention. This becomes important in some diving situations where it may enhance oxygen toxicity, particularly in nitrox diving or closed circuit oxygen breathing military divers.

Rarely, immersion may result in the development of acute pulmonary oedema.37,38 This results in the dive being aborted, but is likely to reoccur with future dives and with increasing severity. It is most common in individuals with a history of mild hypertension.

**BUOYANCY**

The human body is almost neutrally buoyant, but buoyancy varies with the volume of gas in the lungs so breathing in allows the body to float, whereas breathing out allows it to sink. Most diving is carried out wearing thermal protective suits which contain gas within enclosed spaces to provide insulation. In neoprene suits, air is contained within the foam bubbles of the suit and in membrane dry suits gas is contained in the space between the diver’s body and the suit. The gas or air contained within the suits is affected by pressure, so the volume shrinks as the diver descends. While on the surface, the suit increases buoyancy substantially as a result of the gas contained and the diver needs to carry additional weight in the form of lead to counteract this effect in order to get submerged. However, once submerged, the increasing pressure reduces the volume of air within the suit and the added buoyancy of the suit is progressively lost with depth. Hence, the diver who adjusted weight for neutral buoyancy on the surface becomes negatively buoyant at depth. This problem is solved by a buoyancy compensation device which may be either an air-filled jacket or suit in which the volume contained can be adjusted by the diver. This requires use of the diver’s air supply to fill the device and use of valves to exhaust or dump the excess gas as the diver ascends. Such devices expand and rapidly provide positive buoyancy on ascent and hence careful control is required to maintain overall stable depth. Their failure or incautious use have been the cause of numerous episodes of rapid uncontrolled ascent.
CARDIOVASCULAR

Apart from fluid shifts which raise right atrial pressure, immersion of the face in water, particularly when it is cold provokes the diving reflex manifest by vagal stimulation and bradycardia. This is not a potent effect, but may be part of the mechanism which results in the rare development of arrhythmias in some divers and the development of immersion-induced pulmonary oedema.

THERMAL

The water in which divers immerse themselves is commonly cold so rapid loss of body heat is an important physiological challenge. Divers with more subcutaneous fat are better protected, but in almost all situations some form of thermal protection is required. A basic neoprene wetsuit traps a thin layer of water between suit and the diver’s skin which is heated by the diver’s body heat. The suit restricts water movement and provides some insulation, thereby reducing heat loss. Drysuits enclose the diver in a watertight suit which traps a layer of air or gas within the suit, which acts as insulation. The suit membrane is often thin. Fibre pile or other insulated clothing worn inside the suit provides a medium to hold and trap the insulating gas. Drysuits provide better protection than wet-suits, but have buoyancy problems and still do not really allow comfortable long dives. Flooded hot water suits are commonly used. These are essentially a baggy wetsuit with an internal pipe network. Hot water is pumped down to the diver and perfuses the suit. Multiple perforations in the suit pipe network provide a constant supply of hot water to the whole body in a fairly even distribution. Although the diver is wet, body heat can be well maintained for long periods in the coldest water environments. Unfortunately, these suits do not provide any protection from other hazards, e.g. chemical. In these circumstances, a liquid heated membrane suit can be used. These are a drysuit containing a network of thin-walled tubing in the suit material wall, which can be heated with a supply of hot water to maintain the temperature of the suit environment.

A diver’s thermal comfort can be important in the control of decompression illness. Cold and poorly perfused peripheral tissues take up and release dissolved gas less readily. A diver who takes up inert gas while warm during a dive, but becomes cold during the following decompression may have a higher inert gas load at the end of the dive and hence an increased risk of decompression sickness.

Water has very high thermal conductivity compared to air. This is why garments and suits which trap a layer of air provide insulation for a person in either a cold environment or water. Unfortunately, helium also has high thermal conductivity, so when the air used for insulation purposes is replaced with helium–oxygen mixtures, there is a substantial loss of insulation effect.

WETNESS

Divers’ skin is exposed to water or damp conditions during much of their work. In wet or flooded suits, the diver is wet throughout the period in the water. Drysuits are totally enclosed waterproof enclosures and if the physical work rate is high, there is very high humidity as a result of sweating. Saturation diving environments using heliox as the breathing gas require to be maintained at 28–32°C to maintain thermal balance. Keeping the humidity level under control generates significant problems, so divers may be exposed to high humidity for periods of weeks at a time with potential effects on the skin.39

LOSS OF CONSCIOUSNESS

Disturbance of consciousness or incapacitation while in the water prevents the diver from maintaining those actions essential to preserve life while underwater and hence may prove fatal. The ultimate cause of many diving fatalities is drowning, although this commonly results from an initial event which might be a preceding illness, injury or equipment failure. A detailed investigation of diving incidents, which should include assessment of equipment in use, is crucial in understanding how the incident occurred and hence how further events may be prevented in the future.

The causes of loss of consciousness fall into several categories:

- The presence of a gas phase within the body either from a cerebral gas embolism or decompression sickness may cause loss of consciousness either immediately after ascent or during the first few hours.
- The toxic effects of normal air constituents at pressure may result in loss of consciousness from nitrogen narcosis, but only at high pressures (pN2 greater than 6 ata) or from cerebral oxygen toxicity, where the pO2 exceeds 1.5 ata. The latter may occur when breathing an oxygen-enriched gas mixture (pure oxygen or nitrox) at shallow depth or a heliox or trimix mixture at deeper depths.
- Hypoxia can occur when breathing a gas mixture with a low pO2 which can occur as a result of an error in dive planning or on ascent when breathing a gas which had adequate pO2 at depth, but as pressure falls on ascent the pO2 falls. This may occur when making an emergency ascent after losing an air supply. Hypoxia also results in loss of consciousness when it occurs as a result of drowning, aspiration of vomit or breathing a gas supply contaminated with carbon monoxide.
- Hypercapnia can occur when ventilation is restricted by gas density, for example when breathing air at depths below 40 msw. The high pCO2 of air at that depth prevents hypoxia and allows a diver to undertake high levels of physical exertion. The high metabolic rate
Diving and work at increased pressure

DIVING TASKS

Modern commercial diving may involve a number of different diving methods.

Breath-hold diving is only in use for commercial purposes in traditional pearl diving communities. However, breath-hold dives may be undertaken as part of work activity, for example in helicopter underwater escape training (Figure 50.5).

Self-contained underwater breathing apparatus (SCUBA) allows a diver to carry a compressed breathing gas supply and hence be entirely independent in the water. This is most extensively used by recreational divers. The diver carries a cylinder of compressed gas with a regulator which reduces the pressure to a few ata above the diver’s actual environmental pressure. The regulator supplies a demand valve which is usually attached to a mouthpiece held by the diver’s teeth. The demand valve provides a supply of breathing gas as the diver inhales at the diver’s ambient pressure. In the event of emergency, help can only be obtained from the immediate vicinity and hence divers dive with a buddy. Complete independence which is attractive to sport divers represents a hazard in most working diving environments, but the technique is still used in a limited range of applications including some scientific (marine science), media diving, police (search and rescue) and sea food harvesting, but has very restricted application elsewhere. More complex versions of SCUBA, such as closed or open circuit rebreather devices, have limited military or recreational applications.

Surface-supplied diving (SSD) provides a breathing gas supply from the surface by hose or umbilical. The diver normally wears a helmet and breathes through an oronasal mask, rather than a mouthpiece (Figure 50.6).

These two factors allow communications, so the umbilical also contains electric cables for communications and commonly a hot water supply and a depth/pressure monitor (pneumofathometer). The communication link allows the supervisor to listen to the diver’s breathing pattern and talk with the diver and as the umbilical is attached to the diver’s harness, it provides a means by which the diver can be recovered. No buddy diver is required, but a standby diver is available on the surface to follow the diver’s umbilical to provide rapid support if necessary. Wearing a helmet, rather than using a mouthpiece, provides much greater security in the event of any incident involving loss

Comment

High workload when struggling and an element of panic while breathing dense air at 5.5 ata resulted in hypoventilation and acute carbon dioxide retention, leading to a period of anaesthesia. The high partial pressure of oxygen prevented severe hypoxaemia and the reduction of ambient pressure during ascent reduced gas density and alveolar pCO₂ allowing rapid recovery with only residual headache.

Figure 50.5 Diver entering water wearing ‘standard dress’ – a totally enclosed suit and rigid brass helmet supplied with compressed air from the surface.

An air diver attempted a survey dive using a diving helmet at a depth of 45 msw. On arrival on the sea bed, he found his umbilical snagged, was unable to move, struggled and called for assistance before becoming unconscious. He was recovered by the standby diver who found him motionless and apnoeic. During recovery, spontaneous breathing commenced at a depth of 12 msw and he recovered consciousness at the surface, but complained of headache. He was immediately recompressed to manage omitted decompression and because the cause of the episode was uncertain. All symptoms resolved rapidly during recompression and he remained entirely well.

Figure 50.6 Diver wearing a helmet and oronasal mask.
of consciousness or self-control or vomiting. This is the most common method used for air diving in oilfield work, inshore commercial diving and is increasingly being used in police and rescue diving activity. The risks associated with this method increase with the distance from safety (surface) and are widely regarded as unacceptable with an umbilical greater than 50 m in length.

In many commercial diving operations, getting the diver safely into and out of the water is a significant difficulty. A wet bell is essentially a transport device or lift which lowers divers from a surface structure down to the sea surface and on down further to the working dive depth. Although the divers are just standing on an open platform in the water it is possible to have a small air-filled space in the upper part of the structure which provides an opportunity to sort any helmet or breathing apparatus problems without necessarily returning to the surface. The bell, whose depth is controlled from the surface, also allows divers to make decompression stops during the ascent at accurate depths and times.

A closed diving bell is a pressure vessel with a hatchway and trunk in the floor which has doors on both inside and outside. Divers can travel from the surface to depth in the closed bell with pressure maintained at 1 ata with the external door closed. Pressurization of the bell can be delayed until the bell is in the appropriate position and the diver is ready to leave. At this point, the bell is pressurized to a depth equal to the position of the bell so that the door can be opened to allow the diver to exit to perform the task. On returning to the bell, the bell can be raised with the door open until bell depth reaches a decompression stop. At this point, the inside door is closed and while the bell pressure is maintained for the purposes of following the decompression plan, the bell can be lifted out of the water. The bell may then be locked on to a chamber allowing the divers to transfer to complete their decompression in a comfortable environment. Deep bell dives in which the diver completes the dive breathing heliox and then completes a decompression returning to the surface, have in the past been extensively used in oilfield diving. The risk of decompression sickness is high and problems resulting from oxygen toxicity from the high $pO_2$ mixtures used to accelerate decompression are frequent. In most areas, the method has been replaced with saturation techniques.

The use of a chamber on the surface and a closed diving bell is the basis of a saturation diving system. To avoid long decompression periods after every dive, divers are ‘stored’ at increased ambient pressure in pressure chambers on the surface. They can then transfer to a diving bell and then into the water to conduct work without any significant change in pressure. This allows divers to work in the water for prolonged periods over a period of three weeks or more. However, there is then a need for a prolonged decompression which may last several days to retrieve the divers from storage to the surface. The very low risk of decompression illness and the absence of significant time restriction on divers’ working time in the water, together with the more effective work time/decompression time ratio has made this the preferred method for most oilfield diving, other than shallow inspection work. The benefits compensate for the considerable increase in cost of plant and manpower and the method is being increasingly used for shallower work.

**Decompression planning**

Procedures which permit divers or compressed air workers to return to the surface following exposure to increased pressure without the development of decompression illness are critical to safe diving and compressed air work. The mathematics of decompression planning are a complex mixture of limited experimental data, empirical observation and theoretical calculation. The resulting algorithms provide valuable reduction in risk, but do not offer complete control. The risk of decompression illness is best controlled in saturation diving, where complete saturation is certain and one single final decompression is made using an appropriate slow decompression following many hours of underwater work. In all other (surface-orientated) diving, the extent of a diver’s gas uptake is always an estimate and not surprisingly the incidence of decompression illness is much higher. The risk of decompression illness is also greater for longer and deeper dives. The gradual evolution of decompression algorithms continues to reduce the risk, but this appears unlikely ever to be completely eliminated due to variations in working activities and both inter- and intraindividual characteristics. Despite the undoubted benefits of scientific and theoretical calculations in developing decompression schedules, the best predictor of the safety of a diving or compressed air decompression procedure is the practical experience of it gained in actual commercial or military operations.
Decompression procedures or tables

The practical application of decompression algorithms at the dive site can be achieved either by the use of tables or by the use of a portable computer device. Decompression tables comprise a list of procedures defining the ascent profile required following dives of varying depth and duration. Typically, if a dive is planned to a depth of, for example 32 msw, the dive supervisor would select a table for the next deeper depth which might be 35 msw. There will already be an approximate estimate of the time required for the dive, so in the course of the dive the supervisor would have available 35-msw tables for time intervals around the estimate. In the course of the dive, the supervisor would ensure that the planned depth was not exceeded and after the work is complete, would note the time at which the ascent is started. The duration of the dive from leaving the surface to commencement of ascent is called ‘bottom time’. The supervisor selects the table time which is the next longer than the actual bottom time and then directs the diver to make stops during the ascent at depths and for times defined by the table procedure.

Recreational divers plan their dive in advance and then stick to the plan since their access to table data during a dive is limited to what can be recalled from memory or written on a waterproof slate. Not surprisingly, a hand- or wrist-held computer, which accurately measures depths and time and can then compute the required decompression profile while the diver is in the water, overcomes many practical difficulties and is an attractive option.

Diving tables are produced and published by various organizations including navies, commercial diving organizations, and others. The efficacy of decompression tables is somewhat variable, but in general continues to improve and as a result the incidence of decompression illness is falling. Diving tables are a critical component of a commercial diving contractor’s equipment and a legal requirement in some countries.

Despite gradual improvements, there remain considerable differences between tables in the decompression requirement for the same dive. This highlights the fact that decompression table procedures reduce risk, but do not eliminate it. Individuals also differ in susceptibility to decompression illness when exposed to identical pressure exposure, working activity and conditions. Intraindividual variations must also occur to explain why individuals sometimes develop acute decompression illness, for no obvious reason, after many years of similar previous uneventful exposures. These factors have confounded the further development of decompression procedures and the study of associated risk factors.

Computers

The dive computer has revolutionized the conduct of recreational diving and their use is widespread. Currently, they have only limited application in commercial diving and are not used in compressed air operations. The ability to measure depth and duration of the dive accurately without the need to rely on the diver reading a watch and a depth gauge underwater represents a major advance and the opportunity to eliminate many calculation errors made in table selection. The computer can then accurately apply the decompression algorithm and provide a guide to the decompression profile required. However, in the use of tables, there was a consistent methodology to apply safety margins to the algorithm by using a deeper depth than actually dived, a longer bottom time and using the deepest depth reached as the depth of the dive rather than an average. The computer enables an absolute calculation of depth time profile to calculate gas uptake and then applies the algorithm. Effectively, this means that the algorithm is operated close to its limits at all times, whereas when using tables there would commonly be additional inbuilt safety allowances.

Computers are so widely used that direct comparison of table use versus computer use is now impossible. Computers inevitably permit more time in the water than would tables and hence are attractive to recreational divers. The ease with which a diver can conduct a decompression dive has contributed to the increasing depth of recreational diving. It is important that divers fully understand the background and limitations of diving computers and use them in a knowledgeable and sensible manner.

Mixed gas methods

As dive depth gets deeper, an increasing number of problems occur. First, when breathing compressed air, nitrogen narcosis becomes increasingly important at pressures above 4 ata and a major safety risk. Replacing the nitrogen with helium overcomes the narcotic effect and also some of the respiratory limitation resulting from increased breathing gas density. The elevated partial pressure of oxygen in compressed air may result in cerebral oxygen toxicity when the partial pressure exceeds 1.5 ata, i.e. at 65 msw, particularly where gas density results in some CO₂ retention.

These problems can be overcome by using a mixture of helium and oxygen (heliox) at depth. The oxygen content is reduced to ensure that the partial pressure of oxygen at the dive depth is not toxic and narcosis is eliminated. An important disadvantage is that the high rate of diffusion of helium contributes to a rapid uptake during the dive so that the diver approaches saturation more rapidly. As a result, decompression times for surface-orientated diving with heliox are longer than with air. Since decompression times get exponentially longer as the dive depth and duration increase, this becomes an important limitation on the use of heliox for surface-orientated diving. To enhance decompression rate, oxygen-enriched breathing gas mixtures and 100 per cent oxygen are used during the
known as high pressure neurological syndrome, characteristically rapidly may experience a complex neurological effect.

At depths exceeding 150 msw, divers are compressed rapidly and the use of a closed bell is more appropriate. Recreational deep divers, attracted to surface-orientated techniques as a result of cost and logistical factors, usually take a different approach to commercial divers, replacing some but not all of the nitrogen with helium to produce a ‘trimix’ in which the oxygen partial pressure is controlled, and narcosis controlled but not eliminated, while not suffering all the decompression disadvantage of using heliox.

**Saturation diving**

In deep diving, where safety demands the use of a closed diving bell, the number of personnel required to support the operation is large, the amount of time a diver can spend working on the seabed is very limited and a large component of time is taken up with the decompression. Deep surface-orientated dives carry a high risk of decompression illness. The logical solution to all these issues is saturation diving. A team of divers is ‘stored’ in a pressure chamber at a pressure which is very close to the depth at which work is required. Each small diving team comprising a standby diver and one or two working divers is transported by closed bell from the storage chamber to the worksite. The small pressure difference between the bell and the water at the worksite is equalized and the diver(s) can leave the bell to work. At the end of their shift they return to the bell which is then closed and sealed and the divers return to the storage chamber. Because there have been only very small pressure changes, there is no time limitation on the duration of the dive and no requirement for a staged decompression at this point. Another shift of divers can continue the work immediately. In this way, divers can work on the seabed for more than 20 in every 24 hours.

The divers become ‘saturated’ or equilibrated with the gas at the pressure they are stored at over a period of six hours. Once equilibrated, no more inert gas can dissolve in body tissues and hence the decompression time required is no longer after four weeks than after approximately six hours. At the completion of the work, decompressing the divers to the surface may take five to six days or even longer, but the system allows a much more effective use of divers’ time and of plant and equipment and at the same time dramatically reduces the risk of decompression illness. At depths exceeding 150 msw, divers compressed rapidly may experience a complex neurological effect known as high pressure neurological syndrome, characterized by tremor, incoordination and episodes of microsleep. In operational diving, this is readily avoided by appropriate compression profiles, but it is a potential cause of poor diver performance and hence accidents during very deep saturation dives. It may also generate problems when additional support workers, for example medical staff, are compressed rapidly in an emergency situation.

Saturation diving has completely revolutionized subsea engineering. Large numbers of ships have been purpose-built to conduct saturation diving and subsea intervention and the associated technology is being applied to diving tasks in progressively shallower water.

While the saturation method largely protects divers from decompression illness, the mode of work introduces a wide range of different medical problems. Perhaps most important of these is the isolation of the divers who cannot be returned to the surface in less than their decompression time, usually several days. This presents difficulties in the management of illness or injury. Although the concept of transporting an injured diver in a portable pressure chamber to a hospital-based hyperbaric facility has been explored, it is always simpler to transport a medical team and equipment to the dive vessel and provide care on site. Medical staff who attend a diver in saturation are likely to require the same prolonged decompression.

**Dive planning**

The methodology selected for an underwater diving project depends on a number of factors which include water depth, duration of work activity, cost, available equipment and personnel, and acceptable risk. For example, a single dive to a depth of 40 msw for a task lasting a few minutes might be safely conducted by a single surface-orientated air dive involving no decompression stops. A substantial work programme requiring many hours of work at a depth of 30 msw could be conducted by an air diving operation, but would require numerous dives which would all need to be of reasonable duration (30–40 minutes) and hence would involve decompression procedures. There would therefore be a significant risk of one or more episodes of decompression illness. The same work programme might be more rapidly achieved using saturation methodology in which a smaller number of divers could complete the work in shifts, all working for six hours at a time with a very low risk of decompression illness. It would, however, require expensive equipment and trained personnel, so would represent a more costly option.

**CURRENT HAZARDS AND RISKS**

Divers are exposed to a wide range of hazards. These may be considered under two major headings, environmental and related to the work activity. It is important to remember that diving is simply a method of getting workers to the workplace and while diving itself carries significant inherent hazards, there remain significant hazards of the work activity itself, many of which are shared by workers on the surface (Figure 50.7). Some of these hazards are modified by the underwater environment and may be difficult to
assess and control. Some of these issues have been overshadowed by diving hazards and require further attention.

Environmental (dive-related) hazards include pressure-related illness (barotrauma and decompression sickness), drowning, breathing gas toxicity, noise, infection, thermal illness and marine animal attack. Work activity may result in direct trauma, noise exposure, chemical and vibration exposure.

Commercial diving has a reputation as a hazardous occupation, but there are large differences in risks between different sectors of the commercial diving industry. For example, scientific divers and police diving teams have very low incident rates, whereas oilfield commercial diving has much higher rates (Figure 50.8). This difference is mainly explained by the nature of the work environment and the type of work undertaken. Incident rates have fallen substantially over the course of the last 20 years, but diving remains a hazardous employment. Comparison with other groups of workers is difficult because of the pattern of divers’ work. For example, an air diver might undertake 200 dives in a year, but spend between 50 and 600 hours in the water, whereas an onshore construction worker might expect to be at work for 2000 hours in a year. A saturation diver might spend 120 days at pressure (almost 3000 hours), but be in the water for less than 600 hours.

### Incident control

Safety management in the diving industry is complex. Improved decompression procedures and restrictions on divers’ pressure exposure have greatly reduced the incidence of decompression illness. Major improvements in equipment preventing catastrophic failure and control of the use of hazardous techniques, e.g. oxygen burning and high pressure water jetting have contributed to lower accident rates. The introduction of a risk assessment method to every task has also had a contribution, but is highly dependent on the expertise within the dive team to identify potential problems. Much of the risk control is managed by the diving supervisor who has responsibility for all aspects of a diving operation from the operational planning to the handling of problems occurring in the course of a dive.

In diving operations, even a trivial problem may result in a catastrophic outcome, so the severity of outcome is commonly greater than in comparable situations in other industries. In this situation, the efficiency with which potential hazards are identified and brought to the attention of the diving team is critical. In the United Kingdom, the speed with which hazardous incidents have been investigated and the conclusions and recommendations passed on to the industry, both by the Diving Inspectorate (both Department of the Environment and the Health and Safety Executive) and contractors, has been a major contribution to reduction in accident rate and the UK Offshore standards are regarded as a world leader in diving safety.

### Management of incidents

Despite improvement in risk control, the environment in which diving operations are conducted is always
hazardous and contingency planning for the management of incidents remains an important part of diving operation planning.

In the event of an incident resulting in illness or injury, the most immediate assistance is provided by other members of the dive team and hence appropriate first aid training of divers is important. Divers may be subject to the normal range of accidents which occur in working environments and in addition are at risk of specific diving-related illness. The immediate first aid management of the decompression illnesses, near drowning, hypoxia and carbon monoxide poisoning or contaminated gas supply includes oxygen administration and all divers should have this expertise and be familiar with the oxygen equipment available.

Most cases of decompression illness are treated with fluid replacement and recompression. Divers presenting with symptoms on the surface are most commonly treated with an oxygen breathing procedure, such as Royal Navy Table 62 (United States Navy Table 6), in which the individual is compressed in a chamber to a depth equivalent of 18 msw and given 100 per cent oxygen to breath for periods of 20 minutes interspersed with breathing air for five minutes. After three to five periods of oxygen breathing, the pressure is reduced slowly to 9 msw and further periods of oxygen breathing lasting an hour are continued before a final decompression to the surface. A substantial proportion of cases resolve during this primary procedure, but others require further hyperbaric oxygen treatments before the condition has either resolved or reached a stable state. A variety of more complex procedures may be applied in specific situations based upon individual clinical assessment.

Immediate access to specialist diving medical expertise is critical to ensure that continued care follows appropriate lines, and evacuation to an appropriate medical and/or hyperbaric facility occurs when necessary. This is particularly important when a recompression facility is available at the dive site where the opportunity exists for recompression treatment to be given without any direct medical assessment. In the past, a number of inappropriate and unsupervised recompression procedures conducted without adequate clinical support or medical advice have led to tragic outcomes.

Where medical care at a more advanced level than immediate first aid is required at the dive site, for example if a recompression facility is available or if the dive site is remote either geographically or because the affected diver is saturated in a storage living chamber, then it is appropriate for at least a proportion of the diving team to have more advanced first aid training. This is commonly called ‘diver medic training’ and involves a two-week training course which covers more medical procedures, such as venous cannulation and intravenous fluid administration, drug administration, advanced resuscitation, urinary catheterization, vital sign recording, aspects of neurological examination and wound care.

In the event of serious incident, there must be a contingency plan for evacuation of the diver to medical care or the provision of medical care at the dive site. In evacuation, the possible risk of decompression sickness in the period after the dive and the possibility of provocation during evacuation by air needs to be considered, but in most circumstances the risks associated with delay in receiving medical treatment are greater.

**Outcome of incidents**

Most incidents require careful investigation to ensure that the cause is fully understood and particularly that the sequence of events leading up to injury or the presentation of illness is fully established. This may be critical in establishing a diagnosis. For example, the onset of symptoms at stable depth before any decompression has taken place effectively excludes decompression illness as a cause of that symptom.

After illness or injury, reassessment of medical fitness to dive should be carried out by a doctor with diving medical knowledge and with complete information about the prognosis and the impact of any disability.

**LONG-TERM HEALTH EFFECTS**

Divers are at risk of acute diving-related illness, such as decompression sickness and barotrauma, as well as other work-related injury. Incomplete recovery from these events may leave the diver with a significant residual deficit or disability which will never recover.

In addition, divers are at risk of health effects which result in the presentation of symptoms with a substantial delay after any pressure exposure and without a history of acute decompression illness or other overt symptomatology. Dysbaric osteonecrosis is the best example of this phenomenon. This is a form of aseptic bone necrosis which is associated with previous experience of decompression. Although the precise pathogenic mechanism remains unclear, it is assumed that decompression involving the release of inert gas from solution in body tissues is the underlying precipitant. The mechanism may involve microbubble emboli causing infarction in end arteries within bone or pressure change within bone marrow. The lesions which may occur in many bones are painless. The end result is areas of dead bone which usually remain asymptomatic for many years. The radiological classification of dysbaric osteonecrosis affecting divers and compressed air workers was established by the Medical Research Council Decompression Sickness Panel in the 1960s and has been widely used internationally ever since. Two distinct types of lesion are defined. ‘B’ lesions are found in the shafts of long bones, particularly the femur, tibia and humerus. ‘A’ (juxta-articular) lesions occur adjacent to articular surfaces of large joints, particularly the shoulder and hip. Lesions are almost entirely painless and those in long bone shafts cause no symptoms.
and can be regarded as of no clinical significance. Over the course of years, some lesions adjacent to articular surfaces may result in a gradual collapse of the articular surface followed by the development of secondary osteoarthritis. Symptoms of joint pain and stiffness develop at this late stage and may require joint replacement due to severe disability. The prevalence of dysbaric osteonecrosis in different working populations appears to relate closely to the efficacy of the decompression tables or algorithm used. Although the prevalence in the UK commercial diving population was considered to represent a significant potential risk to the diving population as deep saturation diving developed, this has not proved to be the case and the incidence of new cases in commercial (or military) diving appears to be very low. It is however, not possible to be certain because routine radiological screening is no longer considered to be acceptable from a radiation hazard aspect, and magnetic resonance imaging (MRI), which is the alternative screening method, has not yet been widely applied because of cost implications.

The reported incidence of dysbaric osteonecrosis in compressed air work projects in the past has reached as high as 25 per cent in the mid-1900s with a wide variation between different projects. The incidence rates appear to have reduced with improved safety and decompression procedures over many years. However, because of the latency before the appearance of radiological abnormality and even longer period before onset of symptoms, accurate incidence rates are difficult to establish. Cases of disability resulting from dysbaric osteonecrosis still present through the courts representing a significant ongoing work-related morbidity for previous compressed air workers. The risk remains significant particularly considering the relatively small number of exposures when compared to the commercial diving industry. Unfortunately, any beneficial effect on dysbaric osteonecrosis in compressed air workers from the use of oxygen decompression techniques has not yet been proven due to the lack of accurate data.

**Neurological**

There have been many suggestions that divers are at risk of long-term neurological injury as a result of diving in the absence of a history of acute decompression illness resulting in permanent disability. Several reports have indicated that divers are more likely to complain of memory difficulties and possibly concentration problems. However, no distinct symptomatic pattern of illness or pathology has emerged. Many studies have been complicated by the absence of an appropriate control population and by failure to adjust for other factors, such as accidents, head injury and alcohol consumption, all of which influence neurological outcome. The issue has become a significant problem in Norway, where a significant proportion of divers who worked offshore in the 1970s and 1980s have claimed to be incapacitated as a result of diving work. There may, however, be significant psychosocial compounding factors, including the overall sickness absence rates, cultural factors, compensation and medicolegal issues as UK divers working at the same time and often at the same worksites do not appear to have similar problems.

**Pulmonary**

Divers have been demonstrated to have larger lungs than the normal population and this has been associated with abnormalities in the expiratory flow pattern consistent with small airway obstruction. However, although some of these changes appear to progress in the early part of a diver’s career, no specific pathological outcome has yet been identified.

**Recent studies**

A number of recent reports have addressed the concerns about development of long-term health effects in the commercial diving population. Some uncontrolled studies from Norway have suggested that long-term disability due to unspecified neurological deficit is common in a population with experience of diving within the offshore oil industry. However, a large questionnaire survey of commercial divers in the United Kingdom, compared to the offshore non-diving population revealed no major difference in health status, although divers did report more symptoms, particularly of forgetfulness and loss of concentration. More detailed evaluation of symptomatic divers showed only small differences in formal tests of memory, which appeared to be related to work in the offshore oil industry, rather than any particular diving technique, suggesting that other factors associated with work in the industry, for example chemical exposure may be relevant.

**TUNNELLING TASKS**

Tunnelling or caisson work is part of civil engineering activity. Working at pressure becomes a requirement where excavation occurs beneath the level of the water table and where the ground is sufficiently porous to allow water to be forced into the tunnel or caisson as a result of the groundwater pressure. Hence, while it is possible to tunnel through solid impervious rock below water level without risk of flooding, tunnelling through softer water-permeable ground readily results in a water-filled tunnel with the risk of collapse of the (water-saturated) tunnel apex or face. In this situation, to allow work to progress, the open end of the tunnel is closed off with a pressure tight structure and the tunnel is pressurized to a pressure adequate to prevent water ingress and stabilize the tunnel face. A pressure chamber or lock is built into the tunnel enclosure to allow workers to transfer from the surface to the pressurized environment without loss of pressure in the tunnel. This enables the tunnel construction to continue with work conducted in a dry environment.
In the past, much of the work conducted at pressure was manual excavation using hand-held pneumatic tools to progress the tunnel. Tunnelling, therefore, required many man hours of hard manual work in compressed air and the relatively large tunnel labour force (sometimes hundreds of men on large projects) consisted mostly of labourers who worked on a daily shift system with five or six days’ exposure, sometimes during a project which could last several years. Although some small projects still require this activity, most tunnels are now constructed mechanically using a sophisticated tunnel boring machine (TBM) which lines the tunnel as it is constructed and hence the only human work requiring a pressurized environment is maintenance work conducted at the front face of the machine, such as blade or tool changing (often called ‘interventions’) or technical or geological inspections (Figure 50.9). As a result, the number of man hours required at pressure and the number of workers exposed, is greatly reduced in comparison to historical projects. The type of work is often now of a more technical nature rather than simple manual activity, but may still be physically demanding, in very confined spaces under extreme conditions of temperature and humid or wet conditions. TBM interventions or inspections are usually conducted on a periodic basis during the project with the pressure exposure varying from 0.5 to 2 hours (for single inspections) to interventions with shift lengths of two to ten hours (subject to the maximum working pressure and conditions) and daily exposures for two to six days.

TBMs require short intense periods of compressed air interventions, sometimes at high pressures (4–8 ata), but use a relatively small compressed air workforce (typically 30–60 personnel). The number of workers per shift depends on the tunnel diameter and other factors, but usually only three to five men will work under pressure at any one time on a rotating 24-hour shift basis for the duration of the intervention. As the TBM progression is effectively halted until the intervention is completed, it is an operational priority to maximize working time under pressure and to minimize the risk of decompression sickness (since this removes the worker from the compressed air workforce for the duration of that intervention).

Most UK tunnel projects using compressed air in the past have been at relatively low pressure (often below 2 ata and rarely above 4 ata, but exposures tended to be long (six to eight hours)). However, increasing health concerns in the late 1980s and early 1990s led to much shorter pressure exposures being adopted by contractors following recommendations from their medical advisers, especially where working pressure exceeded 2 ata and this was eventually prescribed by HSE in the 1996 regulations. Working pressures greater than 3 ata restrict shift duration and the limit of current air tables is set at 4.45 ata as a result of physiological factors and safety issues. This has led to the need for the development and implementation of safer decompression techniques that give longer working time at higher pressures (4 ata or greater) and with reduced risk of decompression sickness or dysbaric osteonecrosis. Inevitably, this means the application of diving technologies in the civil engineering context, which includes the use of mixed gas and saturation techniques, in addition to oxygen decompression.

Like divers, tunnel workers may also require a gradual return to surface pressure to prevent the onset of decompression illness. The decompression or ascent is conducted in a pressure lock so can be very accurately controlled. Whole shifts will compress together and decompress at the end of the working shift.

Decompression procedures for tunnelling in the past have been quite different from diving procedures and appeared to permit much more rapid decompression from a given pressure exposure. The incidence of decompression illness has often been quite high and dysbaric osteonecrosis
a more frequent result than in divers, often appearing many years after the pressure exposure.

Civil engineering projects requiring work at pressure are intermittent and relatively rare. As a result, the workforce only occasionally takes part in pressure-related activities while doing a wide range of other work usually within the construction industry. Long-term health surveillance has been difficult in this situation as most compressed air workers are not in long-term employment with any given contractor and thus health screening has usually only been managed on a project-specific basis when the need arises.

The development of TBMs has also led to a different type of workforce being involved. Due to the skills required and the technical complexity of the projects, there is now always a minority of workers with previous compressed air or pressure exposure experience and the health and safety culture is mainly derived from the construction industry. This has implications for the induction training, lock supervision and site management of the pressure systems with significant differences from the management approaches employed with commercial offshore divers who will work under pressure usually as a long-term career choice. Where mixed gas or saturation techniques are required in civil engineering projects, the selection and training of the workforce (who will optimally require a mixture of tunnelling and diving experience within teams) will always require careful consideration.

Tunnel and caisson environments have other significant safety issues. They are enclosed spaces and require appropriate ventilation. Carbon dioxide retention may be a contributory factor in decompression illness. It is critical to ensure that the environment is not contaminated by toxic chemicals, particularly carbon monoxide, and that all possible sources of ignition are controlled to avoid fire. Fire in a pressurized tunnel burns more intensely for a given flame size, spreads more vigorously and is harder to extinguish than at atmospheric pressure and all of these effects are magnified by oxygen enrichment. Hence, the fire risk depends on both pressure and percentage of oxygen in the environment and it remains a major safety consideration in compressed air work. Oxygen decompression techniques were effectively delayed in the United Kingdom within the civil engineering industry, until the Health and Safety Executive had fully assessed the possible increase in safety risk from fire compared to the reduction in risk of decompression sickness from breathing oxygen during decompression.

While it is possible to ensure that the structure constructed to enclose the tunnel is sound and adequate to withstand the applied pressure, it is equally important to ensure that the surrounding ground cover and tunnel wall itself is secure. While tunnelling under a river for example, if the depth of ground between the bed of the river and the upper part of the tunnel wall is too thin, then the tunnel may blow out with rapid loss of pressure and flooding of the tunnel. Good management of any compressed air project therefore requires effective and regular communications between management, engineering, hyperbaric and medical staff at all times.

DECOMPRESSION ILLNESS IN COMPRESSED AIR WORK

Historically, decompression sickness was common among tunnel workers and many factors contributed. Long exposure times associated with hard manual work activity, ineffective decompression procedures, inadequate tunnel ventilation and avoidance or incorrect application of the decompression procedure have all contributed. Limb pain has been a more common presentation than any other, although sensory neurological or other clinical manifestations are not uncommon. Severe neurological decompression illness occurs rarely. As decompression is always conducted in a chamber lock which is usually of a significant size, very rapid ascent is virtually unknown and hence pulmonary barotrauma is very rare. In the recent past, considerable effort has been directed at improving the decompression procedures without substantially prolonging overall working hours and this has been achieved by the use of oxygen breathing during decompression for pressures up to 3.45 bar (gauge). While this is a major advantage in terms of decompression safety, there remain some concerns about the safety aspects of using compressed oxygen in some situations, particularly where a lock on a tunnel boring machine may be at the closed end of a tunnel several kilometres long. In practice, this has implications for the competency of hyperbaric technical staff (lock attendants), training and supervision of the workforce and strict management and fire prevention procedures which must be fully implemented on site.

The risk of decompression illness requires the development of a contingency plan which covers surveillance of workers during the at-risk period after pressure exposure, and the provision of a recompression facility with appropriate medical support sufficient to manage a patient with severe neurological decompression illness.

Treatment of decompression illness in compressed air work projects

The treatment of decompression illness arising during tunnelling operations is now identical to that used in the management of diving illness. In the past, recompression procedures using air alone were extensively used with several therapeutic and practical disadvantages, but now that the use of oxygen at the worksite has been accepted, the use of oxygen treatment tables has become normal practice. Therapeutic recompression is carried out using on-site chambers operated by medical lock attendants under the clinical supervision of the contract medical adviser or by referral to the nearest appropriate hyperbaric facility if the compressed air worker is remote from site.
LEGAL FRAMEWORK

Diving

In the United Kingdom, commercial diving is conducted under the Diving at Work Regulations (1997)\textsuperscript{62} issued under the Health and Safety at Work Act (1974).\textsuperscript{63} In addition to the general provisions of the HSW Act, the Diving at Work Regulations place duties on the diving contractor, diving supervisor and diver which aim to support the overall safety of the operation. The regulations also define the requirement for the medical assessment of divers and the necessary contingency plans required for diving operations. Approved codes of practice\textsuperscript{64} are published for different sectors of the diving industry (offshore commercial diving, inland/inshore commercial diving, scientific and archaeological, media, recreational and police) which provide specific interpretation and explanation of how the regulations impact on the different sectors of the industry.

In other countries, various different government authorities have responsibility for the regulation of commercial diving, some having a regulatory system based on a similar model to the UK system. In others, diving is completely unregulated. Within Europe, the European Diving Technology Committee attempts to coordinate standards for diving practice, including standards for medical assessment among member countries of the EU.

However, even within the EU, the regulatory bodies vary. In Norway, the Norwegian Petroleum Directorate regulates oilfield diving, but the Directorate of Labour Inspection regulates inshore diving. In the Netherlands, the State Supervisor of Mines is responsible for all diving activity, while in Denmark, the Danish Marine Authority is responsible. In the United States, the Occupational Safety and Health Administration (OSHA) regulates all diving.

Further complications arise because in various countries police or rescue diving activity is regulated separately and scientific diving may fall within or outwith regulation.

Work in compressed air

In the United Kingdom, tunnelling and caisson work is conducted under the Work in Compressed Air Regulations (1996),\textsuperscript{8} which are currently under revision. The 1996 regulations were a major advance from the previous Work in Compressed Air Special Regulations of 1958. The new regulations formalized much of the contemporary industry guidance (contained in BS6164 and CIRIA 44 publications) and advances in compressed air practice and reflected good modern management of pressure systems similar to the standards of the UK offshore commercial diving industry.

The 1996 regulations accepted the need for oxygen breathing during on-site hyperbaric treatments of decompression sickness, but fell short of requiring routine oxygen decompression (breathing 100 per cent oxygen during decompression) in the tunnel locks due to fire safety concerns. The statutory requirement for oxygen decompression at pressures above 1 bar (gauge) finally took place in 2001 when an addendum to the HSE guidance on the 1996 regulations was issued which also permitted the use of mixed gas or saturation techniques, if required, subject to specific HSE approval.\textsuperscript{65}

The framework of the compressed air regulations is similar to the diving regulations, but some significant differences are of interest because they reflect the different work environments in which diving and compressed air work takes place and the medical historical background. For example, decompression schedules are prescribed in the compressed air regulations or associated guidance. Specific HSE application for alternative decompression procedures in civil engineering projects is necessary from contractors with the full justification for the alternative procedure including the theoretical derivation, any laboratory evaluations and reference to practical operational experience within the UK or overseas. The diving regulations provide a right for a diver to appeal against a medical decision of unfitness. The work in compressed air regulations do not provide this right, but include a specific section relating to abuse of alcohol. Diving contractors are required to keep records of pressure exposure for two years, whereas compressed air contractors must keep records for 40 years. The compressed air regulations have a requirement for each project to have a contract medical adviser with a specific role of the professional supervision of all the occupational health aspects of working in compressed air. This includes the selection of the most appropriate decompression schedules, the planning and pattern of compressed air work, emergency medical response (including hyperbaric treatments), in addition to clinical examinations of medical fitness for work.

ASSESSMENT OF FITNESS FOR WORK AT PRESSURE

Both diving and work in compressed air involve exposure to increased pressure and hence the medical requirements are similar for both activities. The UK regulations for both work activities require that a medical assessment be conducted by a medical practitioner with appropriate knowledge and expertise and that the individual’s fitness be documented or ‘certified’.

The medical supervision of pressure workers involves a pre-employment assessment, periodic reassessment and aspects of health surveillance.

For divers, medical assessments are conducted by ‘approved medical examiners of divers’, doctors recognized by the Health and Safety Executive according to HSE guidance.\textsuperscript{66} Their principal role is to ensure that divers are safe to be working in the water and not a risk to either themselves or other members of the dive team. Health surveillance for occupational health effects is a secondary function. In most countries, medical assessment is required on an annual basis.
The health assessment is fairly extensive. It covers general fitness issues, including the physical ability to undertake the work activity necessary and specific areas which are relevant to working at pressure. These include ear, nose and throat assessment to exclude an increased risk of barotrauma, pulmonary assessment both from the point of view of risk of barotrauma and the physical capacity to work while breathing gas of increased density, cardiovascular assessment to cover risk of sudden incapacitation, increased risk of decompression illness resulting from intracardiac shunt or impaired peripheral vascular perfusion, neurological assessment to exclude risk of sudden incapacitation and to identify pre-existing neurological abnormality which might cause confusion in subsequent diagnosis of decompression illness. Skin disease can be important, as divers often remain wet for prolonged periods on a regular basis. Psychological suitability to work as a diver is a difficult area. Ability to cope with life-threatening emergencies in a challenging environment calmly and efficiently is a valuable asset for a diver, but is difficult to assess. In practice, the diver population is heavily self-selected and individuals who find that the environment induces anxiety or panic are unlikely to pursue a career. However, a change in mental response to the environment, as a result of an accident or other non-work-related life event, is not uncommon.

Where a diver is considered to be unfit, it is important that they fully understand the rationale behind the decision and the practical limitations of any disability. This may require a supervised test dive to demonstrate to all parties the practical effects and safety implications of a disability.

The assessment requires a number of investigations including lung function, vision testing, audiometry, electrocardiograph and assessment of exercise capacity. Measurement of exercise capacity is helpful for a number of reasons. It acts as a useful adjunct to lung function testing, as a crude screening test for ischaemic heart disease and as a guide to the individual’s ability to cope with the physical aspects of the work which are mainly activities carried out on the surface. It also encourages divers to maintain physical fitness by doing regular exercise which provides some protection against decompression illness. However, the actual physical work rate conducted by divers while in the water is in most circumstances relatively low because divers are weightless in the water and other factors, such as restriction of ventilatory capacity by dense breathing gas and immersion, impairs exercise ability.

A saturation diver reported recurrent episodes of wheeze, cough and breathlessness which came on during the course of repeated saturation dives, but which resolved within a few days after surfacing. On the surface, he remained well. Challenge tests revealed the cause to be exposure to a disinfectant agent used for cleaning the chamber (panacide). Changing to an alternative disinfectant agent allowed him to continue saturation diving uneventfully.

### Tunnelling

Medical assessment of compressed air workers is conducted by a doctor approved for compressed air work and appointed to the project by the HSE. Workers are required to be assessed before and at intervals throughout (the periodicity related to the pressure and working conditions), and at the end of the project. The principal role of appointed doctors is to ensure that workers are safe to be employed in the compressed air environment and work role and not a risk to either themselves or other members of the team. Health surveillance for occupational health effects is a secondary, but important, function as exposure to respiratory and skin irritants is quite common and prevention often relies on the use of personal protective equipment.

The clinical assessment follows similar requirements to those for divers in the areas of physical fitness, barotrauma and risk of decompression illness. However, since the work is conducted in a dry environment, without the risk of sudden pressure changes or drowning in most cases, some aspects of the assessment are less critical to safety. The risk of dysbaric osteonecrosis remains higher than in diving, and health surveillance for this is problematic. In the past, routine practice was to include a limited skeletal survey radiological assessment before and after a project. In most cases, it proved impossible to continue surveillance longer as the workforce was mobile and since the radiological abnormalities may appear only some years after the last pressure exposure, this was unsatisfactory. Today, the radiation dose associated with this system is unacceptable. Osteonecrosis is readily detectable by MRI, with a high degree of sensitivity and specificity, but there is limited experience using MRI for long-term health surveillance in asymptomatic working populations of either tunnel workers or commercial divers. It remains possible that lesions detected at an early stage by MRI may resolve spontaneously and not necessarily develop into long-term pathological lesions associated with radiological abnormality. It seems likely, however, that greater experience will be obtained with MRI as a screening method for dysbaric osteonecrosis in compressed air workers, despite the increased costs, once the known health risks and current working practices and future trends (increased pressure associated with TBM interventions) are taken into account. Using MRI assessment of the heads of both radii and femurs or as part of a planned skeletal survey appears to be the most clinically appropriate methodology and, where MRI detects an abnormality, a radiograph should be obtained at least until greater familiarity with the new screening technique is gained. This approach will reduce the radiation dose required substantially, while providing the potential benefit of a more sensitive screening method and further information about the natural history of early lesions detected by MRI.

Compressed air workers in the UK and overseas have benefited considerably from a forum specifically devoted
to their health and welfare. The Medical Research Council formed its Decompression Sickness Panel in the early 1950s. Members consisted of civil engineers, occupational physicians and hyperbaric or technical experts practising in the field of compressed air work. This panel issued advice to industry and the Health and Safety Executive and was replaced in 1986 by the Compressed Air Working Group (CAWG). The CAWG continues to hold regular meetings and issue guidance under the sponsorship of the British Tunnelling Society. The work of the HSE, which has conducted a long-term programme of research into both the safety and health aspects of work in the tunnelling hyperbaric environment in recent years, has helped make a major contribution internationally to improving health and safety in compressed air workers and underpins much of the current stringent legislation in the United Kingdom.

Key points

- Diving and tunnelling as occupations are simply a means of commuting to the workplace. Risks relate both to the environmental exposure and to the work task being undertaken.
- Decompression illness may vary from trivial, often unrecognized, symptoms to a serious and sometimes fatal illness. Fit divers with serious decompression illness are often misdiagnosed because they do not look unwell.
- Any new symptoms presenting within 24 hours of a pressure exposure may be decompression illness and appropriate advice should be sought.
- Saturation diving methodology has almost completely eliminated decompression illness.
- There are long-term health effects. The incidence of dysbaric osteonecrosis which can result in disabling arthritic change relates to the safety of decompression procedures used. Other health effects reported in divers are mainly related to lifestyle issues and trauma.

Working at high altitude

PETER JG FORSTER

HIGH ALTITUDE ILLNESS

The journals of intrepid mountaineers give clear testimony to the discomforts and perils of life at high altitude. In 1879, on Chimborazo in Ecuador, Edward Whymper, conqueror of the Matterhorn in 1865 and the foremost mountaineer of his time, suffered intense headache which ‘rendered us almost frantic or crazy’ and an ‘indescribable feeling of illness which pervaded the whole body … and we were preoccupied by the paramount necessity of obtaining air’. Whymper succeeded in reaching the summit of Chimborazo (6290 m). However, Edward Fitzgerald failed to achieve his personal ambition of the first ascent of Aconcagua (6980 m), the highest mountain in the western hemisphere, because, as he records in his book published in 1899: ‘I got up, and tried once more to go but I was only able to advance from two to three steps at a time and then to stop, panting for breath, my struggles alternating with violent fits of nausea.’

The discomfort experienced by mountaineers on ascent to high altitude is compounded by the additional hardships of exertion, fatigue, exposure, low temperature, gastrointestinal upsets, alteration in diet and dehydration. Fitzgerald’s discomfort was intensified by a diet which on Christmas morning 1896, camping cold and hungry at 4900 m, consisted of ‘some tins of Irish Stew … melting the great white frozen lumps of grease slowly in our mouths, and then swallowing them’. In 1913, TH Ravenhill, medical officer to a mining district in the Chilean Andes, described the features of altitude sickness affecting miners transported by rail from Antofagasta, a seaport on the Pacific Ocean, to mines situated above 4600 m. The miners in Ravenhill’s study were subject to the effects of altitude without other complicating influences. Based on his clinical observations, Ravenhill identified three types of altitude sickness: normal puna (acute mountain sickness), cardiac puna (high altitude pulmonary oedema) and nervous puna (high altitude cerebral oedema). It is tribute to Ravenhill’s astute clinical acumen and observational skills that his classification of the ‘benign’ (acute mountain sickness) and ‘malignant’ (high altitude pulmonary oedema, high altitude cerebral oedema) forms of altitude sickness remains in use in the modern era.

Acute mountain sickness is a self-limiting condition characterized by headache, sleep disturbance, anorexia, nausea, vomiting and cerebral symptoms, such as profound fatigue, dizziness, irritability, lack of concentration and confusion. Physical signs include periorbital and peripheral oedema and manifestations of normal physiological response to high altitude exposure, such as shortness of breath on exertion and tachycardia. Acute mountain sickness (AMS) affects unacclimatized visitors at elevations above 2500 m. Symptoms become manifest after a period of approximately six hours at high altitude and reach their maximum severity at 24–48 hours. Symptoms subside gradually after two or three days’ acclimatization. If the condition is ignored and ascent to greater altitude is attempted, AMS may progress to potentially fatal high altitude cerebral oedema (HACO) or high altitude pulmonary oedema (HAPO).

The incidence of AMS in sea-level residents ascending to altitudes greater than 3000 m has been estimated from large population studies of trekkers and soldiers on single ascents. Hackett and Rennie reported an incidence of 43 per cent in 200 hikers reaching Pheriche (4243 m) on the trail to Mount Everest. One-third of the hikers were symptom free. Of the thousands of climbers making the rapid ascent to the summit of Mount Rainier (4392 m) every year, 50–75 per cent suffer from AMS. Of over 250 hikers walking the Mount Everest base camp trek from Namche Bazaar (3440 m) to a final altitude of over 5500 m, 57 per cent developed AMS; concomitant symptoms of...
respiratory and gastrointestinal infection were common (87 per cent of the study group) and were more prevalent in AMS sufferers. Singh et al. reported an 8.3 per cent incidence of severe AMS in thousands of soldiers transported from sea level to above 3500 m. These published studies have involved young, physically fit and, predominantly, male subjects. In a general population of visitors (age range 16–87 years, one-third female) to modest elevations (1900–3000 m) in the Rocky Mountains of Colorado, 25 per cent suffered AMS within the first 12 hours of arrival. Males and females are affected equally by altitude sickness: the young suffer more than the old. As a rough guide a rule of thirds applies: moderate to severe symptoms of AMS occur in one-third of sea-level residents at high altitude, mild symptoms in one-third and one-third are symptom free.

A study of sea-level residents transported rapidly to high altitude, similar to the experience of the Andean miners in Ravenhill’s paper, was conducted in 1980 on personnel manning astronomical observatories at the summit of Mauna Kea (4200 m, 13 796 ft), on the island of Hawaii. In 1980, four major telescopes were situated at the summit which because of the dry atmosphere, absence of pollution and ready access, was the pre-eminent site for terrestrial infrared and submillimeter astronomy (Figures 51.1–51.3). At the summit, barometric pressure is 625 mbars (62.5 kPa, 475 mmHg) and the ambient partial pressure of oxygen is 60 per cent of the sea-level value.
The partial pressure of oxygen in inspired air is 12.6 kPa (95 mmHg) compared with 20 kPa (150 mmHg) at sea level and 7.6 kPa (57 mmHg) in alveolar air, compared with 14 kPa (105 mmHg) at sea level. Telescope personnel make frequent ascents by four-wheel drive vehicle from sea level to the summit with minimal provision for acclimatization above 3000 m. They remain on the mountain for five day shifts working at the telescopes and sleeping in dormitories at 3000 m. On Mauna Kea, 80 per cent of the shift workers were affected by altitude sickness symptoms on the first day. Headache and breathlessness were the most common and troublesome complaints. Other common symptoms were insomnia, lethargy, poor concentration and impairment of memory.

After five days on the mountain, 60 per cent of workers were free of symptoms, while the remainder continued to experience minimal symptoms of exertional dyspnoea, headache and insomnia. There was no difference in the incidence of AMS in shift workers who worked at the summit following a four-day sojourn at sea level compared to a 30-day rest period at sea level; acclimatization to altitude achieved during five days above 3000 m appeared to be lost within days of return to sea level. Telescope personnel who commuted to the summit for a single day did not suffer from severe AMS symptoms. However, commuters were only at an advantage if the duration of the visit to the summit was limited to less than six hours, the period of time that elapses usually between arrival at high altitude and the development of AMS: symptoms of headache, poor concentration, lethargy and dyspnoea were developing as commuters descended after five hours. The disadvantage of the commuter’s work schedule was that commuters did not acclimatize.

A 2007 study on Mauna Kea used the Lake Louise AMS Questionnaire (Appendix 51.1) to survey AMS amongst telescope shift workers and day visitors. Using this standardized self-report symptom assessment, which was not available in 1980, AMS was detected in 69 per cent of shift workers. Over 65 per cent of the telescope staff reported headache with 13 per cent suffering incapacitating headache. Difficulties with sleeping were common (70 per cent), as were nausea and lethargy. The majority of workers (70 per cent) were aware that symptoms reduced their level of activity.

High altitude pulmonary oedema (HAPO) is a non-cardiogenic form of pulmonary oedema. Pulmonary hypertension is the principal pathological process causing leakage of oedema fluid from intravascular space into the alveolar bed in association with an exaggerated pulmonary vasoconstrictive response to hypoxia and exercise, which is distributed unevenly throughout the lung vasculature. In addition, abnormal endothelial synthesis of vasoactive substances disturbs the balance between vasodilators (e.g. nitric oxide) and vasoconstrictors (e.g. endothelin-1).14 HAPO may follow viral respiratory infections in children15 and HAPO victims may exhibit infective and inflammatory signs: low-grade pyrexia, peripheral leucocytosis and raised ESR. However, examination of bronchoalveolar lavage fluid collected from climbers within hours of arrival at 4559 m has shown no increase in inflammatory markers or neutrophils.16 Hence, inflammation is thought to be a secondary response to extravasation of fluid into alveoli rather than a primary pathological process in HAPO.4

The signs of HAPO are marked breathlessness at rest, a rapid respiratory rate (>30 breaths/min) and a dry cough, which as the condition worsens may be productive of white, frothy or blood-streaked sputum. The victim appears deeply cyanotic and may complain of chest discomfort. Extensive bilateral crepitations (rales) are heard on auscultation. In extreme cases, gurgling sounds from the lungs may be audible to the victim and his companions without the use of a stethoscope. Signs of cardiac failure are not evident, although tachycardia (pulse rate >120 beats/min) and a low systemic blood pressure are frequently present. Cardiac murmurs are not a feature of HAPO. However, the second heart sound is accentuated and sometimes palpable, reflecting elevation of pulmonary artery pressure. An erroneous diagnosis of bronchopneumonia may be suggested by the presence of low-grade pyrexia and moderate leucocytosis, but respiratory infection may coexist with HAPO.

Arterial blood gas measurements confirm severe hypoxaemia with low arterial partial pressure of oxygen (PaO₂) and decreased arterial carbon dioxide tension (PaCO₂) from hyperventilation resulting in respiratory alkalosis. Prominence of the pulmonary arteries and patchy infiltrates seen in chest radiographs in early disease progress to homogenous bilateral infiltration in severe cases. Right ventricular overload pattern (right axis deviation, right bundle block and right ventricular strain) is present on electrocardiograph tracings. Echocardiography may demonstrate incompetence of the tricuspid valve. Cardiac catheterization studies performed on HAPO victims before treatment or descent show a high pulmonary arterial pressure and low or normal pulmonary artery wedge pressure.17 Descent to low altitude and administration of oxygen lowers pulmonary artery pressure, clears radiographic pulmonary infiltrates and relieves symptoms within one to two days. The development of HAPO is related to the speed of ascent, the altitude achieved, the exertion involved and the susceptibility of the individual. An incidence of HAPO has been reported as high as 15.5 per cent in thousands of lowland troops flown up to the Himalayas.18 Seven cases of HAPO were encountered amongst 278 unacclimatized hikers at 4243 m in Nepal, an incidence of 2.5 per cent.19 At the Regina Margherita hut (4559 m) in the Alps Valais, 4 per cent of climbers were diagnosed as suffering from HAPO as indicated by pulmonary crepitations on auscultation.20 On Mauna Kea, one case of HAPO was diagnosed in 41 shift workers during a two-year study (Table 51.1). Calculated in terms of the 2000 ascents per annum to a single telescope, this low incidence of HAPO may reflect the lack of physical exertion involved in ascent to 4200 m. However, in contrast to the low incidence of HAPO reported in earlier studies, a 2002 prospective study of 262 climbers to Monte Rosa (4559 m) found clinical and radiographic evidence of interstitial oedema in 40 subjects (15 per cent) without HAPO-related symptoms. Using airway closing volume as a proxy for interstitial water, 74 per cent of the healthy climbers had subclinical pulmonary oedema without clinical or radiographic evidence. The researchers concluded that ‘even at modest altitudes and rates of ascent, with heavy but not extreme exertion, the healthy lung is on the edge of failure in terms of fluid balance’. Hypoxia was proposed as the putative agent rather than exercise.21,22

Individuals with an over-exaggerated pulmonary vasoconstrictive response to hypoxia and exertion or abnormalities of cardiopulmonary circulation leading to increased pulmonary artery pressure (e.g. unilateral absent pulmonary arteries, primary pulmonary hypertension) are at increased risk of HAPO.23–25 Although it is not possible to predict who will suffer from HAPO on a particular ascent, individuals who have suffered a previous episode have a risk of recurrence of 60 per cent on reascent to over 4500 m.26 A genetic predisposition to HAPO may be linked to up- or downregulation of the genes that control synthesis of the vasodilator nitric oxide and the vasoconstrictor endothelin-1. Other studies of genetic predisposition to HAPO have included investigations of polymorphisms in angiotensin-converting enzyme genes, HLA haplotypes and the amiloride-sensitive epithelial sodium channel which has a key role in clearance of fluid and sodium from the alveolar space.27 Failure to descend or to treat HAPO effectively may result in a fatal outcome within a few hours of onset; the mortality rate is quoted in the range 4–11 per cent. In a review of 166 reported cases of HAPO, untreated victims had a mortality rate of 44 per cent compared to a 3 per cent mortality in subjects who were treated by descent and oxygen administration.28 Half of HAPO sufferers who die have coexistent HACO evident at post-mortem.29

Cerebral oedema (HACO) presents typically with intense headache, profound lethargy, ataxia, impaired coordination, confusion, disorientation and hallucinations. Convulsions and focal features, such as cranial nerve palsies and visual field loss, may occur. Cerebral oedema occurs in people exhibiting ‘benign’ AMS: the progression

<tr>
<th>Case</th>
<th>Patient</th>
<th>Symptoms</th>
<th>Treatment</th>
<th>Outcome</th>
</tr>
</thead>
<tbody>
<tr>
<td>Case 1: High altitude pulmonary oedema</td>
<td>Male, aged 29 years</td>
<td>Progressive dyspnoea, tachypnoea, cyanosis; occurred at rest camp (3000 m) following third night shift at summit</td>
<td>Immediate descent and oxygen administration (6 L/min)</td>
<td>Clinical examination at sea level – symptoms and signs of HAPO resolved; chest radiograph normal; subsequent work at summit without recurrence of HAPO</td>
</tr>
<tr>
<td>Case 2: High altitude cerebral oedema</td>
<td>Male, aged 30 years</td>
<td>Slurred speech, frontal headache with neck stiffness, temporary loss of peripheral vision, impaired coordination, ataxic gait; symptoms presented on first day at summit</td>
<td>Descent and oxygen</td>
<td>Complete resolution of signs and symptoms at sea level; no subsequent work at telescope</td>
</tr>
<tr>
<td>Case 3: Acute mountain sickness</td>
<td>Male, aged 30 years</td>
<td>Headache, nausea, lethargy, poor concentration, impaired memory, cyanosis, periodic respiration: no focal central nervous system signs. Symptoms present on first day of work at summit of every shift, necessitating descent. Subject attempted, unsuccessfully, to ameliorate symptoms by gradual staging of ascent</td>
<td>Acetazolamide prophylaxis (dose 500 mg to 1.5 g/day); minimal reduction in AMS symptoms. Adverse effects – paraesthesia, diuresis</td>
<td>Exemption from work at high altitude</td>
</tr>
<tr>
<td>Case 4: Migraine headache</td>
<td>Male, aged 29 years</td>
<td>History of classical migraine. Eighth day on mountain – symptoms of expressive dysphasia, loss of right peripheral visual field, numbness right arm; nausea: no headache</td>
<td>Descent, anti-emetic for nausea</td>
<td>Neurological symptoms resolved at sea level, EEG, isotope brain scan – normal</td>
</tr>
<tr>
<td>Case 5: Bronchopneumonia</td>
<td>Male, aged 34 years</td>
<td>Cough productive of purulent sputum, dyspnoea at rest, fever, anorexia, ataxic gait – following flu-like illness</td>
<td>Descent under supervision by colleague (patient exhibited marked loss of insight), antibiotics, bed rest</td>
<td>Uneventful return to summit after 4 days</td>
</tr>
<tr>
<td>Case 6: Bronchopneumonia</td>
<td>Male, aged 30 years</td>
<td>Two episodes on consecutive visits to Mauna Kea, cough productive of purulent sputum, severe dyspnoea, central cyanosis</td>
<td>Descent to sea level, antibiotics, bronchodilators, bed rest</td>
<td>Completed work schedule at observatory after 3 days sojourn at sea level; following second episode, persistent dyspnoea; astronomical research aborted, returned home; subsequent examination by respiratory physician – no underlying chest disease</td>
</tr>
<tr>
<td>Case 7: Perforation of ear drum</td>
<td>Male, aged 55 years</td>
<td>Contracted coryza at sea level, developed right otitis media on Mauna Kea. Impaired hearing, ‘pressure in right ear’, discharge from ear</td>
<td>Remained on mountain, antibiotics, decongestant</td>
<td>Healing of perforation</td>
</tr>

</table>

Assuming a complement of three day staff and three night observers, approximately 2000 'man-days' were worked each year at the UKIRT facility during the two-year period of study. An average working day constituted nine hours at the summit.
to HACO is indicated by deterioration in existing AMS, despite treatment and, no further ascent, or the appearance of neurological signs, such as ataxia on walking (poor heel to toe walking) or sitting (truncal ataxia), cranial nerve palsies and visual field loss. Convulsions may occur. Features of HAPo may coexist and complicate diagnosis and management of HACO. Papilloedema develops in over 50 per cent of HACO victims. Retinal engorge- ment and retinal haemorrhage are of minor prognostic significance in HACO as these fundoscopic abnormalities are not uncommon in asymptomatic subjects at high altitude. Rapid deterioration in conscious level leading to death has been widely reported. Investigations off the mountain show raised cerebrospinal fluid pressure on lumbar puncture and increased signal in white matter reflecting oedema of the corpus callosum on T-2 and diffusion-weighted magnetic resonance imaging (MRI). Post-mortem examination reveals extensive cerebral oedema, intracerebral haemorrhages and thrombosis in cerebral veins and dural sinuses.

Current thinking is that HACO is due to vasogenic oedema related to disruption of the blood–brain barrier with extravasation of fluid into the interstitial space rather than cytotoxic oedema related to cell death due to increased intracellular osmolarity. Damage to the blood–brain barrier may be ‘mechanical’ induced by impairment of cerebral vascular autoregulation or ‘chemical’ related to release of mediators of barrier permeability, such as bradykinin and hydroxyl-free radicals. Cerebral hypoxia is exacerbated by exercise which reduces oxygenation further. If swelling of the brain is commonplace in all people on ascent and AMS is a mild form and precursor of HACO, the ‘tightfit’ hypothesis proposes that susceptible individuals have less cranial capacity to accommodate the swollen brain. Capacity would depend on the ratio of cranial cerebrospinal fluid to brain volume which varies between individuals and could explain variability of response to high altitude exposure. Perhaps people aged over 50 years are more tolerant of high altitude because of a degree of cerebral atrophy.

Cerebral oedema occurs usually in unacclimatized people above 3000-m elevation, although cases of HACO in well acclimatized climbers at extreme altitudes (>7000 m) have been documented. Typically, HACO appears as a progression of AMS developing over 24–36 hours: the risk factors for both conditions are the same. HACO is less common than HAPO. In a series of papers published in the late 1930s, RA McFarland reported several studies from the Andes of the effects of high altitude on psycho-physiological performance. Comparing sudden ascent to 5000 m in unpressurized airplanes while flying over the Andes with slower ascent to 4700 m by road or rail, he observed that the performance of mental tests of complex reactions (e.g. mental arithmetic, writing) were more impaired than motor and sensory tests and that there was a ‘close interdependence between the partial pressure of oxygen in the internal environment of the organism and the functional capacity of the central nervous system’: the rate of ascent was an important variable. In a second paper, sensory (auditory threshold, visual after images) and motor functions (reaction times, hand–eye coordination) showed significant deterioration only above 5330 m; acclimatization lessened deterioration. In the third paper, memory, speed of word recognition and mental flexibility were not significantly affected until an altitude of above 4700 m was achieved. The research subjects noted ‘that the effort of mind needed to carry out a task was greater than the loss of capacity to do it.’ In his fourth paper, McFarland reported that Andean sulphur miners working at 5330 m had slower reaction times and blunted auditory sensitivity than aged and race-matched workmen at sea level.

Impairment of higher cerebral functions has been reported at lower altitudes than the threshold altitude of 4700 m in McFarland’s studies. Psychomotor efficiency (eye–hand coordination test) was compromised in accuracy and speed in a group of Indian soldiers over a period of ten months at 4000-m altitude. Although accuracy recovered over the next 13 months, presumably due to acclimatization, recovery of speed of performance did not return to sea-level values, while the subjects remained at high altitude. Psychomotor and information processing tests were not impaired in Mauna Kea telescope staff at 4200 m. Numerate memory was impaired on the first summit day, but corrected by the fifth day.

Elite climbers who had reached summits over 8000 m without supplementary oxygen were found to have residual
cognitive impairment in short-term memory, cognitive flexibility and ability to concentrate two to six months after the last of repeated exposures to extreme altitude. The three most severely affected individuals exhibited EEG abnormalities. In a group of young fit mountaineers using supplemental oxygen to climb Everest (altitude 8850 m, 29 029 ft: barometric pressure 337 mbars, 33.7 kPa, 253 mmHg), transient mild deterioration in learning, memory and expression of verbal material was detected within three days of descent to Kathmandu, but had recovered by one year. Reduction in motor speed (finger tapping test) characterized by rapid muscle fatigue persisted for a year. In a study of mountaineers before and 1–30 days after ascent to altitudes above 5488 m and altitude chamber ‘ascent’ to 8848 m, neuropsychological testing revealed a decline in visual and verbal long-term memory expression. However, in an earlier study, Clark et al. found no evidence of cerebral impairment as judged by neurophysiological tests performed before and 16–221 days after climbs ranging from 5335 to 8848 m in the Himalayas.

Magnetic resonance imaging of the brains of nine climbers before and after a 7500-m climb without supplementary oxygen showed cortical atrophy (high signal areas) in five before the expedition with new areas of cortical atrophy in two of the group. Both had suffered severe neurological symptoms during the climb. In a more extensive study, MRI abnormalities were present in 61 per cent (13/21) of climbers who had ascended to altitudes over 8000 m, but in only 14 per cent (1/7) of Himalayan sherpas with similar high-altitude exposure. Although no relationship was found between the MRI changes and the number of climbs or the duration of exposure to high altitude, these studies confirm the risk to the brain of hypoxia at extreme altitude with over half of sea-level native climbers affected and relative sparing of high-altitude natives.

Female gender

At high altitude, females are equally likely to suffer from AMS as men. Peripheral oedema is more common in females, but the incidence of HAPO is lower. There are no data regarding difference in the incidence of HACO between the genders. Acclimatization is similar as is exercise performance at high altitude. Although females have an increased ventilatory response to hypoxia which is assumed to be due to the protective effect of the respiratory stimulant hormone progesterone, this does not appear to confer benefit in terms of ventilatory acclimatization. Females lose less weight at high altitude than males possibly because they recover from hypoxia-induced anorexia more quickly.

Women are advised to confine their ascents to modest altitudes (<2500 m) during early pregnancy because of the possible risk of hypoxia to fetal development. During the first trimester, prophylaxis with the carbonic anhydrase inhibitor acetazolamide is contraindicated because of the known teratogenic properties of sulphonamide drugs. Recommendations for pregnant women going to high altitude, including who should not go high, based on a comprehensive review of the literature has been published in an International Mountaineering and Climbing Federation consensus paper.

Combined oestrogen and progestogen oral contraceptives (COCP) can be taken to control the menstrual cycle in wilderness conditions, but there is a theoretical risk of increased thrombotic episodes due to dehydration and an increase in haematocrit occurring at high altitude. Synthetic progestogen formulations may be more suitable for stabilizing the menstrual cycle and for use as contraceptives due to the theoretical reduction in risk of thrombosis. However, different preparations have different characteristics and advantages (see Table 51.2). Newer progestogen-only pills containing desogestrel (75 μg) may have advantages over conventional COCPs by inhibiting ovulation as do COCPs without the increased thrombotic risk. Alternatives to oral preparations include the progestogen-releasing (levonorgestrel) intrauterine system or etonorgestrel implants. To establish effectiveness for the individual female, these formulations should be tried for a minimum of three months, ideally six months, before travel.

Children

Children are susceptible to the adverse effects of altitude and suffer AMS, HAPO and HACO. Most studies have shown a similar incidence of AMS in children and adults. Children living at high altitude are more susceptible than adults to ‘re-entry HAPO’ when they return home after a sojourn at lower altitude.

The inherent risks to children travelling to high altitude demand special attention in the planning for and management of altitude-related illness and subsequent specialist follow up.

Lake Louise acute mountain sickness scoring system

To aid diagnosis and to assess the severity of altitude sickness, the Lake Louise acute mountain sickness scoring system was developed at consensus meetings held in Lake Louise, Canada in 1991 and 1993. The scoring system was formulated initially to allow standardization of diagnosis and severity of illness for research studies. Nevertheless, the simple and short self-reporting questionnaire of five key symptoms has sufficient sensitivity and specificity for use by non-medical trekkers and mountaineers for the detection of altitude sickness in themselves and their companions (Appendix 51.1).

The Lake Louise score can be confounded by extraneous factors (e.g. concomitant illness) leading to over-diagnosis of altitude sickness, hence the score should be calculated in the context of a recent gain in altitude.

Reproduced with permission of Dr Jane Preston, Consultant Obstetrician and Gynaecologist, James Paget University Hospital, Gorleston, Great Yarmouth, UK.
A clinical assessment score involving change in mental status, ataxia (heel–toe walking test) and the presence of peripheral oedema, as well as an overall functional score can be added to the Lake Louise self-assessment score for research purposes. The Lake Louise scoring system is not suitable for the detection of altitude sickness in preverbal children (i.e. under the age of three years). A modified scoring system (Children’s Lake Louise Score) has been developed for this purpose.53

Susceptibility to altitude sickness

Susceptibility to altitude sickness varies greatly between individuals; however, in general, individuals respond consistently on each ascent. On Mauna Kea, mean arterial oxygen tension (PaO2) recorded in the study group ranged from 4.4 kPa (33 mmHg) to 7.6 kPa (57 mmHg) at the summit. The worker with the highest PaO2 during the first ascent (7.0 kPa, 52.5 mmHg) recorded the highest PaO2 on a subsequent ascent (7.6 kPa, 57 mmHg). Similarly, one subject recorded the lowest PaO2 (4.4 kPa, 33 mmHg; 5.1 kPa, 38 mmHg) on both ascents.54 The reproducibility of individual response to high altitude exposure implies that the surest means of predicting an individual’s performance at high altitude is their response on previous ascents. Inevitably, anomalies do occur: the healthy 29-year-old male astronomer who suffered from HAPO on Mauna Kea worked for two years before the episode of HAPO, and three years subsequently, without incident.

Predisposition to AMS may be related to individual sensitivity of hypoxic drive.55 Subjects with a low ventilatory response to hypoxia are liable to develop AMS.56 The magnitude of the increase in pulmonary arterial pressure in response to hypoxia is a further risk factor. The search for a genetic marker for AMS predisposition is wide-ranging and on-going.

Rapid ascent by sea-level residents to high altitude

As previously stated, there is a time delay of several hours on arrival at high altitude before the development of AMS; nevertheless, ‘high altitude novice’ sea-level residents report unpleasant symptoms on immediate arrival at high altitude before the onset of ‘classical AMS’. Tourists visiting mountain tops report impaired mental and physical performance. Businessmen on tight schedules feel so unwell on reaching La Paz (3600 m) that their presentations are poor and multimillion dollar contracts are lost.57

In the 2007 survey of AMS on Mauna Kea, day visitors to the summit by vehicle were invited to complete a self-report assessment Lake Louise Symptom Score (LLSS) on descent. The majority were at the summit for less than two hours. Despite the lack of exertion on ascent, 60 day visitors (30 per cent) suffered AMS defined as a LLSS of 3 or greater. Headache was recorded in all sufferers, mental status changes in 17 per cent and shortness of breath in 29 per cent.13 The authors of this study observed that to differentiate symptoms induced directly by hypoxia from those caused by changes in vascular permeability, which are involved in the pathogenesis of AMS,58 would be difficult. Nevertheless, the time scale of the onset of symptoms indicates that these novice visitors to high altitude experienced either AMS of unusually rapid onset or a different condition altogether.

Illness at high altitude which is not high altitude illness

A personal account by a senior physician and experienced researcher emphasizes that not all sickness at high altitude is high altitude sickness. At Pheriche (4243 m) on the path to the Everest base camp, his dyspnoea, chest discomfort (‘a severe weight on my chest – like a dead yak’) and tachycardia were due to atrial flutter with 2:1 block and left ventricular failure and ‘not real AMS’.59

The number of confounding conditions which can mimic or confuse the diagnosis of altitude sickness is legion. Neurological conditions reported include subarachnoid haemorrhage, transient global ischaemia, transient ischaemic attacks and strokes, convulsions, migraine and isolated sixth nerve palsies. Ophthalmic diagnoses, such as radial keratotomy and retinal haemorrhages, need to be recognized. Pulmonary embolism and respiratory infection, so often a mimic of HAPO, occur at high altitude and may be hypoxia-related. Miscellaneous problems may be linked to alcohol and recreational drug use, exhaustion, hyperthermia, dehydration and carbon monoxide poisoning occurring in snow holes and tents. The authors of a comprehensive review of acute medical problems in the Himalayas outside the setting of acute altitude sickness recommend ‘in most instances and when the diagnosis is uncertain it is best to descend’.60

AT-RISK GROUPS

Ischaemic heart disease

On the first day of work on the summit of Mauna Kea, mean PaO2 was 5.6 kPa (42 mmHg) measured in 27 subjects on 40 ascents. Hypoxaemia induces increased sympathetic stimulation. As pulse rate increases, so does cardiac work and systemic blood pressure. The increase in cardiac work can be expressed in terms of the ‘double product’, i.e. the product of heart rate and systolic blood pressure. Among the Hawaiian telescope workers, the mean sea level ‘double product’ was 8925 units (mean resting pulse rate 75 beats/minute × mean systolic blood pressure 119 mmHg). At 4200 m, the ‘double product’ rose to 10 285 units, an increase in cardiac work of approximately 15 per cent.
By five days, sympathetic activity had fallen and the ‘double product’ stood at 9840 units. This indicates that the period of greatest risk for exacerbation or precipitation of ischaemic heart disease is the first three days at high altitude: the threat to coronary patient diminishes by five to seven days. Modest increases in cardiac output at high altitude will have little deleterious effect on people with controlled ischaemic heart disease and these people can work safely at high altitude. However, subjects experiencing angina or exertional dyspnoea at sea level may suffer a worsening of symptoms shortly after arrival at high altitude when cardiac output is highest. Common-sense advice should include recommendations for a slower than usual ascent profile with additional rest days at intermediate altitudes, limitation of physical activity to less than the level that precipitates symptoms at sea level and control of blood pressure.61 People whose level of activity is severely curtailed by ischaemic symptoms at sea level are likely to suffer a marked deterioration at high altitude and must be cautioned against ascent. For such people who decide to ascend, facilities for rapid retreat down the mountain are mandatory taking precedence over other precautions, e.g. provision of oxygen or medical supervision.

In a population study, Shlim and Houston62 surveyed reports of illness in 148,000 trekkers in Nepal during a three-year period. In the 23 fatalities, the cause of death were trauma (11), ‘illness’ (8) and AMS (3); no cardiac deaths were reported. Hultgren63 reports that in the 25 years of his experience, the Chief Medical Officer at La Oroya (altitude 3750 m) never witnessed a myocardial infarction in a known sufferer from ischaemic heart disease among the hundreds of visitors who ascend each year from Lima, near sea level, to La Oroya.

### Hypertension

There is no consistent change in blood pressure reported in normotensive sea-level residents at high altitude. On Mauna Kea, systolic pressure rose after two days at high altitude (mean 124 versus mean 118 mmHg at sea level) and returned to baseline levels on return to sea level. Diastolic pressure rose on arrival at 3000 m, remained elevated during five days on the mountain and fell on descent. No adverse effects related to elevation in systemic pressure occurred (Table 51.3). Hypertensive individuals demonstrate both increases and decreases in blood pressure at altitude.48 Controlled hypertensive subjects can be reassured regarding ascent and advised to continue their prescribed antihypertensive medication.

### Table 51.3  Effect of repeated exposure to high altitude (4200 m) on subjects with pre-existing medical conditions.

Respiratory disorders

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Sea-level dwellers rendered hypoxic by chronic lung disease will suffer a further reduction in PaO₂ at high altitude. Graham and Houston⁶⁴ accompanied eight patients with chronic obstructive airways disease (COAD), who had an average resting PaO₂ of 8.8 kPa (66 mmHg) at sea level, to an altitude of 1920 m. Within three hours of ascent, resting PaO₂ fell to 6.9 kPa (52 mmHg). Six minutes on a treadmill produced severe arterial hypoxaemia (mean PaO₂ 6.2 kPa (46.5 mmHg) compared to 8.4 kPa (63 mmHg) at sea level). Despite levels of PaO₂ which would qualify as respiratory failure in COAD patients at sea level, none of the study patients came to harm and altitude sickness symptoms were trivial. In this study, tolerance of modest high altitude by COAD patients was facilitated by the exclusion criteria of coexistent disease (cor pulmonale, hypertension, angina) or elevated PaCO₂. Many COAD patients will be afflicted by these complications and the results of this study must be interpreted with caution. Other factors may compromise high altitude tolerance in chronic lung disease patients. Smokers experience more profound arterial hypoxia than non-smokers at high altitude.⁶⁵ Obese individuals are more prone to sleep apnoea at high altitude⁶⁶ and during periods of apnoea PaO₂ falls precipitously. Marked nocturnal arterial desaturation contributes to the exaggeration of altitude sickness symptoms present on morning waking.

ASTHMA

Bronchial airway narrowing in asthmatics can be provoked by stimuli, such as exercise and inhalation of cold air. Nevertheless, exposure to mountain air relatively free of air pollutants (tobacco smoke, petrol fumes) and exogenous allergens (house dust mites) is of benefit to asthmatics and treatment clinics have flourished in the alpine regions at altitudes as high as 3200 m in the Northern Tien-Shan mountains in Kyrgyzstan. Asthmatics with well-controlled disease may be encouraged to go to high altitude. Pretreatment with acetazolamide protects against AMS symptoms and lessens arterial desaturation during sleep.⁶⁷ Asthmatics who self-monitor by serial peak flow measurements should be aware that the decrease in air density at high altitude results in under-reading of meters.⁶⁸ Readings taken with a mini-Wright meter can be corrected by adding 6.6 per cent for every 100 mmHg reduction in barometric pressure.⁵⁰ Overall PEF increases at high altitude, while FVC falls. Neither of these changes in pulmonary function measurements correlate with AMS.⁶⁹

Diabetes mellitus

Hypoxia per se does not appear to have a deleterious effect on glucose metabolism and diabetic control. However, the inevitable increase in exercise during an ascent will consume carbohydrate stores and altitude-related nausea and vomiting will reduce carbohydrate intake leading to a reduction in insulin requirements. Hypoglycaemia may develop if insulin dosage is not adjusted accordingly. In wilderness conditions, intercurrent illness and vomiting associated with altitude sickness may predispose the diabetic to ketoacidosis. The respiratory alkalosis of hyperventilation at high altitude may complicate the clinical presentation of a metabolic acidosis. Furthermore, the prescription of a carbonic anhydrase inhibitor, such as acetazolamide as prophylaxis against AMS (see below under Prevention), may exacerbate metabolic acidosis. A climber with diabetes must be prepared to monitor their glycaemic control even more assiduously than usual. This necessity is compromised by under-reading of glucose meters at high altitude and low temperature. People with diabetes and their climbing companions must be well versed in the recognition and treatment of hyperglycaemia and hypoglycaemia.

On Kilimanjaro (5700 m), a group of type I diabetics were not more prone to AMS than their non-diabetic companions, although the diabetic climbers attained Gillman’s Point (5700 m), whilst the non-diabetic others reached Uhuru Peak (5900 m).⁷⁰

Haemoglobinopathies

Sickle cell anaemia, the homozygous form of the disease with HbS accounting for more than 90 per cent of haemoglobin, carries a high childhood mortality and considerable morbidity for adult survivors. People with the heterozygote sickle cell trait (HbA 60 per cent; HbS 40 per cent) are usually symptom-free at sea level and, with normal respiratory function, are unlikely to be at risk at altitudes up to 2000 m. Above this altitude, there is a risk of splenic and renal infarction and hence workers should be screened for the sickle cell trait before they are employed to work at high altitude. Avoidance of dehydration, caution in the event of infection and awareness of the significance of unexplained abdominal pain or haematuria will afford some protection to individuals with haemoglobinopathies who wish to venture to high places.⁷¹ Treatment of a sickling crisis at high altitude is descent, in addition to the administration of oxygen and fluids and the prescription of analgesia.

SLEEP AT HIGH ALTITUDE

Periodic breathing (Cheyne–Stokes respiration) occurs during sleep at high altitude and periods of apnoea interspersed with rapid respiration cause frequent arousals during the night.⁷² Insomnia is a common complaint. At relatively modest altitudes below 1400 m, sleep duration is reduced and the sleep efficiency index (ratio of total sleep time to the time in bed) falls. Above 4000 m, sleep duration and efficiency deteriorate further; sleep onset
latency is increased and rapid eye movement (REM) sleep is decreased. Disruption of the normal respiratory rhythm produces marked hypoxaemia during sleep. Sleep quality can be improved and sleep hypoxaemia alleviated by acetazolamide. The use of hypnotic drugs by climbers at extreme altitude is not recommended because of the accompanying depression of ventilation which exacerbates nocturnal hypoxia. Nevertheless, the prescription of a short-acting benzodiazepine at low doses (e.g., 10-mg temazepam) in conjunction with acetazolamide reduces sleep onset latency and increases sleep efficiency at 4000 m.

**ANAESTHESIA AT HIGH ALTITUDE**

In a review of anaesthesia at high altitude, Stoneham advises that the greater the altitude the greater the risks of anaesthesia and the less the likelihood of available anaesthetic expertise. At all altitudes, general anaesthesia will cause an increase in the alveolar to arterial gradient with physiological shunting. In addition, anaesthetic agents act as respiratory depressants and abolish peripheral chemoreceptor hypoxic drive upon which hyperventilation and survival at high altitude depend. At altitudes of 2000 m (e.g., Denver, Colorado) general anaesthesia should provide no particular problems. At altitudes above 3500 m (e.g., La Paz, Bolivia), the anaesthetic gas mixture should be oxygen enriched: close attention must be given to avoid post-operative hypoxia. At altitudes above 4000 m, general anaesthesia should be avoided unless life saving. Every attempt must be made to evacuate to a lower altitude.

**Oxygen enrichment at high altitude**

The pre-eminence of Mauna Kea as the highest terrestrial observatory in full-time operation has been superseded by the establishment of telescopes on the Chajnantor plateau in Northern Chile (5050 m, 16 470 ft). At this site, the California Institution of Technology has been operating a cosmic background imager (CBI) since 1999.

At 5050-m elevation, the barometric pressure is 551 mbars (55.1 kPa, 419 mmHg) and the partial pressure of oxygen in inspired air is 10.3 kPa (78 mmHg), only 52 per cent of sea-level values. These figures compare with a barometric pressure of 625 mbars (475 mmHg) and partial pressure of inspired oxygen of 12.6 kPa (95 mmHg) at the Mauna Kea summit. The CBI workers are exposed to approximately 10 per cent less oxygen than their Mauna Kea colleagues. To reduce the deleterious effects of hypoxia at over 5000 m, the atmosphere in the CBI control room and laboratory is enriched with oxygen to 27 per cent using oxygen concentrators. Enrichment of oxygen to 27 per cent reduces the equivalent altitude (i.e., the altitude at which the moist inspired PO2, when a subject is breathing ambient air, is the same as the inspired PO2 in the oxygen-enriched environment) to 3200 m. Between altitudes of 3000 and 6000 m, each 1 per cent of oxygen enrichment results in a reduction of equivalent altitude of about 300 m.

Oxygen enrichment was first used at the El Tambo mine in Northern Chile (4200 m) where 16 dormitory rooms were supplied with 24–26 per cent oxygen from a liquid oxygen source. Sleep quality was enhanced. The miners improved in the performance of psychometric tests assessing ability to concentrate, short-term memory, visual perception, attention span and auditory and topographical memory. Oxygen enrichment technology has developed with the introduction of oxygen concentrators and can be implemented without an increase in fire risk at high altitude. In a study at White Mountain (3800 m), Luks confirmed that oxygen enrichment enhanced sleep, but cognitive function improvement did not occur after one night of breathing oxygen-enriched air in this environment. In a 1972 paper, McFarland reported that cognitive function was only minimally impaired at this altitude. However, at a simulated 5000-m altitude, oxygen enrichment improved motor function (hand–eye coordination) and response times, although not cognitive function. Undoubtedly, oxygen enrichment does increases the sense of well-being in workers at high altitude and over the seven years of operation, oxygen enrichment has shown benefit. At Chajnantor, construction of the multinational Atacama large millimeter array (ALMA) started in 2003 and will be completed in 2012: it will become operational in 2010. ALMA is a single instrument composed of 66 high-precision antennas which can be moved across the altiplano desert over distances up to 15 km. In living and enclosed work areas (e.g., main control room, electronics and computing areas, engineering offices and antenna receiver cabins), the atmosphere will be oxygen enriched to 27 per cent.

In a 1984 review of high altitude medicine and physiology, Cudaback concluded that the detrimental effect of hypoxia on performance and health at 4000-m high telescopes was sufficiently severe to warrant intervention. Considering the options of oxygen enrichment of enclosed air spaces, raising inside ambient barometric pressure or administration of medication, he concluded that oxygen enrichment was the answer. However, none of the 13 Mauna Kea observatories in operation employ oxygen enrichment, although the capability exists at two telescopes and neither is this provision available at the dormitory and living facilities at 3000 m. The opinion and experience of Mauna Kea staff was that the evidence of the need for oxygen enrichment at 4000-m altitude was not convincing.

**ALTITUDE SICKNESS**

**Prevention**

Wise mountaineers who wish to avoid the debilitating effects of high altitude respect the maxims ‘climb high, sleep low’ and ‘hasten slowly’. These precepts are of
Working at high altitude

particular relevance for people with a previous history of altitude sickness. A slow ascent of only 300 m/day above 3000 m altitude is recommended.\textsuperscript{84,85} Staging the climb so that a rest day and two consecutive nights are spent at the same altitude every third day (or every 1000 m) facilitates acclimatization. By following these cautious guidelines, the majority of sea-level residents ascend safely, but some will develop altitude sickness above 3000 m. Common sense must prevail: an attempt to climb higher while in the throes of an attack of altitude sickness is foolhardy. Victims of altitude sickness must descend; a descent of 500 m may be sufficient to relieve AMS. Alternatively, AMS sufferers should remain at a safe moderate altitude (below 3000 m) until their condition improves. General measures to ease discomfort include avoidance of strenuous exercise on arrival at high altitude, maintenance of an adequate fluid intake and abstinence from alcohol and tobacco. Cold exposure and lack of sleep aggravate the discomforts of a hypoxic environment. Infection is associated with a higher incidence of AMS and markedly increases the misery of altitude sickness; climbers with infections should ascend at a slower rate or preferably remain at an intermediate altitude.\textsuperscript{7}

People whose work or leisure schedules do not allow gradual ascent can be offered prophylactic treatment with acetazolamide and this is a wise precaution if they have a previous history of altitude sickness. Acetazolamide and methazolamide inhibit the enzyme carbonic anhydrase which regulates CO\textsubscript{2} transport out of cells. Inhibition of the enzyme in the renal tubule promotes renal excretion of bicarbonate and conserves hydrogen ion (H\textsuperscript{+}). The increased arterial H\textsuperscript{+} concentration counteracts the respiratory alkalosis caused by hyperventilation in the low oxygen environment of high altitude. Respiratory alkalosis produces a negative feedback on central respiratory drive: carbonic anhydrase inhibition removes this negative feedback, thus enhancing respiratory activity and increasing oxygen uptake (Figure 51.4). Prophylactic treatment with acetazolamide raises arterial H\textsuperscript{+} concentration and PaO\textsubscript{2} and ameliorates AMS symptoms.\textsuperscript{86-89} Prescriptions of acetazolamide (500 mg/day, sustained release tablet or a dose of >125 mg twice a day\textsuperscript{90}) should be given for 24 to 48 hours before ascent and continued for two days at high altitude. The period of time needed for acclimatization will depend upon the speed of ascent, the altitude achieved and the individual’s unique physiology. Adverse effects of carbonic anhydrase inhibitors include limb and perioral paraesthesia which diminish over time and an alteration of the taste of carbonated drinks. Mountaineers recognize that individuals resistant to altitude sickness urinate profusely on reaching altitude—the ‘Hohendiuresis’ of the alpine climber. Although acetazolamide is a diuretic, the diuretic effect is short-lived and its efficacy in altitude sickness is not due to this property. Frusemide, a potent loop diuretic, has been advocated for the prevention of AMS;\textsuperscript{8} however, there is a danger of aggravating fluid depletion in climbers who are dehydrated by hyperventilation, intense physical activity and the twin scourges of vomiting and diarrhoea. Hypercoagulability of the blood and sequestration of platelets provoke pulmonary thrombosis at high altitude. The dehydrating effect of a powerful diuretic may aggravate this thrombotic tendency.

Dexamethasone, a potent synthetic glucocorticoid with some mineralocorticoid activity, has been demonstrated to reduce AMS symptoms when given prior to simulated ascent to high altitude (4570 m)\textsuperscript{91} and during rapid ascent of Mount Rainier.\textsuperscript{92} In the latter study, dexamethasone was administered at a 4-mg dose every eight hours for 24 hours before ascent. The potentially serious adverse effects of corticosteroids limit the duration of prophylactic treatment. Dexamethasone has no effect upon oxygen consumption or carbon dioxide transport. Reduction of cerebral oedema of vasogenic origin may be the action whereby dexamethasone is effective as AMS prophylaxis.

Theophylline, a phosphodiesterase inhibitor and potent bronchodilator used in the treatment of obstructive airways disease has a range of pharmacological properties advantageous to the AMS victim, including suppression of capillary permeability in lung and brain, decrease in pulmonary artery pressure and stimulation of central respiratory drive. A decompression chamber study (simulated altitude 4500 m) and a mountain study (3454 m) showed that slow-release theophylline (375 mg bid or 250 mg bid for subjects <70 kg) taken three days before ascent reduced AMS (Lake Louise symptom score) and raised arterial oxygen saturation. These benefits were short lived.\textsuperscript{93}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure51.4.png}
\caption{Mode of action of carbonic anhydrase inhibition in prophylaxis of acute mountain sickness (AMS).}
\end{figure}
An alternative remedy for AMS prophylaxis is ginkgo biloba. This herbal extract is reputed to have anti-oxidant and anti-hypoxic properties which led to its use in patients with cerebral and peripheral vascular disease. Ginkgo biloba is reputed to stabilize the cerebral blood–brain barrier, hence the rationale for its use in AMS. A study in the Himalayas of 44 mountaineers ascending to 5200 m showed a significant reduction in AMS with none of the ginkgo-treated group (five days of 120-mg gingko) suffering from AMS compared to 41 per cent of placebo group.94 In a study on Mauna Kea, with subjects following an ascent profile similar to that of shift workers in the 1980 study, gingko (60 mg tds) taken one day before ascent reduced the severity of AMS in the treated group, but there was no significant reduction in incidence of AMS. This study was discontinued early because of the unexpected and unexplained incidence of severe AMS with 42 per cent (11/26) of subjects needing evacuation from the summit. No difference in oxygen saturation was found between the treatment and placebo groups.95 The case for gingko prophylaxis requires further study; however, with few adverse effects (occasional headaches) and available without prescription, gingko will appeal to those unable or reluctant to take acetazolamide or dexamethasone as AMS prophylaxis.

Chemoprophylaxis for HAPO is an important therapeutic intervention because of the recurrent nature of the condition. The calcium channel blocker nifedipine is effective as a slow-release preparation at a dose of 20 mg every eight hours and has been demonstrated to prevent HAPO after rapid ascent to 4559 m. Individuals with a history of HAPO who wish to climb should consider nifedipine prophylaxis.96 However, nifedipine is not recommended as prophylaxis or treatment of AMS or HACO.96 HAPO-susceptible individuals have an impairment of sodium-dependent alveolar fluid clearance. The beta-sympathetic agonist salmeterol facilitates clearance of alveolar fluid by stimulating trans-epithelial sodium transport via effects on the amiloride-sensitive channel and Na+/K+-ATPase pump. Prophylactic inhalation of salmeterol (125 μg by pressurized metered-dose inhaler connected to a spacer every 12 hours), administered on the morning of a day-long ascent to 4559 m, decreased the incidence of HAPO by over 50 per cent in a group of HAPO-susceptible mountaineers.97 Manipulation of pulmonary vasoactive mediators is another possible HAPO chemoprophylactic avenue to explore. The phosphodiesterase-V inhibitor sildenafil is a potent vasodilator of both peripheral and pulmonary vessels. Combined with red wine, a known antioxidant and endothelin-1 suppressor, sildenafil may, in the words of one reviewer, ‘lead to an enthusiastic number of subjects going to high altitude for more than just the enjoyment of the view’.27

**Treatment**

Acute mountain sickness of moderate severity – without respiratory distress or neurological dysfunction – may be managed at intermediate altitudes between 3000 and 4000 m, particularly if the victim is able to sleep at a lower altitude. Exercise induces sodium and water retention, decreases oxygen saturation and increases pulmonary artery pressure, thus aggravating the pathological processes leading to altitude sickness: rest is an important component of treatment for all grades of severity of AMS.98 In difficult circumstances, the need for rest may be outweighed by the need for exertion to descend. Abstinence from alcohol, adequate fluid intake and frequent small meals of carbohydrate content are recommended. Non-steroid anti-inflammatory drugs (e.g. ibuprofen) have been proven effective in relieving high altitude headache in a placebo-controlled double-blind trial.99 The association of nausea, vomiting and visual disturbance with debilitating headache has led to the supposition that AMS could share a similar pathophysiological mechanism to classical migraine.100 However, selective stimulation of 5-hydroxytriptamine receptors by sumatriptan (100-mg dose), a rapid and comprehensive treatment for migraine, was not efficacious for high altitude headache.101 To ease nausea and vomiting, anti-emetics (e.g. prochlorperazine 10-mg oral, or intramuscular injection three times a day) may be administered. To aid sleep short-acting sedatives (e.g. temazepam) should be used at the lowest effective dose for the shortest time possible. The use of carbonic anhydrase inhibitor drugs for the treatment of AMS has been established in several studies. In a double-blind, placebo-controlled trial on Mt McKinley (4200 m), low-dose acetazolamide (250 mg) was prescribed at diagnosis and eight hours later. Symptoms were relieved, arterial oxygenation improved and pulmonary gas exchange was stabilized.102 High-dose acetazolamide (1.0–1.5 g) and methazolamide (400–500 mg) were studied on three separate expeditions at between 3200 and 5486 m: as in the low-dose study, AMS symptoms and arterial oxygenation improved significantly.103 High-dose acetazolamide was associated with more adverse effects and a quarter of subjects suffered headache. This is sufficient reason to favour the lower-dose treatment regime.

The treatment for severe AMS, HAPO and HACO is immediate descent to the lowest altitude feasible and administration of oxygen. All other therapeutic measures are of secondary importance. The consequences of delayed descent may be fatal pulmonary and cerebral disease.104 Once HAPO or HACO are established, oxygen therapy may not be beneficial even at the recommended flow rate of 6–8 L/min; the failure of supplementary oxygen to be invariably effective is because hypoxia, the initiating insult, triggers increased capillary permeability causing oedema of the lungs and brain which can only be reversed by retreat from a hypoxic and hypobaric environment. In addition to descent and oxygen, dexamethasone is administered in severe AMS (4 mg every six hours for 24 hours) and HACO at a dose of 8 mg initially followed by 4 mg every six hours by mouth, i.m. or i.v. injection.105 Nifedipine, a calcium channel blocker, reverses hypoxic pulmonary hypertension and lowers pulmonary artery pressure in HAPO victims.
Oxygenation improves and the clinical manifestations of HAPO are relieved. \textsuperscript{106} Nifedipine is prescribed at a dose of 10 mg sublingually and 20 mg slow release capsule stat followed by 20 mg slow release capsule every six hours until descent for established HAPO. HAPO is not caused by cardiac failure and the use of frusemide may worsen the condition of a hypotensive, shocked HAPO victim.

In remote high altitude regions of the world, many miles from medical attention, the sick climber suspected of HACO and HAPO can be administered dexamethasone (8 mg stat followed by 4 mg six-hourly for 24 hours) and nifedipine (20 mg tablet six-hourly for 24 hours) simultaneously to allow for repatriation to a lower altitude. Carrying these medications for use in an emergency has been recommended by physicians experienced in high altitude medicine. It must be emphasized that such treatment should neither exceed 24 hours nor be a substitute for descent. \textsuperscript{107}

The practical problems of transporting cylinders to high altitude limit the availability of oxygen in an emergency. Simulated descent in a portable fabric hypobaric chamber (Gamow bag\textsuperscript{8}, Certec bag\textsuperscript{8}, portable altitude chamber) is a popular alternative. The Gamow bag (weight 6.6 kg, including foot pump) is inflated to an inside pressure of 103 mmHg above ambient atmospheric pressure. At this inflation pressure, a patient inside the chamber experiences a simulated descent; \textsuperscript{108} for example, at 4500 m (ambient atmospheric pressure 433 mmHg), a treated subject experiences a pressure of 536 mmHg equivalent to an altitude of 2780 m, a ‘descent’ of 1720 m. Hyperbaric treatment alleviates symptoms and PaO\textsubscript{2} rises for the duration of treatment in the chamber, but falls within minutes of return to the outside atmospheric pressure. \textsuperscript{109,110} Symptom relief is greater and quicker with pressurization treatment than with oral dexamethasone (8 mg initially, 4 mg after six hours), but the benefits of corticosteroids are of greater duration: both treatments can be administered together to AMS patients. \textsuperscript{111} It is possible to place an oxygen cylinder in the bag for use by the victim. The inevitable build up of exhaled carbon dioxide in the bag, despite venting by foot pump action, has a measurable beneficial effect in increasing peripheral and cerebral oxygenation possibly by stimulation of the respiratory centre or dilatation of cerebral vasculature. \textsuperscript{112} Hyperbaric treatment is not to be recommended as a substitute for descent, but may obviate the need for storing large quantities of oxygen at high altitude work stations. Other novel methods to improve gas exchange and oxygenation include the use of a portable continuous positive airways pressure in HAPO\textsuperscript{113} and the addition of 3 per cent carbon dioxide to inhaled air in AMS. \textsuperscript{114}

Safe working at high altitude

Assessed against the parameters of the quality of astronomical research and safety of the work force, the Mauna Kea Observatory has been an outstanding success. A visible sign of this success is shown in Figures 51.1 and 51.2: between 1989 and 1998 the number of telescopes increased from six major telescopes with one under construction to 11 telescopes sited at the summit.

According to management staff at Mauna Kea, in a 2007 survey of AMS, there had not been any reported deaths or permanent morbidity related to HAPO or HACO on the mountain. \textsuperscript{13} Remote observation technology has advanced since the early days; nevertheless, in 1999 staffing requirements at one telescope (United Kingdom Infra Red Telescope, UKIRT) still necessitated 2000 man-days per annum. Overall, 30 000 man-days per annum are spent at the major telescopes on Mauna Kea. There has been a single cardiac death at the summit among the telescope personnel. A 37-year-old smoker and diabetic suffered a myocardial infarction after staying at the summit all night and working through the days. Post-mortem examination revealed extensive coronary disease. Following this fatality, revised health screening protocols were established (Table 51.4). All UKIRT personnel undergo a medical evaluation at sea level which includes physical examination, a comprehensive range of blood tests, resting ECG and treadmill stress test, chest x-ray and pulmonary function tests. Recommendations are that medical evaluations should be repeated annually for individuals above age 40 years, every two years between ages 30 and 39 years and every three years for those younger than age 30 years. In the late 1990s, a 40-year-old construction worker suffered a fatal cardiopulmonary arrest at the summit: construction company employees were not required to undergo a rigorous screening programme. \textsuperscript{115} The confidence of the workforce – technical, scientific and managerial – in operating the telescopes on Mauna Kea has been greatly facilitated by ease of descent from the mountain and ready access to high quality medical care in the event of an emergency. Within two hours of leaving the summit by road, a victim of HAPO or HACO could be undergoing MRI or computed tomography (CT) scanning at sea level. Provision of sleeping and living facilities at a mid-level station (Onazaku Center, Hale Pohaku, 3000 m) affords protection and comfort for the staff.

Education of the workforce is essential. The initial trepidation of the telescope staff at the prospect of working in a hypoxic and hypobaric environment has been supplanted by knowledge of the consequences of altitude exposure, and the awareness that problems can be predicted and coping strategies developed. The converse ‘machismo’ attitude of denial of the hazards of altitude has been replaced by respect for the mountain site and acceptance that people react to altitude exposure in an individual manner irrespective of age, fitness, gender or ‘toughness’. Information cards describing the serious symptoms requiring immediate evacuation from the summit are displayed at the telescope. Bottled oxygen is available on site. Experience has established clear directives for the workforce. No individual is allowed at the summit alone and sufficient unlocked vehicles must always be available at the telescope: the so-called ‘two man, two vehicle’ rule. No one sleeps at the telescope. No alcohol is permitted on the mountain. Staff

| **Prevention**       | Gradual ascent. Above 3000 m ascend 300 m per day  
                       Staging ascent. Two days stay at intermediate altitude (i.e. 3000 m): rest day and 2 consecutive nights at same altitude every 3rd day (or 1000 m ascent) 
                       Avoid excessive exertion  
                       Consider prophylaxis. AMS: acetazolamide 500 mg sustained-release or 250 mg twice daily 2 days before ascent and 2 days at high altitude 
                       dexamethasone: 4 mg every 8 hours for 24 hours before ascent (for subjects intolerant or refractory to acetazolamide)  
                       HAPO: nifedipine 20 mg slow release every 8 hours |
| **Treatment**        | Mild AMS 'If in doubt, go down'  
                       Rest: no further ascent, avoid exertion  
                       Analgesia for headache  
                       Anti-emetics for nausea, vomiting |
|                      | Moderate/severe AMS  
                       Descend 500 m or more, sleep at lower altitude  
                       Rest  
                       Adequate fluid intake and small frequent meals  
                       Ibuprofen or paracetamol for headaches, anti-emetics for nausea  
                       Acetazolamide: 250 mg twice daily or 500 mg sustained release  
                       Dexamethasone: 4 mg every 6 hours for severe AMS if descent is not possible  
                       Antibiotics for infection (if suspected) |
|                      | High altitude cerebral oedema  
                       Immediate descent or evacuation  
                       Dexamethasone: 8 mg stat (oral, i.m. or i.v. route), then 4 mg every 6 hours  
                       Oxygen (2–4 L/min)  
                       Hyperbaric pressurization (if descent not possible) |
|                      | High altitude pulmonary oedema  
                       Immediate descent or evacuation  
                       Oxygen 4–6 L/min (then 2–4 L/min if improvement)  
                       Nifedipine: 10 mg oral/sublingual with 20 mg stat, then 20 mg slow release every 6 hours  
                       Hyperbaric pressurization (if descent not possible)  
                       Dexamethasone: as above if neurological features indicate HACO |

are only allowed to drive on the mountain road after having experienced three return trips as a passenger. It is clearly understood that a staff member is the responsible officer at the summit and has the authority to close the facility if hazard threatens. Many of these measures have been adopted at the Chajnantor site to complement the two elements underpinning safe operation at the site – the establishment of an operations support base at a modest altitude (2400 m) and oxygen enrichment of the air inside the buildings at 5000 m.

Over several decades of scientific endeavour on Mauna Kea, the calibre of astronomical research produced has demonstrated that high altitude is not detrimental to high performance. Men endure high altitude for reasons more prosaic than gazing at the stars. At the Acaquilolcha sulphur mines in the Chilean Andes, native miners live and sleep at 5330 m and each day ascend to the mines at 5950 m. Miners refuse to inhabit the camp erected at the mine because of difficulty with sleep at the higher elevation; nevertheless, the top camp is occupied by a gang of caretakers. Each Sunday, the caretakers descend to the comfort of 4220 m to play football. However, at the international level, there is controversy that adaptation to life at high altitude may confer unfair advantage to high altitude natives over sea-level opponents when playing the beautiful game in thinner air. In May 2007, football’s international governing body (FIFA) banned World Cup-qualifying matches from being played at more than 2750 m elevation because of possible distortion of competition to the delight of the Brazilians (Rio de Janeiro, sea level) and the outrage of the Bolivians (La Paz, 3600 m). Under pressure from the Bolivian president Evo Morales, who enlisted the support of Diego Maradona in a campaign against football apartheid and the South American Football Confederation, FIFA relented and awarded a special dispensation for Bolivia to host World Cup-qualifying games in La Paz.

On May 23, 2007, medical researchers sampled femoral arterial blood at the ‘Balcony’ (8400 m) on their descent from the summit of Everest (8850 m). PaO₂ was in the range of 2.55–3.93 kPa. One of the key objectives of the Caudwell Xtreme Everest expedition was to investigate how humans could survive in environmental hypoxia, when at sea level artificial ventilation would be required to
preserve life. It is hoped that the experiments will extend
knowledge which will aid the care of critically ill patients in
whom hypoxia is a fundamental problem.119

‘Because it is there’, answered George Mallory,
reputedly, when asked why he wanted to climb Everest.
Mallory and Andrew Irvine died in the attempt. And yet
men and women still climb and die on the mountain: some
alone and cold, some overwhelmed by avalanche, ice falls
or falling rocks, some in the depths of crevices, and some
stumbling exhausted and incapacitated by high altitude
illness.120 Humans, ascending mountains for many differ-
ent reasons as well as science and commerce, can find there
an unforgiving world.

Key points

● Altitude sickness affects unacclimatized sea-level
residents ascending to altitudes above 2500 m.

● The clinical diseases associated with high
altitude sickness are ‘benign’ acute mountain
sickness (AMS) which is usually self-limiting
and resolves after two to three days and
‘malignant’ high altitude cerebral oedema
(HACO) and high altitude pulmonary oedema
(HAPO), both of which are potentially fatal.

● Altitude sickness is avoided by slow, staged ascent
(‘hasten slowly’) allowing acclimatization, sleeping
at the lowest possible altitude (‘climb high, sleep
low’) and avoidance of strenuous exertion.

● The essential treatment for severe AMS, HACO
and HAPO is immediate descent to lower
altitude. All other treatments (e.g. drugs, oxygen
administration) are adjuncts to descent.

● Experience derived from decades of work at high
altitude mines and astronomical observatories
have shown that working at high altitude is
possible, safe and effective if appropriate
working practices are established and if the
means for descent is always available.

Appendix 51.1 Calculating the Lake Louise Acute Mountain
Sickness (AMS) score.121

Add up the responses to each of the questions of the self-report
score (questions 1–5).
A diagnosis of AMS is based on a recent rise in altitude, the
presence of a headache and at least one other symptom and a
total score of at least 3.
AMS = Altitude Gain AND Headache AND at least one other
symptom AND a total score of 3 or more.

Self-Report Questionnaire:

1. Headache 0. No headache
   1. Mild headache
   2. Moderate headache
   3. Severe headache, incapacitating

2. Gastrointestinal symptoms 0. No gastrointestinal
   symptoms
   1. Poor appetite or nausea
   2. Moderate nausea or vomiting
   3. Severe nausea and vomiting, incapacitating

3. Fatigue and/or weakness 0. Not tired or weak
   1. Mild fatigue/weakness
   2. Moderate fatigue/weakness
   3. Severe fatigue/weakness, incapacitating

4. Dizziness/lightheadedness 0. Not dizzy
   1. Mild dizziness
   2. Moderate dizziness
   3. Severe dizziness, incapacitating

5. Difficulty sleeping 0. Slept as well as usual
   1. Did not sleep as well as usual
   2. Woke many times, poor nights sleep
   3. Could not sleep at all

Additional Lake Louise Scoring: The Self-Report Score above
(questions 1–5) stands alone and this is recommended for
non-medical mountain travellers. Additional observations are
sometimes used by researchers. The Clinical Assessment score
(questions 6–8) can be added to the Self-Report Score, in which
case, in the context of a recent rise in altitude, a score of 5 or
more would be taken as AMS (AMS = altitude rise AND Headache
AND at least one other symptom (from questions 1–5) AND a
total score of 5 or more (questions 1–8)

Clinical Assessment:

6. Change in mental status 0. No change in mental
   status
   1. Lethargy/lassitude
   2. Disoriented/confused
   3. Stupor/semi-conscious

FLYING

INTRODUCTION

Flying can be an exciting occupation or hobby, providing exposure to unfamiliar environmental and physiological stressors. Although over 200 years have passed since the first manned balloon flight by Pilâtre de Rozier, François Laurent and the Marquis d’Arlandes, most of the understanding of the effects of the aviation environment on the human body has come since 1900. In the first 70 years of aviation, when mankind progressed from Kitty Hawk to the moon, aircraft flew ever higher, ever faster. Since then, development has tended to be limited to improvements in noise reduction, range and payload by environmental and economic considerations.

In 1909, there was one fatality for every 1500 miles flown. By 1912, the safety of aircraft had developed to the extent that the mileage flown for each fatality had risen 100-fold.1 Even in the first half of the First World War, accidents accounted for some 25 per cent of all pilot fatalities, more than attributed to enemy action. Flying is now safer than road travel. Every day, 1.7 million passengers board aircraft in the United States.2 At any one time, over half a million passengers are airborne in some part of the world and over 2 billion people fly every year. Civilian aircrew live longer than the general population of England and Wales and their patterns of death do not appear to be attributable to their occupation.3

Although flying has become so much safer since the pioneering days, the risks of exposure to an unforgiving environment cannot be ignored. Physiologically, man has evolved to live at ground level, at normal gravity (9.8 m/s²), within strict temperature limits and with certain limitations to his special senses and his psychology. Adaptation and acclimatization can increase the physiological range to an extent, while training can improve performance. However, flying is usually an acute exposure, so physiological adaptations have a limited role to play. Protection from the environment, by means of engineering solutions, can increase the operating range of the human, but it also has limitations. The potential for failure of that protection necessitates the provision of back-up systems or a restriction in the operating envelope of the aircraft. Thus, human
tolerances have increasingly set the limits to which aircraft can be engineered.

People work in the air in a variety of capacities. Military aviators fly in aircraft ranging from helicopters to high speed, single-seat jets. Crews of military transport aircraft may face additional challenges that do not affect crews of commercial aircraft. Civilian flight in small aircraft can range from recreational flight to instructional duties to crop spraying. Many people, of course, fly just as passengers and many need to be fit for work on arrival at their destination, but some also work while they are flying. This chapter outlines the stresses and hazards of flight, describes the ways of overcoming them and considers fitness for flight, both for professional aviators and passengers.

PRESSURE CHANGE

As altitude increases, pressure decreases exponentially. For fliers, this gives rise to four potential problems: gas expansion, hypoxia, decompression sickness and rapid decompression (Figure 52.1).

Gas expansion

As ambient pressure decreases, volume increases in accordance with Boyle’s law. Where the gas in the human body is enclosed, this may cause problems. Gas is enclosed in the body after surgery. Thus, 30 mL of intracranial air would expand by 30 per cent at a cabin altitude of 8000 ft, resulting in a rise of intracranial pressure from 10 to 21 mmHg or from 20 to 31.8 mmHg. Therefore, it is unwise to fly within ten days of laparotomy (unless a drainage tube is left in place), within three weeks of craniotomy or air contrast x-ray studies of the spine, or within two weeks of thoracotomy or pneumothorax unless a Heimlich valve or similar device is in place. In addition, penetrating injury of the eyeball can produce subluxation of the lens on ascent to altitude and a case of sudden blindness has been reported caused by expansion of an air bubble introduced during retinopexy. Patients with these conditions may be flown, but only if the cabin pressure of the aircraft is held at the ambient pressure of the departure airfield. Similarly, a small gas bubble beneath a badly filled tooth can cause excruciating pain on ascent (aerodontalgia) which usually improves on descent, although occasional dental fracture may occur.

Where the gas is incompletely enclosed, there is less of a problem. The gut normally contains between 100 and 200 mL of gas at ground level in the stomach and large bowel. The rise in intra-abdominal pressure limits the volume increase. The usual symptom is of abdominal fullness or bloating and is reduced by eructation or passing flatus. The problem can be limited by avoiding dietary items which predispose to flatulence, such as fizzy drinks or certain vegetables. Gas in the middle ear also has an outlet to ambient air. On ascent, the gas expands easily along the Eustachian tube and the ears ‘pop’ automatically. On descent, however, the increased pressure in the pharynx causes the Eustachian tube to act as a flap valve. The resulting pressure differential causes the eardrum to be inverted, causing pain (which is often severe) and deafness. In severe cases, vertigo and nausea may occur. Rarely, facial palsy may result. The way to equalize pressures is to yawn, swallow or waggle the jaw if the pressure change is gradual, or to perform a Valsalva manoeuvre (holding the nose and straining against a closed glottis) or Frenzel manoeuvre (holding the nose and raising the pressure in the nasopharynx without increasing intrathoracic pressure) if the change is rapid. Topical decongestants before or during flight may be effective. There is no evidence that earplugs which claim to equalize pressure are effective. Future
developments may include the use of surfactants which play a role in maintaining patency of the Eustachian tube. If descent is continued without the pressure equalizing, there is haemorrhage into the drum and it may perforate with subsequent relief from pain. Colds and upper respiratory tract infections predispose to this inability to ‘clear the ears’. Since ear pain, deafness and vertigo are flight safety hazards, aircrew with these conditions should not fly until they can clear their ears. Inability to clear the ears during flight can, if possible, be helped by a re-ascent to altitude and a more gradual descent. Otitic barotrauma usually clears spontaneously in two to three weeks.

The frontal and paranasal sinuses usually vent to ambient easily on ascent and equally easily repressurize on descent. Again, infection may interfere with this, causing pain. Nasal polyps or deviated nasal septum can also predispose to sinus barotrauma. Topical decongestants before or during flight may help. Symptomatic treatment may be required on the ground for a few days afterwards.

Finally, at an altitude of 63 000 ft, the total ambient pressure is 47 mmHg. This is also the pressure exerted by water vapour at body temperature. At this altitude (known as the Armstrong Line), body tissues begin to vaporize. Small pockets of gas appear beneath the skin within 2–3 seconds, there is gas evolution within the abdominal cavity in 10 seconds and in the heart in about 20 seconds. Although man can recover from brief exposures, it is better to protect an individual at risk by means of a pressure cabin or pressure suit.

Hypoxia

At all altitudes, the fractional concentration of oxygen in the air remains at 21 per cent. However, as pressure falls on ascent to altitude, the partial pressure exerted by oxygen also falls, in accordance with Dalton’s law of partial pressures. Up to an altitude of about 10 000 feet, the amount of oxygen available to the body remains almost the same because of the shape of the oxygen–haemoglobin dissociation curve. However, the oxygen saturation can fall below 90 per cent even in commercial pressurized aircraft and this may have detrimental effects on some patients. Although it is unlikely to affect the occurrence of acute mountain sickness, it may contribute to increased reporting of discomfort in passengers in medium duration flights.

The most common causes of hypoxia in flight are ascent to altitude without supplementary oxygen, failure of personal breathing equipment to provide an adequate supply of oxygen and decompression of the cabin at high altitude. Human failure to turn on the supply, check hoses are connected or to ensure the mask seals to the face properly, plays a significant role in hypoxia in military aircrew.

The symptoms of hypoxia are insidious and include euphoria, loss of insight, impairment of cognitive functions, reduction of visual acuity (including colour vision), incoordination, cyanosis, hyperventilation and, eventually, loss of consciousness and death. The gradual onset explains those cases where loss of cabin pressure has led to all on board becoming unconscious, the aircraft then flying on automatic pilot until it crashed when fuel was exhausted. A survey of helicopter crew showed most had experienced symptoms suggestive of hypoxia at an average altitude of just over 8000 ft. The most common signs were difficulty with calculations, delayed reaction time and confusion; non-pilots were more affected than pilots. It is widely quoted in the literature that mild hypoxia (8000 ft) impairs the learning of a novel task, but later research failed to confirm this. Smokers may take longer to detect hypoxia than non-smokers. Tolerance to hypoxia is reduced by exercise, exposure to cold, the presence of illness and after taking alcohol.

The insidious nature of the symptoms of hypoxia has led many military air forces to adopt a training regime in decompression chambers to allow aviators a greater chance of spotting hypoxia in themselves. In one survey of military aircrew, 76 per cent of cases of hypoxia were recognized by the aviator involved. The symptoms of hypoxia are very difficult to distinguish from those of hyperventilation. Any symptoms in flight which could be either, must be treated as hypoxia until proved otherwise. On acute exposure to high altitude, either from failure of a pressure cabin or of the oxygen supply, the oxygen stored in the tissues allows a ‘time of useful consciousness’ before capability is lost. This time ranges from about 4 minutes at 25 000 ft to about 20 seconds at 40 000 ft and 10–15 seconds at 52 000 ft. Impairment of performance occurs sooner (45 seconds at 25 000 ft, 12–15 seconds at 40 000 ft).

Hypoxia can be prevented by ensuring that the aircraft does not fly above 10 000 ft, by providing supplemental oxygen to breathe or by pressurizing the aircraft to maintain a cabin pressure of equivalent to an altitude below 10 000 ft. The alveolar oxygen tension (P_{A02}) at sea level can be maintained up to 33 000 ft by breathing 100 per cent oxygen and the 10 000 ft equivalent can be maintained up to 40 000 ft. However, there are two disadvantages to providing 100 per cent oxygen. First, if the aircraft has an aerobatic capability, the gravitational forces may occlude small airways in the lung leading to absorption of all the oxygen distal to the occlusion. The localized pulmonary collapse is called ‘acceleration atelectasis’. Second, a similar problem may occur in the middle ear after landing, causing pain (oxygen ear). The usual solution is to provide oxygen/air mix sufficient to allow a ground level P_{AO2} (103 mmHg) until 33 000 ft when 100 per cent oxygen is supplied. The P_{AO2} then falls to a 10 000 ft equivalent at 40 000 ft.

Above this altitude, oxygen has to be provided under pressure to maintain adequate oxygenation (pressure breathing). In military aircraft, pressure breathing is usually applied through an oronasal mask. The barometric pressure at 40 000 ft is 141 mmHg. The aim of pressure breathing is to maintain that absolute pressure delivered to the lungs. Thus the breathing pressure will be (141-ambient pressure) mmHg. Breathing pressures up to 70 mmHg
Decompression sickness

Decompression sickness (DCS) during diving activities is dealt with fully in Chapter 50, Diving and work at increased pressure. It is commonly believed that altitude DCS does not occur below 18,000 ft. However, bubbles in the circulation have been recorded at altitudes down to 13,000 ft. Bubbles do not form at low altitude unless the individual has been diving in the preceding 24 hours. The rate of symptoms of DCS is related to the final altitude and the time spent at altitude. Other predisposing factors are known susceptibility, exercise at altitude, age, body build, general health and previous exposure to altitude within the preceding 24 hours. Female gender per se does not appear to be a risk factor, although women may be more at risk during the first week of their cycle than mid-cycle. Flying after diving is particularly dangerous. At least 12 hours should be spent at ground level after diving; this time should be doubled if the dive lasted more than four hours and redoubled if the subsequent flight is to be at a cabin altitude above 8000 ft.

The symptoms in one series of over 400 cases arising from decompression chamber experience ranged from joint pains (the bends, 83 per cent, with the knee accounting for 70 per cent), respiratory effects (the chokes, 2.7 per cent), skin symptoms (formication or the creeps, 2.2 per cent), paraesthesia (10.8 per cent) to neurological manifestations (0.5 per cent). Visual symptoms include blurred vision, loss of vision, scintillation and scotoma. Neurological symptoms and collapse can occur after return to ground level (one study demonstrated a 45 per cent incidence of symptoms at altitude, with 24 per cent in the first hour after return to ground level and 21 per cent between one and six hours).

The incidence of DCS in those individuals exposed to an altitude of 25,000 ft or less is low. The U-2, however, had an altitude ceiling of >73,500 ft for more than 15 hours unrefuelled, at a cabin altitude of 29,500 ft. Despite precautions, more than 75 per cent of U-2 pilots experienced symptoms of DCS, and 13 per cent had, at some stage, to alter the flight profile or abort the mission.

Treatment depends on the severity and resolution of the symptoms. If the symptoms clear on descent and neurological examination is normal, the patient should ideally breathe 100 per cent oxygen for two hours and undergo aggressive oral rehydration. The patient should be observed for 24 hours. If pain or cutaneous symptoms persist after descent, in addition to 100 per cent oxygen and oral rehydration, the patient should be exposed to treatment in a hyperbaric chamber. In Scotland, advice may be obtained from Aberdeen Royal Infirmary (Tel. 0845 4566000, asking for the diving doctor on call). For the rest of the United Kingdom, guidance is obtained from the Duty Diving Medical Officer at the Institute of Naval Medicine (Tel. 07831 151523). If the symptoms are not relieved within 10 minutes of compression on Royal Navy Treatment Table 61 (equivalent to US Navy Treatment Table 5), subsequent decompression should follow RN Treatment Table 62 (USN Table 6). Travel to the chamber should be by road. If air travel is absolutely necessary, then either a cabin altitude of sea level or an absolute aircraft altitude of 1000 ft should be maintained. The patient should be supine, intubated if necessary, or in the lateral decubitus position. Intravenous fluids should be either normal saline or Ringer’s solution (i.e. isotonic), 1 litre in the first hour and then ~1.5 mL/kg per hour. Avoid solutions (oral or intravenous) containing glucose. If there are spinal cord symptoms, there may be benefit in giving a bolus of 30 mg/kg of methylprednisolone and then 5.4 mg/kg per hour for 23 hours. It is important to control the body temperature of the patient. On recovery from mild DCS without central nervous system (CNS) complications, the pilot can return to flying within 72 hours if there are no symptoms and examination is normal.

Prevention is based on three factors: (1) selection of individuals who are not susceptible to DCS by testing them in a decompression chamber; (2) limiting exposure to altitude by use of pressurized aircraft; and (3) denitrogenation by breathing 100 per cent oxygen before take-off. Prebreathing schedules are a mixture of experience and pragmatism. Pre-oxygenation for 30 minutes will protect against short exposure to 48,000 ft as long as total time above 25,000 ft is less than 10 minutes. Exposure to 40,000 ft for 3 hours requires 3 hours of pre-oxygenation at ground level. U-2 pilots prebreathe for 60 minutes. Exercise while denitrogenating can reduce the time that prebreathing is necessary while retaining the same level of protection, although this effect may be limited.
Rapid decompression

The respiratory passages can easily cope with the expansion of gas in the lung on rapid decompression (except that air embolus may occur if the breath is held). The effects of rapid decompression depend on the altitude at which the aircraft is flying, the pressure differential of the cabin, the volume of the aircraft and the size and location of the defect in the pressure cabin. Hypoxia, exposure to cold and, eventually, DCS may all occur. The initial problem for aircrew in a rapid decompression is that the flow of air can raise dust and debris; visibility may also be restricted by the condensation of water vapour that occurs. Provided $P_AO_2$ remains above 30 mmHg, there will be no expected decrement in the aircrew's performance. The transient cabin altitude can be lower than outside because of the Venturi effect or it may be higher because of a ram air effect. The airblast can even suck passengers out of a window. Because of the physics, the risk is only to those immediately next to the defect. The time of rapid decompression can be as little as 0.005 seconds for loss of a canopy in a military aircraft to 30 seconds if a window is lost in a large passenger aircraft. The incidence is low: 2-3/10^5 flying hours for military aircraft and 30-40 a year worldwide for commercial aircraft.

Low differential pressure cabins, such as in military aircraft, require the aircrew to use oxygen equipment throughout. Provided it can give 100 per cent oxygen at 33 000 ft and pressure breathing above 40 000 ft, hypoxia is unlikely following rapid decompression. In civilian, high pressure differential aircraft, there is little risk of hypoxia in the crew provided they can don oxygen equipment delivering 100 per cent oxygen within 5 seconds of cabin altitude exceeding 10 000 ft. The crew will then make an emergency descent to at least 10 000 feet. In Concorde, the protection was provided by designing the aircraft so that, even if a window were lost at 65 000 ft, the cabin altitude would not exceed 36 000 ft provided emergency descent was started within 30 seconds.28 Sufficient oxygen is carried on all commercial aircraft for passengers' $P_AO_2$ to be maintained above 50 mmHg in the event of a rapid decompression, although it is unlikely that they will all be able to use the drop-down masks successfully.

As already noted, although seemingly less dramatic, slow decompression may occur. Unless prompt action is taken in response to warning signals, there may be a risk to the aircraft and its occupants.

GRAVITATIONAL STRESS

The most common long duration accelerations experienced in flying are radial accelerations – those produced by change of direction of motion without change of speed. Acceleration is conventionally described by a three-axis system (Figure 52.2). The acceleration of most interest in military aviation is $+/-G_z$. Current agile aircraft can easily achieve +9.5 $G_z$ at onset rates of over 10 G/s. In these circumstances, the limiting factor on the performance of the aircraft is the physiology of the aircrew.

Effects of $+G_z$

The effects of acceleration are exacerbated by heat stress, hypoglycaemia, ingestion of alcohol, hyperventilation and intercurrent infection. Even at $+2 G_z$, there is noticeable difficulty in moving the limbs and and the face sags. At levels greater than $+3 G_z$, it is impossible to escape unaided from an aircraft. Movement becomes more difficult as $+G_z$ rises and raising the head once it is flexed becomes impossible at $+8 G_z$ even without a helmet. Head movement generally at high $G_z$ is difficult, particularly with the
new generation of helmets which carry helmet-mounted sights and displays or, when required, night vision goggles. Exposure to high G flight causes a temporary diminution in height of up to almost 5 mm due to spinal compression33 and musculoskeletal symptoms,30 fatigue,31 cervical disc bulges32 and premature cervical spine degeneration33 have been reported.

Acceleration in the Gz axis has a hydrostatic effect on the circulation. The mean arterial pressure at the level of the heart is 100 mmHg at both +1 and +4 Gz. At eye level, some 30 cm vertically above the heart, the respective pressures are 100 mmHg minus the hydrostatic pressure exerted by the column of blood (22 mmHg at +1 Gz and 88 mmHg at +4 Gz), i.e. 78 and 12 mmHg. Similarly, the corresponding pressures in the posterior tibial artery, some 80 cm below the heart in the sitting individual, can be calculated to be 157 and 324 mmHg.

The blood pressure changes at head level affect vision, cerebral blood flow, cerebral oxygenation and the level of consciousness. Eyeball pressure is 20 mmHg. Thus, the blood pressure at head level has to be above that for retinal perfusion to occur. Application of G results in constriction of the pupils which may help to maintain vision.24 In the relaxed individual, peripheral vision starts to deteriorate at about +3 Gz (grey-out) and totally disappears near +4 Gz. The symptom takes a few seconds to develop because of retinal oxygen stores and, at sustained, low rates of +Gz, will often fade in a few seconds because of adaptive changes in the circulation. At +5 to +6 Gz, consciousness is lost (G-induced loss of consciousness, known as G-LOC) but at higher rates of +Gz, consciousness can be lost before visual symptoms arise. The incidence of G-LOC is lower than would be predicted because of various physiological mechanisms which tend to maintain regional cerebral perfusion. In one survey, 21 per cent of aircrew reported that they had experienced black-out and 20.1 per cent reported G-LOC.35 Not all aircrew who experience G-LOC in centrifuge training remember the episode, so the incidence may be much higher than reported. The US Air Force lost 29 aircraft in crashes attributed to G-LOC in one 20-year period.36 There is no evidence that relaxed +Gz tolerance and endurance on simulated air combat manoeuvring (SACM) are any different in females than males.37,38 In this respect, the shorter stature (and hence smaller heart–eye vertical distance) of females may compensate for lack of physical strength.

Below the heart, the effects of +Gz produce pooling of blood in the periphery, transudation of fluid from the blood to the tissues and rupture of unsupported skin capillaries to produce petechiae. The pooling and loss of blood volume eventually produce intense peripheral vasodilatation and bradycardia, leading to syncope. In addition to the effects described above, rupture of the diaphragms39 and acute inguinal hernia40 in response to +Gz and/or the effects of straining against G have been reported.

Negative acceleration (−Gz) is experienced in outside loops and spins and in inverted flight. Tolerance is much lower than for positive Gz. The general effects include heaviness of the limbs, fullness and pressure in the head (which can produce severe headache), congestion of the air passages which can cause difficulty in breathing, bradycardia, epistaxis, eye discomfort, subconjunctival haemorrhages and petechiae in unsupported skin. The transition from −Gz to +Gz (sometimes called the ‘push-pull’) can reduce tolerance to +Gz41 which is worsened by the duration of the preceding −Gz.42

Protection against +Gz

The major ways of increasing tolerance to +Gz are by use of an Anti-G Straining Manoeuvre (AGSM), anti-G suits, posture, positive pressure breathing (PPB) and training, or by various combinations of these. The commonly used AGSMs, which all include isometric muscle tensing, are the M-1 manoeuvre (exhaling forcibly against a partially closed glottis with a rapid inspiration every 4–5 seconds), the L-1 manoeuvre (periods of raised intrathoracic pressure with a closed glottis separated by short inspiratory and expiratory gasps) and the Qigong manoeuvre (rapid panting with tensed muscles).43 Training in a centrifuge can help to maximize the effectiveness of the AGSM.44

Without an anti-G suit, increasing Gz lowers the diaphragm, increasing the functional residual capacity. Inflation of the abdominal bladder of the anti-G suit reverses this. The closing volume of the lung increases linearly with +Gz, and use of an anti-G suit, by raising the diaphragm, increases the number of non-ventilated alveoli in the base of the lung. Thus there is a change to the ventilation/perfusion ratio from the apex to the base of the lung, with the apex tending to be ventilated, but underperfused, and the base tending to be perfused, but underventilated. This is of particular importance when air enriched with oxygen is breathed, for it assists in the development of acceleration atelectasis. The increased respiratory work of anti-G straining manoeuvres produces respiratory fatigue that may contribute to the degree of overall tolerance to prolonged +Gz.45

ADVANCED LIFE SUPPORT SYSTEMS

In the most modern generation of combat fast jet aircraft, the requirements to provide protection against exposure to altitude and high acceleration have driven the development of advanced life support systems. Commonly, the requirement for protection against hypoxia is addressed by the provision of a continuous supply of oxygen derived from compressed air taken from the compressor stages of the aircraft’s engines and passed through a two or three bed molecular sieve oxygen concentrator (MSOC). Such systems cannot produce 100 per cent oxygen, since argon is also concentrated, but do remove the requirement to replenish the main oxygen supply between sorties. A back-up supply of
100 per cent oxygen is therefore required to cope with high altitude decompressions and ejection.

Above 40,000 feet, there remains a requirement to provide positive pressure breathing for altitude protection (PBA) in the event of a decompression, but this can be combined in a common system with pressure breathing for G protection (PBG). Counter-pressure layers can be incorporated in the life preserver, whose main function is to provide buoyancy, allied with inflation of the anti-G trousers to provide lower body counter-pressure. Inflation of the counter-pressure layer of the upper garment, to the same pressure as oxygen is delivered to the mask, prevents over-distension of the chest and relieves the fatigue of breathing against pressurized gas. Inflation of the lower garment improves venous return and reduces the likelihood of pressure breathing-induced syncope. In the most advanced systems, the lower garment inflation pressure is 1.5–2 times the breathing pressure, as this has been found to enhance the circulatory support provided.

Modern anti-G trousers cover a greater part of the body surface than traditional (so-called skeletal) anti-G trousers and are often termed full coverage anti-G trousers (FCAGTs). Such garments are mechanically more efficient and provide enhanced G protection, as well as reducing the fatigue associated with ‘pulling G’. When combined with PBG, there is a very substantial improvement in G protection, commonly allowing a ‘relaxed’ exposure to up to 9 Gz with little or no requirement for physical straining to retain full vision and reduce the risk of loss of consciousness (Figure 52.3).

Such systems carry the additional burdens of increased resistance to movement and greater thermal load because of the additional layers and greater coverage of the body with impermeable materials. In addition, some advanced anti-G systems are associated with an incidence of arm pain, where the vasculature is unprotected by counter-pressure.

### EXTREMES OF TEMPERATURE

Details on heat and cold can be found in Chapter 49, Heat and cold. This chapter will highlight those aspects relevant to flying.

**Cold**

Exposure to extreme cold may occur when operating at high altitude, on the ground in very cold countries and following accidents in isolated locations. At very low cockpit temperatures, simple oxygen systems run the risk of the expiratory valve freezing open because of the accumulation of condensed and frozen water vapour from the expirate. This may lead to hypoxia because the resistance of inspirating through an open expiratory valve is less than that of cracking open an inspiratory valve. Most military oxygen systems overcome the problem by design of the expiratory valve, by the use of safety pressure in the mask above certain altitudes (which would lead to continuous flow being sensed and shown on the flow indicator if there was a leakage) and by the use of cockpit heating.

**Heat**

There are several ways in which a flier may become hot in the aircraft. First, thermal radiation from the sun becomes...
trapped in the cockpit rather like a greenhouse. In small aircraft, the large relative size of the cockpit transparency exacerbates the problem. Surface temperatures of seats can exceed 60°C. Second, electrical components, of which there are many in military aircraft, consume power inefficiently, radiating heat to the aircrew. Third, aerodynamic heating of the aircraft exterior can conduct heat into the cockpit. Temperatures above 110°C have been recorded on the skin of aircraft flying at high speed and low level. Finally, individuals produce heat from their own metabolism. These sources of heat would not be an embarrassment to the aircrew if they were able to dissipate the heat load. Unfortunately, particularly in military aviation, the clothing worn interferes with heat loss by being bulky and insulating and also by incorporating materials impermeable to water vapour, thus preventing sweat evaporation. Moreover, the specialized flying ensemble of military aviators is multilayered, increasing the work required to move while wearing it. Certainly, deep body temperatures of above 38°C have been measured in aircrew at cockpit temperatures below a wet bulb globe temperature (WBGT) index of 30°C. Laboratory simulations of aircrew wearing ensembles including nuclear, biological and chemical (NBC) protection, in cockpit temperatures previously measured in flight suggest that sortie length may be limited in the heat or performance affected. 47

There are two main approaches to solving the problem of heat in the cockpit: cabin and personal conditioning systems. The former are frequently not as effective as they could be, occasionally even being de-rated to reduce cockpit noise. Furthermore, the aircrew are insulated from the cooling air by their flying clothing. Personal conditioning systems do have the advantage that the cooling fluid is circulated where it is most required – next to the skin. However, cool air systems cannot be used in potential NBC conditions and liquid systems, whilst physiologically effective, are not yet in widespread use. Both systems require the aircrew to wear yet another layer of clothing.

**NOISE AND VIBRATION**

**Noise**

Noise is covered in Chapter 46, Sound, noise and the ear. The human tolerance to noise is exceeded in many aircraft with the risks of interference with performance of the flying task, fatigue, degradation of communication and hearing damage. Noise in flight arises from the aircraft power source, subsidiary noise from equipment, flow of air over aircraft surfaces and weapon firing. Sonic booms do not affect the occupants since the aircraft leaves the sonic boom behind. The noise profile will differ between aircraft types, seat positions and profiles flown. Cabin noise levels up to 120 dB have been measured in fixed wing aircraft when flying at 480 knots at 250 ft,18 with the highest peaks being in the 0.5–4.0-kHz range. Even motor gliders can reach a cockpit noise level of 117 dBA at start up with levels of 92–99.5 dBA in the cruise.49 Noise in helicopters is related to the rotors (at about 20 Hz) and the gearbox and transmission chains (from 400–600 Hz). In propeller-driven aircraft, the noise is primarily related to the number of propeller blades and the speed of rotation. In passenger jet aircraft, the major contributors are aerodynamic noise and noise from the conditioning systems; the noise in a window seat may be as much as 6 dB higher than in the centre of the aircraft.

Protection is obtained by careful engineering of the aerodynamic properties of the aircraft and (less frequently) of the cabin conditioning system. In military aircraft, an important degree of protection is afforded by the aircrew helmet. Attenuation is generally low at low frequencies but attenuation of 30 dB at 500 Hz to 50 dB at 4 kHz can be achieved. Careful attention to fitting can maximize the attenuation of perceived noise at the ear. In addition, active noise reduction (ANR, a mechanism of destructive interference by sampling the noise field, inverting the phase and then reintroducing it to the headset to cancel the original noise) can produce a further benefit of up to 10 dB. Passengers in noisy aircraft will benefit from the use of earplugs. Even with protection, workers on the ground and in the air may be at risk of hearing loss50,51 and thickening of the mitral valve with a higher incidence of prolapse than the general population.52

**Vibration**

Vibration is considered in detail in Chapter 48, Whole body vibration. This chapter will address only those aspects relevant to flying. Complex structures, such as human bodies and aircraft, can vibrate in one or more of the six geometric degrees of freedom (three rotational: yaw, pitch and roll; three translational: heave, surge and sway). In flying, the sources of vibration are the power unit and the air through which the aircraft is travelling.

In helicopters, vibration is generally related to the rotor rate and to the number of rotor blades. The former is generally four revolutions per second, which gives rise to vibration within the helicopter of 4 Hz. The rotor rate multiplied by the number of blades gives the blade pass frequency which can give vibrations generally in the region of 8–20 Hz. Further vibration is generated at higher harmonics of the blade pass rate and also at levels related to the tail rotor. Vibration is usually similar in intensity in each of the x, y and z axes and is worse on transition to the hover.

In fixed-wing aircraft, the vibration from the engines is usually at a higher frequency than in helicopters. A single-stage turbine usually produces vibration at about 130 Hz, while a dual stage one produces 230 Hz. In propeller-driven aircraft, the blade pass frequency is about 100 Hz, although desynchronized propellers may give beating at lower frequencies. In fixed-wing aircraft, the most noticeable turbulence is caused by the atmosphere, for example during cloud penetration, during low level flight or in
‘clear air turbulence’. In military aircraft, the firing of weapons can also give rise to vibration.

The effects of vibration in the aviator can range from imperceptible to inconvenient to unpleasant. The body is least tolerant of vibration between 4 and 8 Hz. The main symptoms limiting tolerance in the laboratory are precordial and abdominal pain. However, in flying, the most important effect for the pilot is on vision. The instrument panel and the pilot’s eyes are usually vibrating out of phase. This results in degraded visual acuity. This is often exacerbated when helmet-mounted display systems are in use, particularly at frequencies of 4–6 Hz. 53 Outside the aircraft, the image is stable in space and at optical infinity, with other aircraft unlikely to be moving so fast that they exceed the angular velocity limitations of the pursuit reflex. In addition, vibration can also give rise to illusions of motion and to symptoms of motion sickness. At normal levels of vibration in flight, there are no great effects on the cardiovascular system, although there may be an increase in metabolic rate reflecting an increase in muscular activity required to maintain posture. Vibration can cause hyperventilation. A fall in $P_a CO_2$ to less than 25 mmHg has been recorded after 2 minutes of vibration at 9.5 Hz with an acceleration-amplitude of 1 Gz. 54 This is sufficient to reduce cerebral blood flow by 35 per cent. 55 Vibration has also been implicated in orthopaedic problems in helicopter aircrew, although seating, posture and ergonomic factors undoubtedly play a part.

Protection can be afforded against vibration by careful engineering of the aircraft, the use of dynamic vibration absorbers and by vibration isolation of the aircrew seat or of stretcher mounts and the use of seat cushions. 56 Finally, if the source of vibration is turbulent air, the effects may be minimized by routing away from it, changing cruising altitude and by ensuring passengers remain in their seats with seat belts fastened.

Casualties from military operations tend to be evacuated by helicopter before definitive surgery is conducted away from the front line. Vibration of unstabilized fractures can cause severe pain and may contribute to complications. Casualties evacuated by helicopter must be given adequate analgesia and their fractures adequately stabilized.

Eye protection

In civil flight and military transport aircraft, protection from glare is given by sunglasses. Sunglasses and visors should have a transmittance of 10–15 per cent. In addition to increasing visual acuity in bright sunlight, they also protect the eye from the effects of UV light.

Military fast jet aircrew usually wear helmets whose polycarbonate visors (one clear, one tinted) afford protection against glare, birdstrike and blast. Ideally, the cockpit transparency should be tough enough to withstand birdstrike, but this often conflicts with the need for rapid escape in an emergency. About 95 per cent of birdstrikes occur below 750 ft 60 and therefore are more commonly suffered during take off, landings and high speed, low-level flight. The clear visor can also protect against lead spatter from canopy fragmentation devices used to clear the ejection path. Although lead spatter usually causes superficial damage only, cases of ocular penetration have occurred. Visors also form an integral part of the overall protection against windblast during the ejection sequence. Design of the ensemble of helmet, visor and mask is important so that they remain on the head during ejection. Current RAF systems provide adequate protection up to 650 knots and aircrew are advised to have at least one visor selected down at all stages of flight.

The fireball from a nuclear explosion can cause direct and indirect flash blindness and may even cause a retinal burn. The problem is worse at night when, theoretically, a pilot could be effectively blind for as long as a minute after
exposure. Various protective devices have been proposed, ranging from an eyepatch which could be raised after exposure to complex electro-optical devices.

Lasers, on the other hand, are more likely to pose a problem. Damage can range from transient stress temporary conditions (e.g. acute keratitis) to permanent damage, such as cataract, corneal opacity or retinal burning. The international aviation community is attempting to minimize the problem by legislation controlling the use of such devices near airfields. In military flying, lasers are used for target designation and thus may be deliberately aimed at aircraft. Protection is best provided by distance, but visor coatings designed to protect against specific wavelengths may be necessary. These have the disadvantages that they only protect against specific threats, they produce a blending of surface colours and loss of terrain features, a reduction in depth perception and difficulties with warning lights and displays.

**Spectacles and contact lenses**

The clinical indications for visual correction and visual standards are covered below. Approximately 27 per cent of pilots, 51 per cent of navigators and 40 per cent of other aircrew in the US Air Force need to wear glasses. Over 12 per cent need bifocals. More then half of civilian pilots need lenses to correct defective vision in order to satisfy licensing requirements. Evidence suggests that there is no difference in civil accident rates or in US naval carrier landing in military aviation than contact lenses. Generally speaking, contact lenses are the preferred option for visual correction for aircrew.

Both soft (SCL) and hard contact lenses (HCL) have been used in flight. High water content SCL are preferred in the low humidity of aircraft cockpits, but HCL are still required in some conditions such as keratoconus. Rigid, gas-permeable lenses may offer advantages for this group in the future. Daily, disposable contact lenses are convenient and give rise to fewer problems for aviators with simple myopia. The major difficulties quoted in flight are foreign body incursion and movement off-centre. In both of these, the incidence is greater for HCL than SCL. The greatest difficulty experienced in the Gulf War related to resupply problems with replacement lenses. Some US Air Force aircrew have lost SCL or HCL during ejection, but the overall experience is small.

Overall, sunglasses and visors should give as wide a field of vision as possible. The optical quality should be high and it may be necessary to incorporate anti-scratch and anti-reflection coatings. Corrective flying spectacles must be capable of integration with the rest of the aircrew equipment without impairment of hearing protection or interference with the seal of an oxygen mask. They must be comfortable, resistant to fogging, minimize internal reflections and not move under conditions of vibration or G. Tinted spectacles should not be worn with tinted visors (see below). Photochromatic lenses are not yet sufficiently reactive to respond quickly enough on entering a cloud layer from high sunlight. Many military aircrew have reported losing a lens from their spectacles in flight and thus it seems sensible to carry a spare pair. In the RAF, most spectacles and helmets are retained on the head during ejection. In the US Air Force, on the other hand, sorts are flown higher with clear visors up and up to 80 per cent lost their eyewear.

**Eye surgery**

As laser techniques have evolved, radial keratotomy (RK) has declined as a surgical method of correcting myopia. Photorefractive keratotomy (PRK) usually produces visual stability in three to six months. Laser in-situ keratomileusis (LASIK) produces a more predictable and safer method of correcting higher levels of myopia than PRK. The results are good for both PRK and LASIK. About 85 per cent of such patients achieve 6/6 or better. The eye often becomes dry and requires lubricants for up to six months after operation and some patients experience night vision problems, such as haloes or starbursts around light sources. Recertification for military flying depends on the outcome and the type of procedure. For civilian flying, the Civil Aviation Authority (CAA) will consider class 1 certification three months after LASIK and six months after PRK as long as certain criteria are met.

The use of intraocular lenses is compatible with both military and civil flying once vision has stabilized. In one reported case, the implanted lens remained stable during ejection when the imposed acceleration reached an estimated $+14 \, G_z$ for 200 ms.

**Night vision**

During the Second World War, interceptors had to pick up their targets before they themselves were spotted, bomb-aimers needed to be able to place their bombs accurately despite the attentions of searchlights and tracer and pilots had to be capable of judging their landings correctly on darkened airfields. In the Second World War, much emphasis was given to dark adaptation of aircrew before take-off.

The introduction of night vision goggles (NVG) has changed things, but has introduced new problems. Some accidents have been directly linked to the use of NVG. In effect, NVG present an isochromatic view of the world limited in contrast and detail. Visual acuity, as well as visual fields, are degraded. For example, switching from forward-looking infrared (FLIR) to NVG gave a 4-second visual loss, a two-fold reduction in visual acuity and a three-fold reduction in contrast sensitivity. The cockpit lighting
Spatial disorientation (SD) occurs when a pilot does not sense correctly the position relative to the ground, motion or attitude of himself or his aircraft. The broader term ‘situational awareness’ (SA) is taken to include a tactical appreciation of the position of other aircraft, as well as a sense of geographical location. SD is caused by inadequate or erroneous cues to the brain and by central processing errors, such as errors of perception or coning of attention.

SD is a significant cause of aircraft accidents. The majority of accidents occur in poor visibility when the pilot may not be aware that his interpretation of aircraft attitude is incorrect. However, some occur in good conditions when visual cues are misinterpreted. The type of incident where the pilot is aware that there is a mismatch between his aircraft instruments and what his brain is telling him is less likely to lead to an accident if appropriate training is given. Spatial disorientation is more likely at times of high workload, when undergoing treatment with certain drugs or with upper respiratory tract infections. It is also more prevalent in poor weather, at night, at high altitude and during flight over sea or featureless terrain. Certain flight manoeuvres contribute, such as prolonged linear acceleration or deceleration and prolonged angular motion, particularly when combined with head movement. Transfer to instrument meteorological conditions (IMC) when landing in helicopters, when the downwash from the rotor kicks up dust or snow, is also a potent cause of SD. Subthreshold changes in attitude are unlikely to be detected and thus can also lead to SD.

Types of illusion

The illusions may be caused by false information from the otoliths and kinaesthetic receptors during sustained acceleration (somatogravic illusions) and on moving the head in an atypical force environment (G excess illusions) or from the semicircular canals on recovery from prolonged rotation (somatogyril illusions) and on moving the head during rotation (cross-coupled or Coriolis illusions).

Man is habituated to expect any sustained acceleration to be due to gravity. When a sustained acceleration is applied, the resultant combined acceleration is interpreted as the vertical. For example, when an aircraft accelerates on take-off, the resultant acceleration from the rearward inertial force and downwards gravity is between the two; the pilot senses this resultant force and mentally orients it so that it is vertical. He thus senses that the aircraft nose is high and tends to want to push the stick forwards. A brief $G_\alpha$ acceleration of 5 G for 2–3 seconds, such as in a catapult launch from an aircraft carrier, gives an apparent nose-up attitude of 5° for a minute or more. There is little time to overcome this particular illusion on take-off. If the pilot pushes the stick forward, he introduces a radial acceleration that will make matters worse. When performed at high altitude, pilots approaching the vertical in a bunt manœuvre have reported feeling as if the aircraft was flipped on its back. Similarly, a pilot in a flat turn will feel as if he is rolled out of the turn and a pilot in a banked turn may feel himself to be level. Head movement during these manœuvres can induce further illusions.

When external visual clues are inadequate, for example at night, the apparent movement of light sources in the external environment may be interpreted as a change in attitude of the aircraft. For example, during linear acceleration, the backward rotation of the resultant force vector may make a bright star appear to move upwards. This may be interpreted as a nose-down change in the aircraft attitude.

One of the most common illusions is ‘the leans’. If a pilot is in a gentle turn to the right, at a rate below that which would stimulate the otoliths, he could feel that the wings are level. If he then rolls wings level abruptly, he can feel that he is banking to the left. Even though this can be recognized as level flight on the instruments, there is a distinct temptation to lean to align the body with the perceived vertical.

In the same way that the otoliths can misinterpret linear accelerations, so can the semicircular canals misinterpret angular accelerations in yaw, pitch and roll. At constant angular speed, the body’s sensors will only give the correct information during the first 8 seconds of the manoeuvre. During recovery from a prolonged spin, not only is there a somatogyril illusion that the aircraft is turning in the opposite direction, but vision may also be degraded by the nystagmus induced by the spin; this will make reading of instruments difficult at a critical time. In reduced light conditions, oculogyric illusions may occur with an illusory perception of movement of an isolated light. Responses during banking may be complicated by the optokinetic cervical reflex where pilots tend to move their heads to keep a constant horizon rather than keep them in line with the vertical axis of the aircraft.

Movement of the head during angular accelerations can produce quite compelling sensations of movement by cross-coupled or Coriolis forces. For example, a head movement in roll from 45° left to 45° right while rotating at a steady speed about the z body axis will produce a strong sense of pitching forward. In highly manœuvreable aircraft, there is a potential for cross-coupling illusions independent of pilot head motion.

Imbalance between middle ear pressure on ascent or descent can also cause vertigo which, although usually lasting only seconds, can last some minutes. It is more common when there is a respiratory tract infection. The flicker of propellers or rotor blades have also caused vertigo and nausea, but the more usual presentation is irritation.
Occasionally, pilots in single-seat aircraft at high altitude report a feeling of detachment, isolation or remoteness from the aircraft. Some even describe it as an ‘out of body’ experience, watching themselves controlling the aircraft. A similar ‘break-off phenomenon’ has been described in helicopters flying at lower altitudes, but in conditions of limited visual cues.

Another form of misinterpretation is caused by the error of expectancy. When flying in cloud, the cloud is brighter in the direction of the sun. The brain interprets this direction as ‘up’ and stimulates the pilot to ‘lean on the sun’. Another example of expectancy is when lights on fishing boats at night are interpreted as stars, which are expected to be above the aircraft; the pilot then inverts the aeroplane. Other errors can occur when interpreting heights of mountains or trees, in misinterpreting a short runway as a longer one seen from a greater height or in assuming a sloping cloudbank to be the horizon.

**Incidence**

Spatial disorientation is surprisingly common. In one survey, 92 per cent of respondents had experienced the leans, 82 per cent had lost the horizon because of atmospheric conditions, 79 per cent reported misleading altitude cues, 75 per cent had experienced a sloping horizon and 66 per cent reported SD arising from distraction. Helicopter pilots using NVG reported more SD than fast jet pilots. Similar estimates are not available for general aviation pilots, although confidential reporting for commercial flights gives a much lower incidence.

**Protection**

There are some aircraft factors that can help to reduce SD. The instruments should be reliable and able to be read clearly and unambiguously by day and night. The instruments should be able to cope with the manoeuvres flown by the aircraft and the conditions in which it will operate. A head-up display will also help. The instruments should be laid out so that they can be read without undue head movement.

Aircrew factors include rejection for licensing of those likely to be affected by SD, for example those with Menière’s disease. Aircrew should not fly while suffering from upper respiratory tract infections or acute labyrinthitis, nor should they fly while taking medications whose potential side effects include nausea, vertigo or sensory disturbance. Alcohol has been shown to compromise a pilot’s ability to detect angular acceleration and this may continue even after blood alcohol level reaches zero.

Training in the air, as well as on the ground, plays a major part in preventing SD. Instrument flying must be continually practised. In military aviation, spatial disorientation familiarization devices can give valuable experience on the ground of the various illusions.

**AIR SICKNESS**

Air sickness is a normal response to flying in the unadapted individual. The incidence is related to the intensity of the motion stimulus, the frequency spectrum of the motion and the time of exposure. The condition reduces tolerance to acceleration and may have significant effects on flight safety. It is most commonly experienced during flying training, when the quietness and withdrawal it produces may be misinterpreted as disinterest or inaptitude by the instructor. Severe air sickness in a trained aviator is uncommon unless the stimulus is unduly provocative, for example during flights to study hurricanes. Commercial flying as a passenger does not induce much air sickness, but paratroopers or special forces, who may be flown tactically in more adverse weather, may be particularly affected. Their performance on the ground immediately after landing may suffer.

Some people may not be affected at all, some may experience minor inconvenience, while others will be prostrated. In addition to individual susceptibility, there is a gradual decrease in susceptibility with increasing age from 12 years onwards. Females are more susceptible than males and there appear to be ethnic differences.

**Symptoms**

The condition does not differ essentially from any of the other forms of motion sickness and presents commonly as nausea, vomiting, pallor and cold sweating. The first symptom is usually epigastric awareness which progresses to nausea. Cold sweating with facial pallor then occur. There is then a crescendo of symptoms (the avalanche phenomenon) with increased salivation, lightheadedness, yawning, and often depression and apathy. Vomiting then follows, which often temporarily improves the symptoms. The feelings of lethargy and drowsiness can last for some hours after landing.

**Prevention and treatment**

The best treatment is adaptation, particularly for aircrew who should not fly while taking drugs for air sickness. Flying training should introduce exposure to the more adventurous flight manoeuvres gradually. Return to flying after a period away should follow the same principle. The distraction of flying the aircraft or other demanding mental activity rather than being a passenger often keeps the symptoms at bay. However, reading does not help because of the risk of introducing anomalous visual cues. Passengers generally can reduce their incidence by closing their eyes and limiting movement of the head.

About 5 per cent of military aircrew do not manage to adapt by normal means. However, desensitization to strong vestibular stimuli has proven to be transferable to aircraft
motion. In the RAF, about 85 per cent of those affected have been salvaged by a programme of increasing exposure to cross-coupled stimuli on the ground before a similarly progressive exposure to aerobatic flight in a dual controlled aircraft. Later work has suggested that it is the number of challenges rather than the severity of malaise achieved that is the important factor determining habituation.

The number of remedies available is large and none can completely prevent everyone from experiencing air sickness in all conditions. One of the most effective drugs is L-hyoscine hydrobromide (1-hyoscine hydrobromide in the United States; Kwells®). In conditions where 10 per cent of the population would be airsick, 0.4 mg of the drug can increase protection so that only 2 per cent suffer symptoms. In more severe conditions, when 50 per cent of those exposed would be sick without prophylactic treatment, 1.0 mg of the drug can provide protection for all but 8 per cent. Unfortunately, most of the drugs used have side effects unacceptable for use by aircrew. Hyoscine can cause blurred vision, dry mouth, sedation, dizziness and significant performance decrements. Promethazine (Phenergan®, Avomine®) 25 mg can also impair psychomotor performance, while dimenhydrinate (Dramamine®, Gravol®) is a central depressant. For short-term protection in passengers, oral L-hyoscine hydrobromide (0.3–0.6 mg) is the drug of choice. For longer benefit, transdermal administration of hyoscine by patch may be useful if placed at least six hours before protection is needed. Antihistaminic drugs, such as cinnarizine (Stugeron®) give protection for six hours, while related drugs, for example, promethazine can give protection for 12 hours. One study found that a combination of 25-mg promethazine and 200-mg caffeine (to counteract the sedative effect of the promethazine) was most helpful. Other proposed prophylactics, such as wristbands, which claim to work by pressure on the acupoints, have not proved effective. Although the severity of symptoms can be reduced by the use of stroboscopic illumination or shutter glasses with a frequency of 4 Hz (to reduce retinal slip), such devices are not yet practicable in aviation.

**FATIGUE AND JET LAG**

Chapter 91 (Shift work and extended hours of work) addresses the subject of shift work and extended hours of work. For crews of both short-haul and long-haul flights, sleep deprivation occurs because of the work schedules. For the short-haul pilot, the adaptation to encroachment of duty hours on sleep is mainly by prolongation of sleep periods. Rapid and large time zone changes, coupled with sleep disturbance related to overnight flights, are particularly important in flying. Jet lag adds to the acute fatigue for the crews of long-haul, transmeridian flights. Older people tend to be more affected than younger individuals.

Time zone changes may lead to lethargy, loss of appetite, a general feeling of malaise and disruption to the normal pattern and quality of sleep. Until rhythms are resynchronized, the nadir of psychomotor performance no longer coincides with sleep. After flights westward, when the normal sleep onset is delayed, individuals tend to fall asleep quickly and sleep more deeply. Sleep later in the night is more disturbed. By the third night, the sleep pattern is more adapted to the new time zone and this is reflected in daytime alertness and general well-being. Eastward flights impose an advanced sleep onset time. If sleep during the flight and during daytime at the destination is avoided, the first night’s sleep may be good. However, once the immediate effects of sleep loss are overcome, the sleep pattern does not adapt to local time for several days. Sleep quality is reduced and there are more night-time awakenings.

**Protection**

Airline scheduling is largely governed by commercial factors. In an ideal world, an overnight, eastwards flight, after a period of desynchronisation caused by the flight west, would be timed to arrive when alertness and performance would be high. However, this is not always possible and flight safety is maintained by imposing statutory flight time limitations. For aircrew required to work overnight, an anticipatory sleep of about four hours in the afternoon or evening will improve overnight performance. Light visor treatment for jet lag may accelerate circadian re-entrainment, but the effect is modest and unaccompanied by subjective improvement in symptoms. An alertness device based on wrist inactivity may be useful in preventing long-haul pilots from falling asleep in the cockpit, but does not obviate the need for sensible rostering.

For the statesman or businessman, there are two ways of limiting the effects of time zone changes. One is to time the trip so that adaptation to the local time zone is complete by the time important business is transacted and to allow adequate time for recovery on return. Another is to travel by supersonic aircraft (if and when these are available again), conduct the business and then return by supersonic aircraft; adaptation to a new time zone is therefore unnecessary. For those who have neither the time nor the money to adopt these techniques, napping when necessary and the use of hypnotics may be the only answer.

Hypnotics have been used for some years to impose sleep at unusual times or in unusual conditions. A rapidly absorbed drug with a short half-life, such as temazepam 10–20 mg has been found to have an acceptable margin of safety when used sparingly. It was used successfully in the Falklands campaign and in the Gulf War. Psychostimulants have not been used by the RAF since the Second World War, but dextroamphetamine (5 mg every two to four hours) has been used extensively and effectively by the US Air Force and 20 mg doses of caffeine every hour have been reported to be useful after sleep deprivation. More recently, attention has been focused on the use of melatonin, which has been reported to prevent jet lag symptoms in east and west
transmeridian flight. A dose of 10 mg can advance bed and rise times by two to three hours and maintain sleep duration between seven and eight hours compared to placebo, and produces fewer performance errors on awakening than placebo. In general terms, all use of such drugs requires medical oversight.

FOOD AND DRINK

Food

Food has been recognized as an important factor in flight safety from the earliest days of flying. First, gastrointestinal upsets are the most common cause of in-flight incapacitation. For this reason, flightdeck crew must select different menu items for meals both in-flight and when down the route. In addition, it is sensible, for obvious reasons, for the flightdeck crew to stagger their times of eating when in flight. Second, hypoglycaemia can reduce tolerance to Gz and has been cited as a significant finding in more than 50 per cent of incidents of unconsciousness in the air. This has led to a requirement to eat sensibly before flying and to provide in-flight rations during long flights.

Drink

The cabin air of all aircraft is dry, as is the breathing mixture provided by military aircraft oxygen systems. This, combined with fluid shifts in the body caused by sitting for long periods, produces dehydration. In turn, dehydration can affect tolerance to Gz and to heat load and may contribute to an increased risk of deep venous thrombosis. An adequate fluid intake on long flights is therefore important.

However, alcohol in large quantities is not sensible. Not only does alcohol itself contribute to dehydration, but it also affects performance, tolerance to Gz, incidence of DCS and can potentiate SD. Most airlines and military air forces impose a ‘bottle to throttle’ time for aircrew. The usual time allowance, of 8 to 12 hours, could be considered insufficiently stringent bearing in mind its continuing contribution to accident rates. Alcohol plays a significant role in cases of passenger misconduct in flight.

EXPOSURE TO CHEMICALS

Ordinarily, the aviator should not be exposed to noxious chemicals. However, there are four main circumstances in which exposure may occur: toxic fumes in the cockpit, fire, aircraft crash and deliberate release, for example crop spraying or when attacked by chemical warfare agents. In an incident, gas chromatography of blood samples taken as soon as possible after landing may identify the chemicals concerned. Protection against toxic fumes in the cockpit is given by use of an oxygen system with 100 per cent oxygen selected, thereby avoiding inhalation of air from the cockpit environment. Exposure of crop sprayers to chemicals may require skin decontamination and systemic treatment. Protection of aircrew against chemical warfare agents is provided by deployment of detection devices, a robust reporting system, training, protective clothing including respirators which maintain a positive internal pressure to prevent inward leaks, decontamination schedules, filtered air in accommodation for briefing and rest and, finally, medical treatment if required. Pyridostigmine 30 mg every eight hours may be given as pre-exposure treatment against nerve agents.

The aviation worker is also exposed to jet fuel fumes. Chronic exposure can affect neurocognitive functioning in refuelling workers. The effect is greater at the end of the working day and in smokers, who smoke downwind of the site. From time to time, claims are made about exposure to other chemicals in the normal cabin environment. To date, no evidence has been found of exposure to toxic substances at levels that would be expected to cause acute or cumulative embarrassment.

AIRCRAFT ACCIDENTS

Not all accidents involving aircraft require flight. The airfield and the hangar both entail significant working hazards. Ground crew accidents have occurred at the rate of 0.47 per 106 aircraft departures, approximately 25 per cent of which were fatal. Over 40 per cent of incidents were caused by a vehicle collision with the aircraft, 34 per cent by individuals coming into contact with moving aircraft parts and 11 per cent from jet blast or fires. Procedures for working airside need to be carefully devised and strictly applied. Medical standards are required, particularly for vision and hearing, and frequent airfield safety training is essential.

In addition, not all injuries in flight relate to crashes. Injuries caused by turbulence amount to 1.9 injuries per 106 flying hours with fractures of the ankle being the most common. Not surprisingly, cabin staff are most at risk. Most injuries to passengers occur when the ‘fasten seat belts’ sign is not illuminated, allowing them to move around the cabin. Thus, most injuries occur in the cruise.

Aircraft crashes are, fortunately, relatively rare events. Commercial flying is the safest form of mass transport. Military flying, when conducted at high speed and low level, is inherently more dangerous, but the risks are reduced by meticulous planning and training. Crashes can occur following engineering or design failure; home-built aircraft accounted for 3 per cent of the hours flown in the United States in 1993, but for 10 per cent of the crashes. The majority of accidents is caused by human factors which may include physiological or psychological causes. SD was a major contributing factor in 20 per cent of one series of military aircraft crashes. Adverse weather is a recurring theme in aircraft accidents and may be associated with greater pilot workload increasing the risk of pilot error.
The most common pilot errors in an analysis of American civil crashes over a period of 14 years were mishandling of the aircraft, inattentiveness and poor decision making. However, there is no evidence of an increase in pilot error with increasing age of the pilot up to the early 60s. The majority of crashes occur in the vicinity of an airfield, being related to take-off or landing. Many crashes occur during training: in one series of civilian crashes, an instructor was present for 50 per cent of crashes following stalls and 32 per cent of those resulting from fuel mismanagement.

Aircraft have notoriously been used for acts of terrorism but are also used as a method of committing ordinary suicide, accounting for between 0.72 and 2.4 per cent of all accidents. Such pilots have tended to be younger than those involved in other accidents; 24 per cent had used alcohol and 14 per cent illicit drugs. Other factors involved were domestic and social issues (46 per cent), legal problems (40 per cent) and pre-existing psychiatric disorder (38 per cent).

Most accidents involve ground impact. Injury can result from sudden deceleration, crushing loads on the fuselage, break up of the floor structure or by fire. Protection from mechanical forces is given by restraint harnesses and, in military aircraft, energy-attenuating seating. The more efficient the restraint in the seat, the higher is the likelihood of survival. In one study of fire in 134 fatal civil aircraft accidents, 360 individuals had insignificant antemortem injury, but carboxyhaemoglobin levels >20 per cent, enough to impair chances of escape. Almost 60 per cent of fires start during the impact sequence, with another 17 per cent occurring after the aircraft has come to rest. Rescue is then hampered by terrain, bad weather and the dark. Smoke hoods for passengers have been developed but are not in use by the airlines.

Many military aircraft have ejection seats which can allow the aviator to be on a fully deployed parachute within 3 seconds of initiating ejection. The risks are of not initiating ejection soon enough, of back injury as a result of the forces of ejection, of collision with canopy or canopy fragments, windblast and flail injuries and landing injury. The design of the seat, the use of miniature detonating cord (MDC) to fragment the canopy to clear the escape path and use of leg and arm restraint can minimize the risks. Although more modern aircraft are associated with a lower risk of injury from ejection, there will always be injuries caused by ejection outside the design specifications of the ejection seat. However, injury can occur from anticipated, in-envelope, ejection forces alone, with anterior wedge fractures of the thoracolumbar region being the most common. The risk is greater with taller and heavier aviators.

After ejection, a full spinal radiographic screen from C1 to the sacrum should be carried out. Even with a negative screen, a Technetium-99 bone scan will often demonstrate ‘hot spots’ indicative of fresh bony injury. Treatment is by total bed rest for three weeks in hospital followed by gradual mobilization. Resumption of flying on ejection seats is possible after three months.

Escape from helicopters offers different challenges. Up to half of military helicopter accidents involve ditching in water. The problems of escape include physical restriction from equipment or trapped air, limited air supply, poor underwater visibility, exit design and fear. The solutions include comprehensive training in a crash simulator, better design of exits and hatches, more streamlined personal equipment, underwater lighting and breathing aids. The death rate in helicopter crashes on land is reduced by using the shoulder restraint harness.

At a crash, the first priority is to save life. The next priority is to preserve evidence. Fire and crash sites are controlled by incident commanders who restrict access depending on risk. The risks to accident investigators can range from bugs to bears, encompassing explosive, chemical, biological, terrain, meteorological and psychological hazards. The chemicals involved at a crash site include aviation fuels, hydraulic fluid, metals (such as cadmium, beryllium, chromium, mercury and their salts), plastic resins and surface coatings and products of combustion. Unexploded ordnance, for example ejection seat cartridges when ejection was not initiated, may also be present.

**FITNESS FOR FLIGHT**

The formation of the Special Royal Flying Corps Medical Board in 1916 significantly improved the proportion of candidates who passed flying training. Nowadays, it can cost over £1 million to train a military fast jet pilot. The aircraft flown can cost over 100 times that figure. Moreover, medical factors frequently feature in accident reports. One study cited medical factors as causing or contributing to 4.7 per cent of fatal accidents. Aviation medicine policy must therefore balance the risks to individual health, flying safety and mission completion against conservation of resources, flying experience and training costs. Civilian aviation authorities have set a goal of one fatal accident in multicrew aircraft in each 107 flying hours. If the medical contribution to this is an arbitrary 10 per cent, then incapacitation in flight should cause an accident no more than once in every 107 flying hours. This is attainable if the risk to an individual pilot of incapacitation is <1 per cent a year, although there has been recent discussion about the logic of reducing this to 2 per cent. The actual figure for the United States Air Force over a ten-year period was 1.9 in 106 flying hours. Although some doubt has been expressed regarding the predictive value of periodic aircrew medical examination, one retrospective study showed that there were no important risk factors that could have been detected at such examinations in a series of military aircraft crashes. The only blood test that has shown any value is a blood lipid profile which should be carried out on initial examination and repeated at age 40.

It is a generally accepted principle that not only should aircrew be protected against the rigours of the aviation environment, but also that the general public should be protected from accidents caused by aircrew illness. This is
achieved by agreeing to medical standards which are the minimum compatible with professional flying. Aircrew are then selected for training who meet those standards. They are required to be not abnormally susceptible to the stresses of flying, either by disease or by unusual physiological response. Once the aircrew are trained, they are regularly examined to ensure that they continue to meet medical standards. Military aircrew are subject to the standards imposed by their parent armed force. Civilian aircrew in the United States in the United Kingdom are subject to licensing by the CAA. The frequency and content of the examination depends on the age of the pilot, the type of flying envisaged and the existence of risk factors. For many years, the upper age limit for captaincy of civilian passenger aircraft was set at 60 years. Experience reduces, but does not eliminate, age-related decline. However, the Aerospace Medical Association has concluded that there is insufficient evidence to support restriction of pilot certification based on age alone.\textsuperscript{134}

To allow any aircrew to fly with particular medical conditions, the following criteria must be satisfied:

- There must be minimal risk of sudden incapacitation.
- There must be minimal risk of subtle performance decrement.
- The condition must have resolved or be stable and be expected to remain so under the stresses of the aviation environment.
- If there is a risk of progression or recurrence, the symptoms and signs must be easily detectable and must not pose a risk to the safety of the individual or others.

In addition, for professional aircrew, the condition must not need exotic tests, regular invasive procedures or frequent absences to monitor for stability or progression. Finally, for military aircrew, the condition must be compatible with performance of sustained flying operations in austere environments worldwide.\textsuperscript{135} The role of the doctor dealing with aircrew must be clearly understood. Most aviators regard doctors as only marginally better than the angel of death because of the risk of being grounded. The medical officer must work to obtain and hold the trust of the aircrew and make it clear that his main aim is to maintain their flying status – but that he also has a responsibility to the employer and the general public as one of the guardians of flight safety. The three most common conditions seen by the United States Navy requiring a decision on fitness for flying are allergic rhinitis, obesity and decreased visual acuity.\textsuperscript{136} In one series in a European airline, the rate of grounding was 9.2/10\textsuperscript{3} crew members a year. Ear, nose and throat disorders accounted for 30.1 per cent, musculoskeletal disorders for 21.3 per cent and psychiatric conditions for 12.5 per cent.\textsuperscript{137} The rate of disqualification on medical grounds in the United States Air Force declined from 4.1 per cent a year in 1984 to 0.18 per cent by 1999, largely as a result of the use of clinical management groups to provide an evidence base, new therapies and effective preventive medicine efforts.\textsuperscript{138} In the final analysis, the decision on whether or not to return an aviator to flying rests with the appropriate national authorities, civil or military.

### Miscellaneous conditions caused or affected by flight

Backache is one of the most common conditions reported by aircrew and this is related to the relatively poor ergonomics often found in aircraft. Helicopter pilots have a greater incidence of prolapsed intervertebral disc,\textsuperscript{139} osteoarthritis of the spine\textsuperscript{40} and backache than controls.\textsuperscript{141} Over half of Sea King helicopter crew reported backache in the previous two years, sufficient to interfere with performance, and this incidence increased with the total numbers of hours flown.\textsuperscript{142} In addition, almost all flight attendants report musculoskeletal symptoms in one year, particularly in the lower back.\textsuperscript{143} Active female flight attendants report more menstrual irregularity than former flight attendants.\textsuperscript{144} In addition, an increased incidence of skin cancer has been reported in civilian airline pilots;\textsuperscript{145} this may be related to behavioural factors but some influence of exposure to cosmic radiation could be implicated.\textsuperscript{146} An elevated risk of brain cancer and carcinoma of the prostate for male pilots and of breast cancer for female flight attendants compared to the ground-based population has been described, but both occupational and non-occupational risk factors may have contributed.\textsuperscript{147}

Most airlines are now smoke-free. The withdrawal of nicotine from an addicted smoker may cause decrements in psychomotor performance. Aircrew who try to stop smoking should ideally be grounded for one to two weeks. Nicotine replacement therapies, such as patches or gum, may be allowed but systemic drugs such as buproprion (Zyban\textsuperscript{\textregistered}) should not be permitted when on flying status.\textsuperscript{148} Most aircrew who have had a hip replacement may be able to return to civilian flying. The risk for military aircrew would be expected to be greatest during the ejection sequence,\textsuperscript{149} but some methods of ingress to and egress from cramped cockpits may predispose to dislocation and vibration may contribute to loosening of the prosthesis.

### Use of therapeutic drugs

The use of therapeutic agents, whether by self-medication or prescribed, may be particularly dangerous in aviation. Most have side effects, some of which may be hazardous in aviation. Particular care should be taken with over-the-counter medication and unlicensed, herbal remedies. The key questions that have to be asked are:

- Does the condition for which the drug is being taken necessitate grounding in its own right?
- What monitoring of the condition is required?
- What are the potential side effects relevant to aviation?
- Does the patient have any untoward reaction to the drug on the ground?
The use of statins to reduce cholesterol levels has been found to be aeromedically safe provided side effects are minimal.150 Hypertensive patients undergoing treatment with selected anti-hypertensive agents may be returned to flying duty once their blood pressure is within limits, provided there are no untoward side effects and other risk factors are under control. In the end, the final decision on medication and flying rests with the relevant licensing authority.

Fitness for flight as a passenger

Passengers fly with all sorts of medical conditions every day and survive. However, with some conditions there is a degree of risk. The doctor asked to advise a patient must bear in mind the inactivity of a long flight, the relative hypoxia, the low humidity, the hassle, the ready availability of alcohol and the time zone changes. These may all impact on the timing of medications, particularly relevant to insulin-dependent diabetics. The swelling of legs may cause circulatory embarrassment to patients in plaster of Paris leg casts. Susceptible passengers may be at increased risk of deep vein thrombosis.105 Risk factors are:151

- Low: Age over 40, active inflammation, minor surgery in last three days. These passengers should be given information about mobilization and hydration. Support tights or non-elasticated long socks may be helpful.
- Medium: Varicose veins, uncontrolled heart failure, heart attack in the last six weeks, the taking of either hormone replacement therapy (HRT) or the oral contraceptive pill, polycythaemia, paraplegia, injury to the lower limb in the last six weeks, pregnancy or six weeks post-natal. These passengers should follow the advice above and use graduated compression stockings. The doctor may advise the use of aspirin if there are no contraindications.
- High: previous stroke or pulmonary embolus, major surgery within the last six weeks, malignancy, family history of pulmonary embolus. The advice for the above two groups should be followed, but the doctor may recommend the use of low molecular weight heparin instead of aspirin.

Airlines expect that passengers with known medical conditions will need to be medically cleared before flight, either by their own or an airline doctor. One survey found one request for medical clearance for almost every 5000 passengers.152 Almost one-quarter of requests were for musculoskeletal disorders or fractures, with psychiatric patients accounting for 17.6 per cent. Three-quarters required either a qualified escort or travel companion. Wheelchairs were needed by 30 per cent, in-flight oxygen by 28 per cent and stretchers by 27 per cent. When such patients are accepted as passengers, on-board oxygen, special diets or individual embarking, debarking or transfer arrangements may be made available. Kerbside check-in of baggage may be recommended. The airlines reserve the right not to accept infectious patients, patients who would be expected to deteriorate in flight or those whose conditions would be offensive to fellow travellers. Carriage of unstable patients is a skilled business which should only be undertaken by specially trained operators.

Transmission of disease

Worldwide flight exposes aircrew and passengers, as well as ground personnel, to a variety of disease vectors. For example, transmission of Mycoplasma tuberculosis from one crew member to another on a single flight has been reported.153 Communicable disease can enter the country by an infected person, infected vector or by infected material. International Health Regulations exist to detect, reduce and eliminate sources of infection, improve sanitation around airports and prevent the dissemination of vectors. Despite disinfection, cases of malaria have occurred in non-travellers living in the vicinity of airports in non-malarious countries. The regulations provide for notification of disease, health organization at airports, procedures at and between airports, documentation and disinfection. In the United Kingdom, the Public Health (Aircraft) Regulations 1979 cover cholera, plague, yellow fever, the viral haemorrhagic fevers and rabies.

It should be remembered that aircrew travel and therefore need to be immunized.154 The number of mandatory immunizations is small, but there are additional ones that may be recommended. Aircrew should not fly immediately after immunization because of the risk of side effects. Some malaria prophylaxis, for example mefloquine, should not be taken by aircrew for the same reason. Chloroquine (300 mg weekly, despite an occasional, temporary effect on visual accommodation) and proguanil (200 mg daily) have been overtaken as the mainstay of malaria prophylaxis for aircrew by malarone. Other drugs, such as doxycycline, may be given in areas of chloroquine resistance. The main actions to be taken are avoidance involving use of mosquito nets, sprays, long-sleeved and long-legged clothing. For aircrew staying overnight in malarial areas in air-conditioned hotels in urban or semi-urban areas, and transferring there in air-conditioned cars, the risks are very low, provided al fresco dining or safari trips are eschewed.155

SPACEFLIGHT

BACKGROUND

‘Never before has medicine been called upon to certify that an individual will be healthy enough to perform for three years following the examination’.156 On July 21, 1969, Neil Armstrong became the first man to walk on the moon. It is only a matter of time before some nation or group of
nations will return to the moon and then go on to explore Mars. Such plans depend on political will and support. When this happens, the success of the mission will depend upon the health of the crew.

Over 500 people have flown in space since Yuri Gagarin became the first in 1961. Space travel has changed greatly over the intervening decades and is set to progress dramatically in our lifetime. The space shuttle programme is drawing to a close and plans are being made to return to the moon and on to Mars. Space travel will become more available to paying ‘space tourists’. Man will be spending longer in space and at greater distances from Earth. Maintaining astronaut health is vital to the success of future missions. Space medicine studies the effects of microgravity on the human body and develops strategies for dealing with medical conditions and emergencies in space. This section summarizes the most important issues affecting the health of astronauts.

## THE SPACE ENVIRONMENT

The space environment is inhospitable. Space starts at 63,000 feet above sea level (Armstrong’s Line) and has a barometric pressure of less than 1 mmHg. Temperatures range from +150°C to −130°C. Astronauts experience microgravity since spacecraft are in a state of freefall. Objects retain their mass, but have no weight.

Space radiation poses a serious threat to astronaut health since there is little protection from Earth’s atmosphere or magnetic field. Three main sources of space radiation exist: galactic cosmic radiation (very high energy electrons, protons and heavy atom nuclei), solar radiation (mainly x-rays and high energy electrons and protons) and trapped radiation in the van Allen belts (energetic protons and electrons). Solar particle storms generate potentially lethal fluxes of radiation approximately every 11 years, so future exploration class spacecraft will require a ‘storm shelter’ to protect crews. Spacecraft may not protect the crew from background cosmic radiation, which has the highest energy and so is the most penetrating and potentially damaging. When solar activity is at a minimum, astronauts are exposed to a dose equivalent of 0.78 mSv/day on the international space station (ISS). Career limits for low-Earth orbit astronauts are 1500 mSv for males and 900 mSv for females aged 45. Annual limits for astronauts en route to Mars are yet to be determined, but astronauts are likely to be exposed to several sieverts during a three-year Mars mission.

Effects of radiation on the body are covered in Chapter 53, Ionizing radiations. Chronic effects relevant to space are the increased risk of carcinogenesis, CNS damage and cataract formation. Acute radiation sickness (ARS) from solar particle events would cause nausea, gastrointestinal upset, pancytopenia, seizures and even death. Drugs, such as amifostine, may be used to scavenge radiation-induced free radicals and protect tissues from ionizing radiation damage.

## PRE-LAUNCH AND LAUNCH

Safety of both astronauts and ground crew is of paramount importance to the on-site flight and occupational physicians. In 1967, a ground test of the Apollo 1 spacecraft killed three astronauts when the pressurized 100 per cent oxygen atmosphere caught fire from a spark from an electrical cable. Cabin atmosphere composition was changed as a result. Launch of the spacecraft is a dangerous time with high levels of vibration and noise. Risk of fire, explosion and toxins on the launch pad are posed by the large quantities of pressurized highly explosive propellants present. Gravitational pull reaches 3 G on the shuttle and 4 G on the Russian Soyuz capsule. In 1986, the space shuttle Challenger disintegrated shortly after launch killing all seven astronauts on board.

## THE SPACECRAFT ENVIRONMENT

The spacecraft is a pressurized vehicle which provides atmospheric control, waste management and shielding against micrometeorites and some radiation. The international space station is maintained at 1 atm, 80 per cent nitrogen and 20 per cent oxygen. CO₂ is actively removed using lithium hydroxide filters to keep levels below 0.01 per cent. Charcoal in the mixture removes odours. Toxicology, water quality, microbiology and radiation levels of the spacecraft environment are regularly monitored. Noise levels on the international space station are 75 dB mainly generated by the environmental control system, avionics and experiments. This may affect hearing, concentration and sleep.

Toxic chemical exposure is a potential hazard. Chemicals, such as freon, from cooling loops are toxic in small quantities if the leak enters the spacecraft, the airlock or crystallizes on extra-vehicular activity (EVA) suits. Chemicals used for orientation control systems, such as hydrazine and nitrogen tetroxide, can immediately irritate the respiratory tract and eyes or be absorbed through the skin. More long-term effects include kidney failure, hepatic failure and respiratory arrest.

Analysis of the space shuttle atmosphere detected benzene, acetaldehyde and dimethyl sulphides at levels below the maximum allowable concentration limits. Dichloromethane and formaldehyde have also been detected and are potentially toxic. Toxic contamination of the spacecraft occurred in 1975 when nitrogen tetroxide was released into the Apollo craft as it undocked from Soyuz. Three astronauts developed pneumonitis as a result; one lost consciousness briefly as they were putting on the oxygen masks.

Damage to the spacecraft’s protective shell could lead to decompression sickness. Astronauts had a ‘near miss’ in 1997 when the unmanned Progress module collided with and punctured the Spektr module of the MIR space station causing it to lose pressure. Fire in a spacecraft is even more dangerous than on Earth since it behaves differently and more unpredictably. Oxygen canisters caught fire on MIR releasing smoke and particles (Ewald, personal communication).
#### EXTRA-VEHICULAR ACTIVITY

The first EVA was performed by Alexei Leonov in 1965. EVAs are necessary for repair, construction and maintenance of the international space station and Earth satellites. The spacesuit contains its own life support system. The spacesuit atmosphere is 100 per cent oxygen at a pressure of 300 kPa. This lower pressure in the suit allows it to be more flexible. Astronauts ‘pre-breathe’ 100 per cent oxygen before initial depressurization to prevent decompression sickness. Russian and American pre-breathing protocols differ, the Russian one being shorter which may be useful in emergency situations.

Basic medical checks (blood pressure, heart rate, temperature) are recorded before EVA permission is granted. During EVA electrocardiogram, respiratory rate, heart rate, temperature, spacesuit pressure, radiation exposure, and spacesuit FiCO2 are measured. A liquid cooling garment is used for thermoregulation and hydration is maintained using a drink bag with straw inside the spacesuit.

EVAs are very arduous and metabolic use is high. At the peak of activities, astronauts’ heart rates have risen to above 170 with a respiratory rate over 40. Blunt or penetrating trauma may be caused because of the momentum of the large masses often moved during EVAs. Should the astronaut need medical help, he would need to be moved into the airlock before removal of the EVA suit. In extreme situations, if the suit becomes disrupted during EVA, the astronaut’s ambient pressure would quickly drop to zero and result in hypoxia and ebullism causing the astronaut to lose consciousness in 15 seconds.

#### RE-ENTRY

During re-entry, gravitational pull depends upon the trajectory (1.5 G in the shuttle and 3–4 G in the Russian Soyuz). An emergency return in Soyuz may reach 8 G. Increased G forces may put the astronaut’s already deconditioned cardiovascular systems under extra stress. Vladimir Komarov died in 1967 on impact when the parachutes on his returning Soyuz capsule failed to deploy properly. In 1971, three cosmonauts died on return from Salyut 1 following a sudden depressurization of their Soyuz capsule. More recently, Space Shuttle Columbia disintegrated on re-entry in 2003 as a result of failure of a heat shield tile damaged during launch. During re-entry, the temperature of the heat shield can rise to 3000°C.

#### SPACE PHYSIOLOGY AND PATHOPHYSIOLOGY

Because humans evolved in a 1-G environment, our physiology is significantly altered in microgravity. Many of these physiological changes are similar to those occurring in old age. Some of the changes can be regarded as pathophysiological and return to 1 G can be problematic.

Space physiology research requires a balance between regarding astronauts as research subjects and patients in their own right.

#### Space motion sickness

Space motion sickness (SMS) affects up to 70 per cent of Shuttle astronauts. As spacecraft size has grown, the incidence of SMS has risen. Symptoms of SMS are similar to motion sickness and include drowsiness, nausea, vomiting (often with little warning), stomach fullness, loss of appetite, facial flushing, dizziness, headache, inability to concentrate and sweating. SMS also includes the ‘sopite syndrome’ of fatigue, mood and personality changes and lack of initiative. These symptoms start within a few hours of weightlessness and recover after 72–96 hours. Symptoms like this affect astronaut productivity and EVAs are not routinely recommended during the first three days of spaceflight. Forty-seven per cent of medication used on board the international space station is for the treatment of space motion sickness.

There are several hypotheses regarding the aetiology of SMS, including sensory conflict, otolith asymmetry and otolith tilt–translation reinterpretation. Astronauts recover due to neuronal plasticity and remodelling of the CNS, but suffer from similar symptoms on return to Earth (‘mal de débarquement’). Manual control of a returning space vehicle when the pilot is experiencing such symptoms may be hazardous.

#### Cardiovascular system and orthostatic intolerance

The lack of gravitational pull results in blood shift into the thorax and head. Activity in carotid and aortic baroreceptors increases and activates mechanisms to decrease the central blood volume (BV). It was initially thought that BV decreases due to diuresis, but astronauts’ urine volumes do not increase and total body water remains constant. Fluid is thought to move from the intravascular space to the interstitial space. These changes happen within a matter of days. Decrease in thirst compounds the relative dehydration. Red cell mass decreases creating a ‘space anaemia’. This follows decreased erythropoietin levels rather than increased destruction (the number of reticulocytes falls). This is a response to the decreased plasma volume so haematocrit is normal in microgravity but falls on Earth when plasma volume recovers.

These changes in fluid distribution are appropriate for the microgravity environment, but can be problematic on return to Earth. Two-thirds of astronauts suffer from orthostatic intolerance (OI) on return to Earth with longer flights being associated with higher incidence. This causes symptoms of pre-syncpe and syncope which could be dangerous if astronauts had to egress the capsule in an emergency. The aetiology of post-flight OI is multifactorial,
including decreased central blood volume, decreased
inability to increase peripheral vascular resistance, cardiac
atrophy, baroreflex dysfunction and increased venous
compliance. Left ventricular mass falls by an average of 14 per
cent after just ten days in space.178 Stroke volume falls
significantly post-flight.179 As a result, VO₂max measured in
astronauts in space for 9 and 14 days decreases by an aver-
age of 22 per cent post-flight.180 This means that astronauts’
endurance is reduced in flight, which may be of particular
importance during an EVA.

Several countermeasures are used to counteract the
cardiovascular deconditioning seen in astronauts, none
with complete success. These include fluid loading before
re-entry, medication (e.g. midodrine181), anti-G suits
inflated to 1 psi during re-entry, exercise and lower body
negative pressure. Astronauts may re-enter the atmosphere
in the recumbent position to try to minimize the +G, load
on re-entry. It is uncertain how a reduced gravitational
field, such as occurs on Mars (0.38 G) and the moon
(0.18 G) will affect the incidence of OI.

Whether exposure to microgravity increases the risk of
cardiac arrhythmias or not is still disputed. The QT inter-
val is increased in space182 and an episode of asymptomatic
ventricular tachycardia has been recorded,183 the signifi-
cance of which has yet to be ascertained. Although debated,
the NASA Bioastronautics Roadmap recognizes arrhyth-
mia as a potential risk during spaceflight.184

Musculoskeletal

Muscle atrophy increases with time spent in microgravity,
the greatest reduction being seen during the first month in
space. This atrophy occurs since use of postural and lower
limb muscles decreases in microgravity. Losses of muscle
mass, force, power and increased fatigability have been
reported.185 Following an eight-day mission, a reduction
in postural muscle size up to 11 per cent was recorded.186
Countermeasures include exercise and the elasticized
Russian ‘penguin’ suit, which provides resistance exercise.
However, these countermeasures do not completely pre-
vent muscle atrophy. Backache is commonly thought to be
related to lengthening of the vertebral column.187

Decreased mechanical loading in microgravity leads to
bone mineral density (BMD) loss of weight-bearing bones
at an average rate of 1–2 per cent per month186 and up to
3–5 per cent per month in some bones.188 The extent to
which osteoclast activity increases and osteoblast activity
decreases is yet to be ascertained. Unlike disuse osteopor-
sis during bed rest on Earth, rate of bone loss in micrograv-
ity does not appear to plateau. On return to Earth, the rate
of recovery is slower than the rate at which it was lost189
and the extent to which bone fully recovers is debatable.190
A three-year Mars mission could potentially result in los-
ing 50 per cent of BMD at some skeletal sites if untreated.
Such losses of BMD would increase the risk of fractures
during long-term spaceflights.

Several countermeasures have been tried, but none
found to be completely effective. Bisphosphonates, resis-
tive exercise and artificial gravity may work synergistically
to combat osteoporosis.191

Renal/urinary

Urinary calcium and phosphate levels increase as a result of
the decreased BMD.192 This increases the risk of renal calculi
which are expected in 0–5 per cent of astronauts. Other
reasons for the increased risk of renal stones are decreased urine
output, dehydration, increased urine pH, magnesium and
citrate. These factors increase urinary super-saturation of
renal stone-forming salts. Hypercalcuria may affect sodium
and water balance. There was one incidence of calculi in
flight which would have caused early evacuation of the astro-
naut, but the stone was passed spontaneously. Eleven US
astronauts have had 14 calculi after flights of over a fortnight.
There have been four cases of urinary retention requiring
catheterization on the Shuttle. Ten per cent of astronauts fly-
ing on the Shuttle between 1981 and 1998 (89 missions, 438
males, 69 females) suffered from genito-urinary symptoms
during flight. Good hydration and potassium citrate may be
a useful countermeasure to this problem.191

Immunology

The immune system is suppressed by microgravity which
may increase the risk of infection, reactivation of latent
viruses (e.g. Epstein–Barr,193 varicella zoster194) and may
alter wound healing, regulation of autoimmune disease and
tumour growth.195 Cell-mediated immunity is decreased
during spaceflight.196 Escherichia coli and Staphylococcus
aureus have been found to have increased resistance to
some antibiotics in space.197 Rates of microbial mutation
increase in space and there is reduced diversity of the
body’s normal microflora.

Respiratory effects

The apicobasal gradients in lung perfusion and ventilation
diminish in microgravity. Lung vital capacity decreases
initially by 8–10 per cent because of engorgement of the
pulmonary circulation.198,199 This normalizes to pre-flight
values after nine days. Membrane diffusion capacity
improves with the increased thoracic blood volume.
Respiratory changes in microgravity are not regarded as
detrimental.

Psychological aspects

The psychological stresses of being in space are just as impor-
tant as the physiological challenges. The mental and psy-
chological health of astronauts is vital to the success of the
mission and coping strategies for being in such a remote environment are required. The unique dynamics of mixed sex, race and multicultural groups are important. Behavioural, cultural and social differences are all important. Problems which have occurred during spaceflight to date include stress, anxiety, altered concentration, depressed mood, malaise and fatigue. Sleep disturbance is common: on average, astronauts get six hours sleep a night. The potential for dysfunctional relationships between crew members and ground staff is possible. Careful crew testing, selection and training may decrease the likelihood of this occurring.

ASTRONAUT SELECTION

Selecting healthy astronauts aims to minimize medical and behavioural problems in space. Physical requirements differ depending on whether the astronauts are to become pilots, commanders, mission specialists or payload specialists. Pilots and mission specialists must pass a NASA class I or II space physical, respectively (similar to a military or civilian class I or II flight medicals). Selection criteria for astronauts and cosmonauts differ. Commercial spaceflight participants (‘space tourists’) have a different set of selection criteria, likely to be less stringent than typical current astronaut selection. Psychological testing is as important as fitness testing. Future crews will need to be cross-trained and multi-skilled, perhaps in several specialities, e.g. doctor and geologist (Cockrell, personal communication).

MEDICAL EMERGENCIES IN SPACE

To date, more astronauts have died as a result of equipment failure than from medical problems. However, medical emergencies can occur in space and they would have a major impact on mission success. Medical events occurred on 1867 occasions in 508 astronauts on shuttle flights STS-1 to STS-89 between 1981 and 1998. 498 astronauts reported medical symptoms other than SMS, including general malaise, respiratory events, digestive symptoms and injuries. The potential conditions which may occur are very varied. In descending order of frequency, the conditions which occurred were anorexia, space motion sickness, fatigue, insomnia, dehydration, dermatitis, back pain, upper respiratory infection, conjunctivitis, subungual haemorrhage, urinary tract infection, arrhythmia, headache, muscle strain, diarrhoea, constipation, barotitis, decompression sickness (limb pains mainly) and chemical pneumonitis. The median age of astronauts is increasing which may increase the likelihood of medical problems occurring.

Several medical evacuations from space have been necessary as a result of septic prostatitis, urinary retention, possible appendicitis and supraventricular tachycardia. Toothache in space has been reported and is potentially debilitating. Not every mission flies a medical doctor, but each mission has a designated medical officer. Crew medical officers (CMO) receive at most 40–60 hours of training. They refresh their training using one hour of computer training per month. Non-CMO crew receive 17 hours of medical training. In close Earth orbit, astronauts can take guidance from flight surgeons in Mission Control. However, signals take approximately 20 minutes to travel to Mars and back, so exploration-class crews will need to become more medically autonomous.

Equipment is limited because it costs €20 000 (US$28 000) to launch 1 kg into space. Storage space and power are restricted. However, medical capabilities are similar to those available on board a submarine or Antarctic mission. Capabilities for basic first aid, treating minor medical problems, performing a physical examination, wound closure, inject medications, minor dentistry, advanced life support (drugs and defibrillator with pacing capabilities), maintaining an airway, ventilation and patient monitoring are present. Monitoring includes electrocardiogram, blood pressure, PETCO2, pulse oximetry (Christgen, personal communication).

Administration of intravenous fluids requires a pump due to bubbles forming in intravenous bags in microgravity. The problem of inadequate supplies of intravenous fluids for treatment of haemorrhage, for example, may be solved by onboard production of sterile intravenous fluids using reverse osmosis and other ultrafiltration methods (Scarpa, personal communication). Hypotension in such a situation could be exacerbated by pre-existing low blood volume and increased gravitational forces during emergency re-entry (e.g. 8 G during an emergency Soyuz trajectory).

Making a diagnosis in microgravity

Physical examination must be adapted for the unique environment and physiological changes of microgravity – the ‘microgravity examination technique’. There are, for example, decreased bowel sounds, distended jugular veins, altered posture, hyper-reflexia and the diaphragm is elevated by two intercostal spaces. Using a stethoscope may be difficult in the noisy spacecraft environment. The crew medical restraint kit allows astronauts to be examined more easily.

Ultrasound is the only imaging modality presently flown in space. Ultrasound sensitivity and specificity are likely to be no different in microgravity than on Earth. It can be used for obtaining images of a great variety of systems including abdominal, urinary pathology, echocardiography, sinus or dental infection, ocular trauma, musculoskeletal injury. Ultrasound has reliably diagnosed pneumothorax in anaesthetized pigs in microgravity and could also be used to diagnose haemothorax. Endotracheal tube position could be checked using ultrasound to rule out oesophageal positioning and endobronchial intubation. Ocular ultrasound has been performed in space under the real-time guidance of doctors on the ground. Musculoskeletal ultrasound of
the shoulder has been performed successfully on the international space station.211 These images can be relayed to physicians back on Earth for interpretation, although transmission delays require acute medical problems on an exploration mission be diagnosed initially by a well-trained, on-board clinician. On-board computer training may help astronauts retain and improve their diagnostic skills.207

**Surgery in space**

It has been predicted that one medical event requiring anaesthesia and/or surgery will occur every three to four years of spaceflight.212 As missions increase in length and leave Earth’s orbit, space crews will require the capability to perform surgery on board the spacecraft since return to Earth may not be possible or timely. Alternative approaches to surgical conditions may be required. For example, non-operative treatment of appendicitis has been shown to be effective in remote environments213 as has prophylactic appendicectomy. Protection of the surgical field from the surrounding air will be needed in microgravity. There are more antibiotic-resistant bacteria in space, so sterile techniques are paramount.

Surgery in a microgravity environment has been shown to be possible, although conditions are clearly different. The surgeon’s tactile sensation and proprioception are altered.214 Laparotomies on rabbits were carried out by Russian research teams on board parabolic flights in the 1960s.215 Rats have been operated on in a neutral buoyancy tank, during which a variety of surgical techniques were practised, including nephrectomy, small bowel resection and splenectomy.214 Tissue planes separate more easily and comments have been made on improved visualization during laparotomy (Campbell M, personal communication). Bleeding behaves differently in microgravity. Arterial bleeding forms droplets and streamers, while venous bleeding stays close to the wound because of surface tension.214 Surgical instruments float and so attachment aids (e.g. Velcro, magnets) are necessary for safety and ease of use.

**Anaesthesia in space**

In order to perform surgery, anaesthesia is required. In microgravity, the anaesthetist faces logistical challenges and altered physiological norms. There is no liquid–gas interface in microgravity and so anaesthetic vaporizers would not function.203 Total intravenous anaesthesia may be the most practical technique since regional blockade is likely to be limited by the skills available. Pharmacodynamics and pharmacokinetics may be altered, e.g. neuromuscular junction physiology is affected by muscular atrophy. The changed acetylcholine receptor function may preclude use of depolarizing muscle relaxants to avoid theoretical hyperkalaemia.

The best way of securing an airway is likely to be the laryngeal mask airway (LMA). Intubating LMA and endotracheal tubes are flown (Christgen and Williams, personal communications). Tracheal intubation may be difficult because of facial oedema and the need to tether both the patient and the intubator. Gastric motility is decreased in microgravity so the risk of aspiration during general anaesthesia increases.

Anaesthesia could be altered on return from microgravity. Two rhesus monkeys who flew 14 days in space on the Bion 11 mission experienced significant complications, one dying, after anaesthesia to obtain biopsies.

**Adult life support**

Should chest compressions be required in microgravity, a modified technique will be required to maintain contact between the patient and provider.204 Studies on mannikins and pigs during microgravity on parabolic flights have demonstrated that successful chest compressions
are possible in this environment. Several methods of performing chest compressions have been devised: the Evetts–Russomano method, reverse Heimlich (bear hug), vertical-inverted (hand stand (Figure 52.4)) and conventional 1-G method with patient and provider restrained. Performing chest compressions in a hypogravity environment, such as the moon or Mars, will require use of upper body strength rather than simple body weight.

RESEARCH AND GROUND-BASED ANALOGUES

Studies into health in microgravity have been limited by small sample sizes and expense. To address this, space researchers use ground-based analogues to microgravity to carry out research relevant to microgravity. Such analogues include head-down bed rest, head-out water immersion and head-out dry immersion. Parabolic flights on aircraft nicknamed ‘the vomit comet’ produce brief periods of microgravity (approximately 20–30 seconds) up to 40 times each flight. Analogue environments (e.g. Antarctica, submarines) can be useful in trying to predict the sort of conditions which may occur as a result of long-term spaceflight since such explorers live in cramped isolated conditions.

THE FUTURE OF SPACEFLIGHT

Commercial spaceflight

In 2004, history was made when the Ansari X prize was won by the first private spaceship to go into space. Commercial space passengers may be older than the average astronaut and more likely to have chronic medical problems. Standards for such paying space participants are less rigorous than those of career astronauts. This has already been seen when a recent 57-year-old space participant visited the international space station despite a history of moderately severe bullous emphysema, previous spontaneous pneumothorax, a lung parenchymal mass, renal cyst and ventricular and atrial ectopy. He underwent thorascopic pleurodesis pre-flight to prevent pneumothorax occlusion by proxy: A cause for sudden blindness in an airline passenger. Aviation, Space, and Environmental Medicine. 2002; 73: 385–7.

Artificial gravity

Artificial gravity may be used in future long-term, exploration missions to counteract some of the physiological changes occurring in microgravity. This can be achieved by rotating future spacecraft or flying on-board, short-arm centrifuges. Artificial gravity is different from terrestrial gravity because of gravity gradients, Coriolis forces and cross-coupled angular accelerations.

Key points

- Flying and spaceflight expose the human to a variety of stresses which can destabilize the physiological equilibrium, degrade performance and can pose a risk to flight safety.
- These stresses, and the resulting physiological strains, can be ameliorated by selection against predetermined medical standards, training, protective equipment, suitable exposure planning, development of techniques and protocols, appropriate engineering design and, occasionally, suitable medication.
- If financial considerations are ignored, human, rather than engineering, factors will continue to limit the future development of flight and space exploration.

INTRODUCTION

On November 8, 1895, Wilhelm Roentgen was examining the effects of passing an electric current through a glass tube from which air had been evacuated, when he found that a sheet of photosensitive paper glowed when the current was switched on. He had discovered x-rays and by the turn of the last century radiographs were being used in many fields, in particular for diagnostic purposes. In 1896, Henri Becquerel discovered that certain types of substances, in particular radium, darkened photographic plates. He called this phenomenon ‘radiation’ and, with a student who worked with him, Madame Marie Curie, continued to investigate and experiment in this field. Due to a lack of knowledge of the harmful biological effects that radiation could produce, they adopted no precautions or gave no thought to the hazards. As a result, Madame Curie received very high doses of radiation and died of leukaemia, possibly due to her radiation exposure. Similarly, many radiologists received high doses of radiation to their hands resulting in erythema and subsequently many died of radiation-induced cancers. Throughout the twentieth century, the use of radiation increased, so that now radiation sources and radioactive elements are found in wide and diverse environments, embracing, inter alia, nuclear medicine and therapy, non-destructive testing, nuclear power and smoke detectors.

Accident and emergency personnel, hospital specialists, occupational health and public health physicians are likely to become involved with radiation issues if the stringent statutory controls for radiation sources or equipments are bypassed or ignored. For example, the theft of a caesium-137 source in Goiânia, Brazil led to 50 people receiving significant exposure and four deaths. Large areas of land and property were affected. There have been many accidents with irradiator sources using non-destructive testing or irradiation of foods and materials where individuals have received very high doses, often leading to death. In the Chernobyl nuclear power plant accident, 28 members of the workforce died of radiation-related injuries and the release of radioactivity led to widespread contamination of houses, land and foodstuffs. These low probability events can lead to significant radiation exposures to both the workforce and the public and their clinical management would clearly involve hospital physicians, occupational and public health physicians, and general practitioners. Experience suggests that in all these scenarios both the individual employee’s health outcome and the public’s health concerns dominate the agenda and place a burden on health professionals. Coherent plans to deal with these events are essential.

IONIZING RADIATIONS

Atoms, radioactivity and radiation

All matter is made up of atoms. Each atom contains a nucleus around which electrons orbit. In the nucleus, there are protons and neutrons. All atoms of the same chemical element have an identical number of positively charged protons in the nucleus and negatively charged electrons on
the number of protons defines the atomic number of the element. The mass of the atom is determined by the number of protons and neutrons and the total number is called the mass number. The same element can have different numbers of neutrons and consequently different mass numbers. These variants of the elements are known as isotopes. Some of these isotopes are unstable and eventually transform into atoms of another element with the simultaneous emission of alpha (α) or beta (β) particles and accompanied usually by gamma (γ) rays. This property of the unstable atom is called radioactivity; the change itself is called radioactive decay and the unstable atom is said to be a radionuclide. The time necessary to reach a stable form depends on the particular isotope and may take a few fractions of a second to several thousand years. The time for the activity to decay by one-half is termed the half-life ($t_{1/2}$). For example, sodium-23 (23Na) is the stable form of sodium and 24Na is a radioactive isotope with a $t_{1/2}$ of 15 hours. The latter decays emitting a β-particle to become 24Mg, a stable isotope of magnesium. This activity is measured by the numbers of disintegrations per unit time. The unit by which radioactivity is measured is the becquerel (Bq) and 1 Bq equals one atomic disintegration per second; 60 Bq is the average amount of natural potassium-40 ($^{40}$K) in every kilogram of the average person. This means that about 15 million $^{40}$K atoms disintegrate inside a person each hour.

### What are ionizing radiations?

Ionizing radiation may be higher energy electromagnetic radiations (x-rays and γ-rays) or energetic subatomic particles such as α- and β-particles and neutrons. According to their energy, x-rays and γ-rays interact with matter and tissue and although the mechanisms may be different, they all produce positively and/or negatively charged ions, which then interact with the absorbing matter to produce physicochemical changes by adding or subtracting electrons. The energy of these electromagnetic radiations will also determine their penetration, higher energy photons penetrating further than low energy ones. When they do interact with tissues and cells, energy is deposited within the tissue.

The different radiations penetrate matter in different ways, the properties being determined by the size, charge and energy of each type; α-particles are stopped by a thin piece of paper or the dead layer of the skin, while β-particles can penetrate the hand but will be stopped by a thin sheet of aluminium; x- and γ-rays penetrate the body and an aluminium sheet, but are stopped by lead. Neutrons penetrate most materials, but may be stopped by thick polythene or concrete (hydrogenous materials); high energy neutrons have a high penetrance in tissue but low energy neutrons can be absorbed in the body because of the body’s high water content (see Table 53.1). These overall properties of radiation affect the degree of cellular damage following exposure and the methods needed for protection.

In general α-particles do not constitute a significant hazard as an external source, but are hazardous when taken into the body. When incorporated, they can irradiate adjacent cells in, for example, the liver. Neutrons, because of their absence of electrical charge, produce ionization indirectly and tend to be more penetrating. Ionizing radiations have sufficient energy to break chemical bonds and ionize atoms and molecules, producing an ion pair. These ions are charged and capable of causing further ionization and energy deposition leading to physicochemical changes in cellular constituents.

### DOSE QUANTITIES

Some of these changes may be of no biological consequence and others may be repaired, but there is a finite probability that damage may cause cell death or irreparable damage to vital cell constituents. The absorbed dose is a measure of the mean energy absorbed by unit mass of tissue, and the absorbed dose in grays (Gy) is equal to the deposition of one joule (J) of energy in 1 kilogram (kg) of tissue. Overall, the greater the dose, the greater the likelihood of a biological effect being seen. Energy is deposited along the path of ionizing radiation as it traverses tissues in the form of ionizations. The average deposition of energy per unit length is called the linear energy transfer (LET).
Charged particles tend to have higher LET values than x- or γ-rays. The International Commission on Radiological Protection (ICRP) has introduced a weighting factor related to LET to take into account these differences. These radiation weighting factors (\(w_R\)) may range from 1 to 20 for different radiations. Thus photons, such as x- or γ-rays, are assigned a \(w_R\) of 1 (low LET) and α-particles 20 (high LET). Tissues are also assigned weighting factors (\(w_T\)) to differentiate the wide variation in tissue sensitivity to radiation, the lymphopoietic stem cells and gonadal germ cell cells being the most sensitive and bone being relatively insensitive. These radiation and tissue weighting factors are used to convert the absorbed dose in grays to an effective dose in sieverts (Sv). This system allows external and internal exposures to be combined into one dose – on the basis of equality of risk. Once a radionuclide is incorporated, it will continue to expose surrounding tissues until final decay or it is excreted. It is usual to calculate this committed effective dose following the ingestion or inhalation so that extra care can be taken to reduce future external exposures.

Submultiples of the sievert are commonly used, such as the millisievert (mSv), which is one-thousandth of a sievert; for example, the world average individual dose received due to exposure to natural background radiation is about 2.4 mSv per year compared with the occupational dose limit of 20 mSv average per year over defined periods of five years. It is sometimes useful to have a measure of the total dose to groups of people or a population. The quantity used to express this total is the collective effective dose: it is obtained by summing the product of all the doses in a group and the number of people in the group and is usually expressed in person-sieverts. Throughout this chapter, these various dose quantities will be referred to as dose, except where further clarification is required.

**NATURAL BACKGROUND RADIATION**

Radiation of natural origin pervades the whole environment. Cosmic rays reach the earth from outer space, the earth itself is radioactive, and natural activity is present in our diet and in the air. Everybody is exposed to natural radiation to a greater or lesser extent, and for most people it is the major source of exposure.

**DETECTION OF RADIATION**

**Physical**

Ionizing radiations cannot be directly detected by the human senses, but they can be detected and measured by a variety of means, such as photographic films, Geiger tubes and scintillation counters. There are also relatively new techniques using thermoluminescent materials and silicon diodes. Some of these techniques are used to measure individual doses on dosimeters (generally called film badges). Measurements made with such dosimeters can be interpreted to represent the energy deposited in the body or in a particular part of the body by the radiation concerned.

**Biological**

When a radionuclide is deposited in an internal organ, for instance via ingestion or inhalation, doses are generally calculated, because the activities are too small to be measured. The dose (or activity) can be assessed or measured by taking urine or blood samples and applying biokinetic models or be measured directly by special detection systems, e.g. whole body monitors. These systems are only available at special sites in the United Kingdom, such as British Nuclear Fuels, the Atomic Weapons Establishment, the Health Protection Agency, Sellafield Ltd or Harwell.

In an accident situation, estimating the whole body dose by changes in circulating absolute lymphocyte counts in the first 48 hours is possible and by cytogenetic assays for chromosome aberrations in cultured lymphocytes. These techniques use either dicentric counting or more recently fluorescence in situ hybridization (FISH) painting of chromosomes and measuring the translocation of genetic material. The threshold for whole body dose-validated chromosomal changes is around 1–200 mSv. More recently, electron paramagnetic spin resonance techniques have been developed using teeth or, in the case of cadavers, bone, which permits a retrospective assessment of the dose. The accurate range for this technique is from around 100 mGy to lethal doses. Another technique using post-subcapsular lens opacities also offers a possible way to assess historic doses; however, its accuracy is not yet proven.

**HEALTH EFFECTS OF IONIZING RADIATION**

Any organ or tissue may be affected, the degree varying with the dose and the radiosensitivity of the given organ or tissue. Distinguishing two types of effects is possible, somatic and hereditary. The somatic effects relate to the individual who is exposed, and may be early or late, and in the embryo or fetus may be teratogenic. The hereditary effects would occur in the offspring, through genetic damage to germ cells of the exposed individual.

**Somatic effects**

Somatic effects are classified as deterministic and stochastic. Deterministic effects are those for which the severity increases with the dose and for which a threshold exists. Stochastic effects are those whose probability of occurrence increases with the dose and whose severity is independent of the dose and without a threshold. With
deterministic effects, cause and effect can be seen. However, due to the random nature of the interaction of radiation with matter, for stochastic effects the inference of cause can only be based on an increase in the probability of that effect. Where the dose is low (as is likely in occupational exposures), only stochastic effects might be seen. The severity of stochastic effects is not dose dependent as it is with deterministic effects. So an increase in a dose produces an increase in the probability of a stochastic effect.

**DETERMINISTIC EFFECTS**

Generally, dose–response relationships are sigmoid in shape and exhibit a threshold. For each deterministic effect, the two main parameters to consider are the threshold dose (ED0), at which the given effect may appear, and its relative severity. These effects are characterized by the median dose, ED50, at which 50 per cent of exposed individuals will exhibit the effect, and by the slope of the curve at the median. The dose–response relationships are generally quoted for acute exposure; protraction of exposure increases the median dose for the effect.7,8

Doses below which selected deterministic effects should not occur in a normally distributed population (ED0) are given in Table 53.2. These levels take into account the individual variation and sensitivity rather than the average value. They are not complete and are for guidance only. The values should not be used in conditions of known radiosensitivity, e.g. ataxia telangiectasia.

**Table 53.2 Approximate threshold levels of dose (ED0) for deterministic effects (adult exposure).**

**Haematopoietic system**

The bone marrow is the main organ of concern since exposure to penetrating radiation at high dose rate can lead to death within a few weeks. This early mortality results from stem cell depletion in the marrow. The lymphocytes are the most sensitive indicators of injury to the bone marrow. Acute doses of 1–2 Gy reduce their concentration in blood to about 50 per cent of their normal level within about 48 hours. Neutrophils and platelets also show a dose-related decrease in concentrations and the levels can be used to predict the likelihood of survival and the necessity for treatment. People with bone marrow aplasia show an increased susceptibility to infection and frequently spontaneous bleeding (from thrombocytopenia) as a direct result of damage to the immune and haematopoietic systems. In severe cases of radiation injury, marrow aplasia is the likely cause of death.6,9

Because of the lack of quantitative human data, there has been considerable uncertainty about the dose–effect relationship for death due to irradiation of the bone marrow following acute or chronic radiation exposure. Extensive data have been published on the effects of whole-body irradiation in animals.10 However, they cannot be used directly to predict dose–response relationships for man due to marked variation between species, but they do provide information on the likely shape of the dose–response relationship.

The median lethal dose for humans is not precisely known. Several estimates have been published ranging from 2.4 to 5.1 Gy bone marrow dose. The higher values of the estimates of the LD50, involved cases where significant supportive and therapeutic medical treatment was provided. With minimal medical treatment involving no more than basic first aid, a value for LD50 of 3 Gy has been adopted by United Nations Scientific Committee on the Effects of Atomic Radiations (UNSCEAR),6 the National Radiological Protection Board (now part of the Health Protection Agency)7 and the Nuclear Regulatory Commission, USA (NUREG).11 For supportive medical treatment which includes procedures such as reverse isolation procedures, the use of antibiotics, white cell and platelet transfusions and intravenous feeding, NRPB7 and NUREG11 recommend a value for LD50 of 4.5 Gy. This is based partly on human and partly on animal data. Recent advances in rescuing depleted marrow with stem cell stimulating growth factors12,13 would now be included in treatment. These offer hope that the LD50 will be raised, possibly to the point where death no longer depends on haematopoietic damage.

The lymphocyte count decreases within a few hours of irradiation and the platelet and granulocyte counts within a few days or weeks, while the erythrocyte count begins to decrease rather slowly only after a number of weeks. The exposed individual may die from infection or from haemorrhage. The consensus value for the median lethal dose within 60 days (LD50/60) is estimated to range from 2.5 to
Gastrointestinal tract

There is considerable variation in response as the different parts of the gastrointestinal tract have markedly different radiosensitivity. The oesophagus and rectum are relatively radioresistant, while the stomach and small intestine are much more sensitive. The small intestine is the most sensitive because of the rapidly proliferating mucosal cells of the mucosal epithelium in the crypts of Lieberkühn. Single acute doses to the abdomen of around 6–16 Gy produce early onset of nausea, vomiting and diarrhoea, the symptoms occurring earlier and being prolonged broadly in proportion to the dose. These symptoms are thought to be caused by the release of 5-hydroxytryptamine (5-HT) into the bloodstream which stimulates the nausea/vomiting centres in the brain and other 5-HT receptors. There is a concomitant increase in bowel motility which may be caused by bile salts and other substances acting on the damaged mucosa. Very few human data are available on this gastrointestinal syndrome. It is known, however, that cancer patients given whole body doses of 10 Gy or more (generally as a single dose delivered in about four hours, in conjunction with bone marrow transplantation) have survived the gastrointestinal syndrome. Data obtained from studies in which x-rays were used to irradiate acutely the gastrointestinal tract of rats indicate an LD50 of about 15 Gy, an LD10 of 10 Gy and an LD90 of 20 Gy.

For gastrointestinal symptoms, the following figures are given as guidelines for adults; anorexia may be seen in 5 per cent of those at 0.4 Gy and 95 per cent at 3 Gy, nausea in 5 per cent at 0.5 Gy and 95 per cent at 4.5 Gy, vomiting in 5 per cent at 0.6 Gy and 100 per cent at 7 Gy, and diarrhoea in 5 per cent at 1 Gy and over 20 per cent at 8 Gy. If the time from exposure to onset of any of the above symptoms is less than one hour, the whole body dose is likely to be >3 Gy, if more than three hours <1 Gy and if they last for more than 24 hours, the dose is likely to be >6 Gy. The onset of symptoms within 30 minutes indicates an abdominal dose >3 Gy. These signs and symptoms are sometimes referred to as the acute radiation syndrome.

Lung

The lung can be exposed to external radiation from a beam or internal radiation after inhalation of radioactive materials. Radiation pneumonitis appears some weeks or months after exposure. It is a complex phenomenon, including oedema, cell death, cell desquamation, fibrin exudate in the alveoli, fibrous thickening of alveolar septa and proliferative changes in the blood vessels. The main effect is interstitial pneumonitis, followed by pulmonary fibrosis, resulting principally from the damage and response of the fine vasculature and the connective tissues. Development of the lesions is highly influenced by the volume of the organ irradiated and the dose. An acute exposure of both lungs shows a threshold at about 6–7 Gy, with an ED50 at about 9 Gy.

Thyroid

The adult thyroid is not especially sensitive to radiation; however, it should always be considered if iodine isotopes are inhaled or ingested by some employees as it accumulates rapidly in the gland. The radiation-induced diseases include acute radiation thyroiditis and hypothyroidism. Total ablation of the thyroid requires high doses, about 1000 Gy delivered within a short period (two weeks). Hypothyroidism is produced by much lower doses, with 50 per cent incidence at about 60 Gy for acute external exposure and 300 Gy for prolonged internal exposure. The childhood thyroid is more sensitive to radiation (see under Carcinogenesis, p. 629).

Skin

The skin is a relatively radioresistant organ, but is likely to be exposed in any type of accident. Skin responses depend upon various factors, such as size of the irradiated area, depth distribution of dose, duration of exposure and dose rate. Radiation damage to the skin may be observed as erythema, moist desquamation and necrosis, with thresholds of 2, 12–20 and >18 Gy, respectively. Moist desquamation often results in chronic changes, with hyperkeratosis and telangiectasia of the capillaries and of superficial and deep blood vessels. The chronic phase may lead to ulceration, atrophy and necrosis.

Protraction of exposures for 1–14 days will increase the threshold and ED50 values by a factor of about two compared with acute exposure. As radiation burns involving large areas can precipitate the same systemic effects as thermal injury, overall management may be complicated especially where other body systems have been affected, e.g. bone marrow.

Eye

Experience has shown that radiation doses received by the lens may result in lenticular opacities or cataracts. There is currently a debate as to whether these changes are deterministic or stochastic. The eye may be exposed either after local irradiation – acute or protracted – or after whole body irradiation. The threshold level for detectable opacity is estimated to be less than 0.5 Gy. Protraction does not increase the threshold so much as for some other organs. The cataract does not appear early after exposure; the latent period varies from six months to 35 years, with an average of three years.

Gonads

The germ cells of the reproductive system are highly radiosensitive. The threshold dose for transient sterility lasting for several weeks averages 0.15 Gy for men and about five to ten times higher for women. Recovery time in men is dose dependent and may take many years. Doses...
Ionizing radiations of 2.5–6 Gy or more are required for permanent sterility in both men and women.

**Embryo and fetus**

The embryo and fetus should also be considered, as women in the workforce may become pregnant. The developmental effects of radiation in the embryo and fetus are strongly related to the gestational age at which the exposure occurs, i.e. whether it occurs during organogenesis. The most serious health consequences of prenatal exposure are embryonic death, gross congenital malformation, growth retardation or severe mental retardation. For exposures at high dose rates, severe mental retardation has been shown for exposure occurring during the 8th–15th week and to a lesser degree during the 16th–25th week after conception. The threshold dose is estimated to be around 0.4 Gy between the 8th and 15th week and 0.1–0.2 Gy between the 16th and 25th, respectively.

**Central nervous system**

The acute central nervous system effects are generally reached only when the whole body radiation dose exceeds about 50 Gy. The survival time is usually less than 48 hours. Death is believed to be a function of several causes, including vascular damage, meningitis, myelitis and encephalitis. Fluid also infiltrates the brain causing marked oedema. However, any person who exhibits even mild symptoms of central nervous system syndrome would inevitably die from gastrointestinal or haematopoietic damage.

### Effects of acute whole body radiation exposure

The effects which are likely to be seen following a homogenous whole body irradiation over a short period (minutes or hours) are shown in Table 53.3. Experience from several accidents has shown that most casualties have only part of their bodies exposed to the radiation. The non-uniform and heterogeneous nature of the exposure leads to variable signs and symptoms and the outcomes are different. Some high localized doses do not present with the classical prodromal signs of nausea and vomiting. This complicates the initial triage and subsequent therapy. For example, in patients with severe but partial bone marrow irradiation residual stem cells in unafflicted bone marrow can reject bone marrow grafts causing host-versus-graft disease. This was one of the prime reasons why most of the transplantations at Chernobyl were unsuccessful.

### Effects of whole body chronic radiation exposure

In a chronic exposure (measured in days, weeks, months), the symptoms are usually more subtle. The usual feature is of general malaise, with influenza-type symptoms, fever and/or diarrhoea and vomiting. Several cases have arisen where people have been exposed chronically to an industrial or a medical therapy radiation source, sometimes discarded or procured illegally. In one case (unpublished), where a radiation source had been taken into a house, it was only after an elderly member of the household died and others started to suffer from general malaise that radiation exposure was suspected. It has been reported that chronic radiation exposures have been implicated in life

Dose clinically undetectable

Expected laboratory findings:

- Small decrease in lymphocyte count in blood (1–4 days)
- Increase in accuracy of chromosome dosimetry from limit of sensitivity

Laboratory findings:

- Diagnostic changes in blood within days
- Accurate chromosome dosimetry

Laboratory findings:

- Early diagnostic changes in blood
- Accurate chromosome dosimetry (Note: Lethal dose 50% without treatment ~3 Sv)

Early diagnostic changes in blood
shortening, accelerated ageing and premature atherosclerosis, but the evidence was inconclusive, when the data were critically reviewed by UNSCEAR in 2006. They concluded that while there was an increase in circulatory diseases at doses in excess of several grays, the evidence for an association in the range of 1–2 Gy comes only from the atomic bomb survivors and that at lower doses there was not sufficient evidence to establish a causal relationship. For other non-cancer diseases, there was even less evidence of a radiation dose–response relationship.

Carcinogenesis

In almost all partial body exposures, whether acute or chronic, the skin will be affected. Table 53.4 shows the severity of skin damage with increasing dose. The effects would only be seen in accidental situations or where flagrant breaches of safety practices have occurred. Depending on the type of exposure, deeper tissues may also be affected. Incidents where small sources have been carried in shirt pockets for short periods have given rise to exceptional doses (measured in hundreds of Gy) leading to serious necrotic lesions of the chest wall.

STOCHASTIC EFFECTS

Carcinogenesis

Following irradiation, a viable but modified somatic cell may retain its mitotic capacity and may result, after a prolonged and variable period, in the development of a malignancy. The cancers induced by radiation, with or without the contributions of other agents, are indistinguishable from those occurring ‘spontaneously’ or from other causes. Since the probability of cancer resulting from the radiation is related to dose, this type of effect of radiation can only be detected by statistical means in epidemiological studies carried out on exposed population groups. If the number of people in an irradiated group and the doses that they have received is known, and if the number of cancers eventually observed in the group exceeds the number that could be expected in an otherwise similar but non-irradiated group, the excess number of cancers may be attributed to radiation, and the risk of cancer per unit dose may be calculated, i.e. the risk factor. The probability of causation can be ascribed based on radioepidemiological tables (see below).

A major source of information on the risk of radiation-induced cancer following whole body irradiation is the follow-up studies of the survivors of the atomic bombing in Hiroshima and Nagasaki in Japan in 1945. Data have also been obtained for a number of tissues from other exposed human population groups, for example, tuberculosis patients who had high x-ray doses during treatments, and from people exposed to nuclear weapons fallout in the Marshall Islands. Risk estimates have also been developed for cancers of some individual organs, based on information on the effects of incorporated radionuclides, in miners exposed to radon and its decay products, from employees exposed to radium in the luminizing industry, and from patients given the x-ray contrast medium thorotrast (thorium oxide). Some of the available epidemiological data of second cancers, for example of the breast, in patients who have been irradiated for Hodgkin’s disease are far from ideal for calculating risk estimates because of the confounding influence of various chemotherapy and radiotherapy regimes. A further example is the significant increase in childhood thyroid cancer in Belarus, the Ukraine and the Russian Federation following the inhalation and ingestion of radio-iodines after the Chernobyl accident. It has proved difficult to reconstruct the thyroid doses and so the risk estimates are not yet robust. Furthermore, the accuracy of the dosimetry involved in many of the large epidemiological studies is also a potential source of error and needs careful evaluation. Recent risk estimates are based largely on the Japanese bomb survivor data, and one drawback to the use of these data for risk estimates at low dose and dose rates, is the contribution from neutron exposure, although this forms only a small part of the total exposure. Estimates of the dose were revised in 2002 which has led to a revision downwards of about 8 per cent in the risk estimates.

Information of this nature has been reviewed in BEIR VII in ICRP 103 and in the 2006 report of UNSCEAR. These reports assess the risks of radiation-induced cancer, based predominantly on data on the Life Span Study (LSS) of the atomic bomb survivors. Recent risk assessments have used data on cancer incidence in the A-bomb survivors, as well as data on mortality in this population. Where risk factors are not available from the LSS, they have been developed from the many other epidemiological studies.

The risks have increased partly as a result of new estimates of tissue doses received by the Japanese population, because more cancers have appeared in the longer period of follow up to 1990, and because different models have been used to predict the risk over a lifetime. However, there is uncertainty in how many cancers will arise in the future as almost half of the Japanese cohort were still alive in 1997.

The research on the atomic bomb survivors in Japan has shown that leukaemia appears first after whole body irradiation, with a latent period of two years and peaks at six to seven years. Solid tumours generally begin to appear after about ten years and their incidence continues to increase for several decades. No threshold is detectable and statistically significant increased risks exist at doses down to 150 mSv.26 This is important for setting acceptable occupational dose limits (see under Occupational doses, p. 632).

However, as discussed earlier, the cancer risks derived from such exposed groups are influenced largely by exposures to high doses, which were delivered over a short period of time. In practice, most people are exposed occupationally to low doses of radiation received over relatively long periods. On the basis of available information, therefore, UNSCEAR5 and ICRP5 have assessed that the risk factors obtained directly from observations at high doses and high-dose rates should be reduced by at least a factor of two to give more realistic risk factors for low doses and dose rates. The risk factor or lifetime fatality probability coefficient from ICRP for a reference population of both sexes and of working age is $4.1 \times 10^{-2}/$Sv for the sum of all fatal malignancies, i.e. a dose of 1 Sv in a working lifetime results in a 4 per cent chance of a fatal cancer occurring.5

More recent epidemiological studies involving lower dose exposures from the UK National Registry for Radiation Workers have shown that the leukaemia incidence trend with dose is consistent with the ICRP risk estimates.41

Probability of causation

The concept of the probability of causation ($PC$) has been developed to answer the question: if a person has been exposed to ionizing radiation and subsequently develops a cancer, what is the probability that the cancer was due to the earlier exposure? The US National Institutes of Health42 used data on the Japanese atomic bomb survivors to compile tables on the probability of causation relating an individual’s cancer to a prior radiation dose. This topic has also been reviewed by the International Atomic Energy Agency (IAEA).43 In essence, the probability that a radiation dose to an organ of a person’s body leads to the subsequent development of cancer can generally be calculated as:

$$PC = \frac{ERR}{1 + ERR}$$

where $ERR$ is the excess relative risk associated with the exposure, i.e. $ERR$ is the relative increase in risk, with the value 1 subtracted. For example, an $ERR$ of 1 represents a doubling of the risk, relative to that in the absence of exposure. This gives a probability of causation of $PC = 1/(1 + 1) = 0.5$

i.e. a 50 per cent chance that the cancer was induced by radiation. The $ERR$ can depend on a number of factors. Among them, the size of the radiation dose is very important. Generally, the $ERR$ varies in direct proportion to the dose, although in some circumstances the trend in risk with dose is more complex. For example, data on the Japanese survivors indicate that the risk of leukaemia varies not as a simple linear function of dose, but according to both linear and quadratic functions of dose. As well as dose, $ERR$ can be affected by factors such as sex, the age at which the exposure occurred, and the time between exposure and the development of the disease. For example, for leukaemia and for many solid cancers, data from the Japanese survivors and other studies indicate that the $ERR$ is greater for exposure in childhood than in adulthood. Also, the $ERR$ for leukaemia tends to be higher soon after exposure than at later times whereas – at least for exposures in adulthood – the $ERR$ of solid cancers is fairly stable over time. The degree to which the dose was protracted may also need to be taken in calculating the $ERR$, since various animal studies have suggested that, for a given total dose, radiation risks may be higher if received acutely rather than over a prolonged period.

For a given exposure scenario, i.e. the size of the dose, the sex of the person exposed, the age of exposure, the time between exposure and the onset of disease, the degree of dose protraction, it is therefore possible using models such as those developed by the US BEIR VII Committee39 to derive an estimate of the $ERR$. This can then be used, via the approach described above to estimate the $PC$. However, in instances where the dose is not known or where there are differing views about its magnitude, the calculation can be reversed to obtain the dose required to produce a given value for $PC$. For example, it was explained earlier than a 50 per cent probability of causation (i.e. a $PC$ of 0.5) corresponds to an $ERR$ of 1. For a given person and a likely time of exposure, it is then possible using a standard risk model to derive an estimate of the dose required to give such an $ERR$. This approach could be used to calculate the doses required to attain various values for the $PC$ in individual employees who have cancer.

In the United Kingdom, the nuclear industry has set up a no-fault compensation scheme based on $PC$ calculations, to avoid unnecessary litigation and allow the current scientific risk factors to be used in a generous manner for those claiming a radiation-induced cancer.

Hereditary effects

The other main late effect of radiation is the concept of hereditary damage and arises through irradiation of the
germ cells. Ionizing radiation induces mutations which are frequently harmful in the germ cells or their precursors. The hereditary diseases that mutations may cause range from afflictions, such as colour blindness or minor disorders of metabolism (e.g. disorders of amino acid metabolism) to serious defects which may cause early death or severe mental retardation (e.g. Down’s syndrome).

The study of genetic or hereditary effects caused by radiation is even more difficult than the study of cancer. However, no conclusive evidence for hereditary effects attributable to exposure to radiation has been found in human offspring. Genetic and cytogenetic studies of the progeny born to the atomic bomb survivors in Japan have so far yielded no evidence of a statistically significant increase in severe hereditary defects. Extensive studies made on experimental animals provide some information of the frequency with which genetic effects, including chromosome aberrations (numerical or structural) and mutations of genes (dominant and recessive), can be expected to occur. The research so far suggests that the doubling dose for all genetic effects is around 1–1.5 Gy. ICRP estimates that for exposures at low dose rates, the radiation detriment due to hereditary effects is a few per cent of the corresponding detriment for cancer.

Follow up of the atomic bomb survivors and their offspring has not yielded evidence for a statistically significant excess of malignancy in those children conceived after exposure; a study in the UK suggested a link between paternal occupational exposure to radiation at the Sellafield nuclear reprocessing plant (West Cumbria, UK) and the incidence of leukaemia in the offspring. However, this finding has generally not been confirmed in other studies and the UK Committee on the Medical Aspects of Radiation in the Environment (COMARE) has concluded that those excesses that have been reported may be associated with lifestyle factors, work practices or population mixing.

**BIOLOGICAL BASIS FOR RADIATION EFFECTS**

It is generally accepted that for carcinogenesis, the cellular DNA of the genome is the critical molecule. Damage to this molecule leading to cancer can be mediated through direct ionization by the radiation or by its indirect action in the formation of free radicals in the fluid in close proximity to the genome. This indirect effect accounts for about two-thirds of the biological effect in the case of low LET radiation, but the direct effect predominates with high LET radiation. Evidence is building that there are fragile sites unusually prone to breakage and rearrangement in DNA, which could explain particular sensitivities.

In some medical conditions, such as ataxia telangiectasia and Li-Fraumeni syndrome, there exist genetic defects in cell repair mechanisms which produce an increase in individual sensitivity to ionizing radiation. At high doses, cell death will predominate leading to organ malfunction, whose severity is dependent on the dose.

**FACTORS INFLUENCING RADIOSENSITIVITY AND MODIFICATION OF EFFECTS OF EXPOSURE**

Susceptibility to the carcinogenic effects of radiation is summarized in BEIR VII, and can be affected by a number of factors, such as genetic constitution, sex, age, physiological state, smoking habits, drugs and various other physical and chemical agents. The genetic basis of some diseases including increased cancer susceptibility is becoming clearer. For example, it has been shown that the full expression of ataxia telangiectasia, including enhanced cancer susceptibility, results from homozgyous mutated genes on chromosome. In addition, the heterozygous carriers, who do not express the full-blown disease, are known to be subject to a higher cancer incidence, especially for breast cancer. This mutation is thought to act through inactivation of repair mechanisms. The mechanisms through which these factors influence the radiosensitivity are, however, not fully understood. They depend on the particular type of cancer, the tissue at risk and the specific modifying factor under consideration.

Cancer rates are highly age dependent and, in general, increase exponentially in older age groups. The expression of radiogenic cancers varies with age in a similar way, so that the age-dependent increase in the excess risk of radiogenic cancer is conventionally expressed in terms of relative risk; that is, the increased risk tends to be proportional to the baseline risk in the same age interval. However, in some cases such as breast cancer, the change in the baseline cancer rate with age is more complicated. For lung cancer, the situation is also not simple. Smoking and prolonged exposure to inhaled α-particle emitters interact synergistically and this is then said to be a multiplicative effect.

For lung cancer and most other non-sex-specific solid cancers, it is unclear how a person’s sex affects the risk of radiogenic cancer. In general, baseline rates for such cancer in males exceed those in females, possibly because of increased exposure to carcinogens and promoters in occupational activities and lifestyle factors, such as increased smoking and consumption of alcohol. While sex-specific excess rates of cancer can generally be modelled adequately as being proportional to the corresponding sex-specific baseline rates, in many cases an additive excess risk model fits the data equally, that is, the number of radiogenic cancer per unit dose is nearly the same in both sexes.

For example, as it is known, the carcinogenic process includes the successive stages of initiation, promotion and progression. The promotion phase, appears to be particularly sensitive to cigarette smoking.

**SOURCES AND MAGNITUDES OF HUMAN EXPOSURE**

**Cosmic radiation**

Cosmic rays come mainly from our galaxy and some come from outside it. In addition, they may arise from the sun in bursts during solar flares. The numbers of cosmic rays
entering the earth’s atmosphere are also affected by the earth’s magnetic field: more enter near the poles than at the equator. As they penetrate the atmosphere, they are gradually absorbed, so that the dose decreases as altitude decreases. The average annual dose from cosmic rays at ground level in the UK is about 0.3 mSv. The intensity of cosmic rays for a typical flying altitude is greater than on the ground and also varies with latitude.

**Gamma rays from the earth**

All materials in the earth’s crust are radioactive. For example, uranium is dispersed throughout the soil and rock at various low concentrations around a few parts per million (ppm). Potassium-40 constitutes 120 ppm of the stable element, which in turn makes up 2.4 per cent by weight of the earth’s crust. The $\gamma$-rays are emitted by the radionuclides in the earth and since building materials are extracted from the earth, they too are radioactive, and people are irradiated indoors as well as outdoors. Doses are affected by the geology of the area and the structure of the buildings, but the average dose from earth $\gamma$-rays in the United Kingdom is about 0.35 mSv in a year.

**Radon**

The average annual effective dose in the UK from radon decay products is estimated to be 1.3 mSv. There are pronounced variations about this mean, and in some dwellings the dose to the occupants was found to be more than two orders of magnitude higher (range 0.1–500 mSv). The indoor radon levels depend on the geology of the area and also building structures. Poorly ventilated properties or workplaces, e.g. mines, have higher levels (see Chapter 36, Uranium, p. 243). Radon-affected areas have been identified in Cornwall, Devon, Derbyshire, Northamptonshire and Somerset and in parts of Scotland and Northern Ireland. The UK action level for radon in homes is 200 Bq/m$^3$. A lifetime exposure in dwellings at this level would lead to a 50 per cent increase in fatal lung cancer. Among smokers and non-smokers combined, about 6 per cent of deaths in the UK are due to lung cancer. A lifetime exposure at the UK action level of 200 Bq/m$^3$ would increase the risk of fatal lung cancer from 6 to 9 per cent. Many other parts of the world have higher radon levels (e.g. Finland and Germany). A number of large pooled studies of residential radon exposure have validated the risk of residential radon.52–54

Activity in diet

Other radionuclides from the uranium and thorium series are present in air, food and water, in particular lead-210 and polonium-210 which irradiate the body internally. Potassium-40 is taken into the body in the diet and is the major source of internal irradiation apart from radon decay products. A number of radionuclides, such as carbon-14, are created in the atmosphere by cosmic rays, and these also contribute to internal irradiation. The average annual dose from these sources of internal radiation in the UK is estimated to be 0.25 mSv in a year.

**Total doses**

The total dose from radiation of natural origin is, on average, about 2.2 mSv in a year in the UK. Differences in average doses from one locality to another may exceed 10 mSv in a year, and differences in individual doses may exceed 100 mSv in a year owing to the existence of dwellings with particularly high concentrations of radon.

**Occupational exposures**

Radiation is used in electricity generation (nuclear power), general industry (primarily for process and quality control), and for diagnostic purposes in medicine, dentistry and veterinary practice. Furthermore, it is used as a research tool in colleges, universities and industry. All these processes result in occupational exposures to ionizing radiations and in the first years of the twenty-first century, the total numbers of people working with ionizing radiations in the UK was about 34,000 in the nuclear power industry, and about 115,000 in general industry, health, defence and research. Some employees receive increased exposure to natural sources of radiation, the most notable being underground miners to radon and aircrew exposed to elevated levels of cosmic rays. About 96,000 employees are exposed to elevated levels of natural radiation.

**Occupational doses**

Legal controls (see under Legislation, p. 634) require that the doses received by the more exposed employees are routinely assessed and records kept of their doses. These employees are often referred to as ‘classified’ persons. A significant proportion of the non-classified employees are also monitored, but the records for this group, who generally receive low doses anyway, are less comprehensive. Approximately every four years, the Radiation Protection Division of the Health Protection Agency, UK (formerly the National Radiological Protection Board) conducts a major review of the radiation exposure of the UK population, which along with public and medical exposure routes, also provides comprehensive data on all occupational exposure. The last such review was published in 2005 and related to data from 2001–2003.55 It is these data that are primarily quoted below.

In the period, no nuclear power industry workers received annual doses in excess of the dose limit of 20 mSv in a year. Most employees, however, received doses that are a relatively small fraction of the limit. The average dose in the nuclear power industry was 0.4 mSv and the collective dose was 14.6 person-Sv. The measure of the collective dose allows the employer and the regulators to assess whether the total dose for a site has remained static or been reduced and acts as a method of assessing the amount of sharing of dose. Doses had decreased significantly from the previous survey. The averages and collective doses are around a third of that in the 1990s.

The equipment used in general industry is normally well shielded and doses to employees are generally very low. One major exception had been where radiographers
in the construction and engineering industries are required to carry out their radiography *in situ* and appreciable doses, sometimes in excess of the limit, were received. Improvements in techniques and vigilance are being instituted to reduce these high doses. The average dose in industry as a whole was 0.4 mSv, but encouragingly that for industrial radiographers was the same. However, 0.67 per cent of radiographers were over 6 mSv and 0.04 per cent over 15 mSv. The doses to those who work in medicine, dentistry and veterinary practices are generally low. In many cases, monitoring is conducted more for the reassurance of staff than to fulfill statutory requirements. To establish exposures, a sample of 26 000 workers in the group were surveyed. Ninety-eight per cent had doses under 1 mSv and only 1.9 per cent over 6 mSv. The overall average was 0.14 mSv, slightly higher than previously, probably due to the increased use of interventional radiography – mainly due to increased exposures to radiologists.

In round terms, about 96 000 people in the UK are routinely monitored for occupational exposure to artificial sources of radiation. Their dose was 2.7 mSv on average in the latest survey. However, the figure disguises a wide range of exposures.

**Occupational doses from natural radiation sources**

The average annual dose to crew members of supersonic aircraft is currently estimated to be about 2.4 mSv. Higher dose rates were experienced by the crews of Concorde (now out of service) with the result that the annual doses were somewhat higher at ~3 mSv, at the hours typically flown. The introduction to service of long-range aircraft has increased the potential for higher doses for supersonic flight crews, with the possibility of doses up to 5–6 mSv per year for some personnel. However, when ICRP reviewed the most recent scientific information it came to the conclusion that the weighting factor for protons was too high and reduced this from 5 to 2. This would have the effect of reducing doses by around 50 per cent, in most aviation circumstances. In round terms, about 96 000 people in the UK are routinely monitored for occupational exposure to artificial sources of radiation. Their dose was 2.7 mSv on average in the latest survey. However, the figure disguises a wide range of exposures.

**MEDICAL EXPOSURES**

On average, individual doses to medical personnel are of the order of 1 mSv/year with values usually somewhat higher for radiologists and those involved in interventional radiological procedures. In nuclear medicine, there is a need for protection against ingestion or inhalation during the production, analysis and administration of radiopharmaceutical preparations. In some cases, there can also be external exposure, as with technetium-99 m, which can deliver substantial doses at very high dose rates to the hands of the operator if no protection is provided. The average doses here are around 1.6 mSv per individual per year. Female nuclear medical technicians who are pregnant may be exposed above the special recommended dose limits if they continue their work for the duration of their pregnancy (see under Reassurance, p. 635).

Overall, workers in the UK had a collective exposure of 385 manSv, 3.8 per cent in the nuclear industry, 0.6 per cent in defence, 0.8 per cent in general industry, 2.7 per cent in health, 21 per cent in aviation, 0.01 per cent in mining and 70 per cent from radon in other places.

**RADIATION PROTECTION**

The main principles of radiation protection are set out and promulgated by the ICRP in Publication 103. They can be summarized as follows:

1. No practice involving exposure to radiation should be adopted unless it produces at least sufficient benefit to the exposed individuals or to society to offset the radiation detriment it causes (termed ‘justification of a practice’).
2. In relation to any particular source of radiation within a practice, all reasonable steps should be taken to adjust the protection so as to maximize the net benefit, economic and social factors being taken into account (termed ‘optimization of protection’).
3. Finally, a limit should be applied to the dose (other than from medical exposures) received by any individual as the result of all the practices to which he is exposed (termed ‘application of individual dose limits’).

In simple terms, this framework is derived from three principles that apply to many human activities, and especially to medicine:

- The justification of a practice implies doing more good than harm.
- The optimization of protection implies maximizing the margin of good over harm.
- The use of dose limits implies an adequate standard of protection even for the most highly exposed individuals.

These three principles overall avoid the possibility of deterministic effects and minimize the risk of stochastic effects in normal operations.
Protection against external irradiation

The general principles deployed in the workplace to keep external doses as low as reasonably practicable are to keep exposures as short as possible, keep as far away from the source as possible and wherever possible place shielding between the source and the employee. This simple concept of time, distance and shielding is practised routinely in all clinical radiography departments with screens, lead aprons and special rooms for exposures.

Protection against external contamination

The use of protective clothing prevents contamination of the skin; however, loose contamination on such clothing will still irradiate the skin and so exposure times need to be strictly limited. Containment of contamination is essential wherever possible to prevent activities producing an inhalation hazard.

Protection against internal irradiation

The use of containment, such as with fume cupboards or glove boxes, is effective and is used at a level appropriate to the level of hazard. Work with α-emitting radionuclides presents a major hazard and these facilities require special detection systems for leaks to reduce the possibility of either inhalation or contamination of wounds.

LEGISLATION

In the UK, the use of ionizing radiations at work is governed by the Ionizing Radiations Regulations 1999 (IRR99). The legislation was enacted in the UK to implement the EU Council Directive 96/29/Euratom. The Directive and the regulations incorporate the guiding principles of the ICRP and the dose recommendations in its Publication No. 60. Employees who are occupationally exposed to radiation and who are likely to receive 6 mSv in any one year are known as ‘classified persons’. Those who are occasionally exposed to radiation by virtue of their employment and at levels below 6 mSv are known as ‘non-classified persons’. The third category is the general public and the dose limitation placed upon this category takes into consideration radiation doses from natural background. Table 53.5 shows the annual dose limits in mSv for the foregoing three categories.

The regulations require exposures to be limited to no more than 100 mSv in any consecutive period of five years, i.e. effectively 20 mSv per year, and with a maximum in any single year of 50 mSv. This will equate to an annual risk of early death from radiation exposure at work of around $10^{-3}$ per annum. The dose limits take account of increased knowledge of the radiation risk factors and the present acceptability of risk for occupational exposures.

An investigation level has been set at 15 mSv whole body dose for any classified person and, if exceeded, a local investigation is undertaken to establish whether all steps are being taken to keep radiation exposures as low as reasonably practicable (ALARP).

$^2$The dose limit in any three-month interval for female employees of reproductive capacity is 13 mSv to the abdomen, concurrent with a whole body dose limit of 20 mSv. Once a female employee has declared pregnancy, the employer must ensure the dose to the fetus is unlikely to exceed 1 mSv in the rest of the pregnancy. This is practically interpreted as an external dose limit of 2 mSv to the abdomen over the declared term of pregnancy.

MEDICAL ASPECTS

Classified persons are required to have health surveillance conducted by a doctor formally appointed by the Health and Safety Executive (HSE) under the IRR99. In large organizations, this occupational health cover may include one or more occupational physicians, health physicists, occupational nurses, occupational hygienists and safety specialists, and the workers themselves. The routine health surveillance of people occupationally exposed to ionizing radiations is no different from that for other groups exposed to other hazards. However, the physician will require special training, especially where radioactive contamination is anticipated.

It is emphasized that the statutory dose limits are set at levels well below those at which deterministic effects will occur and so no changes will be detectable by clinical examination, routine blood examination or special examinations, such as cytogenetic studies. For this reason, routine medical examinations and investigations are not necessary. However, routine biological investigations, such as urine analyses, are sometimes performed for reassurance purposes.

HEALTH SURVEILLANCE

Employees should be medically examined prior to employment, and thereafter their medical fitness should be reviewed at periodic intervals (normally annually). The primary purpose of this medical surveillance is to assess the initial and continuing fitness of employees for their intended tasks. The nature of the periodic reviews will depend on the type of work that is undertaken. The frequency of examinations should normally be comparable with that of any other occupational health surveillance.
programme. Three situations may arise where special surveillance may be required:

1. Fitness for wearing respiratory protection devices;
2. Fitness for handling unsealed sources in the case of employees with skin diseases or skin damage;
3. Fitness of employees with psychiatric or psychological disorders.

Employees who wear respiratory protective equipment in the course of their radiation work, for example, inside contaminated confined spaces, need to be checked periodically to verify their lung function. Employees with skin diseases, such as psoriasis, may need to be excluded from work with unsealed radioactive materials, unless the levels of activity are low and appropriate precautions are taken, such as covering the affected parts of the body. However, there may be a need for periodic medical checks to ensure that unprotected areas have not become affected by the skin disease. In employees with psychiatric or psychological disorders, the primary concern is whether the employees could pose a danger to themselves or their colleagues, particularly in high radiation dose-rate areas and the handling of unsealed and portable sources.

There is no particular reason why employees who have previously been treated for malignant disease should be excluded from work with radiation if they are otherwise fit for the job. Any additional risk of radiation-related disease caused by future occupational exposure is likely to be small in comparison with the risks from the treatment with surgery, chemotherapeutic agents and/or radiotherapy. However, it may be necessary to restrict their employment in emergency teams where high doses in accident situations might be permissible, and essential when saving life.

Reassurance

Two types of employees may need special reassurance by the physician, sometimes supported by other medical specialists. These are:

- women who are, or may become pregnant;
- individual employees who have been or may have been exposed substantially in excess of the dose limits.

Once the physician or the management has been informed that a woman believes she is pregnant, arrangements may need to be made to change her conditions of work. The physician is often the best person to advise management on the need for any particular precautions or procedures to be adopted regarding the working conditions of pregnant women. The physician should also be able to inform the pregnant woman of the risks to her conceptus associated with her work and, in particular, reassure her on all the health issues. Pregnancy does not require a ban from working in designated areas or on handling radioactive sources, but does imply restriction where there is the potential for high-dose exposures. Separate dose limits apply to pregnant women.

In the case of accidental exposure or overexposure, the physician needs to liaise with the management and other safety specialists to ensure that all suitable arrangements for evaluating the scale of the exposure are undertaken. The medical aspects of the management of overexposed employees is dealt with below.

MEDICAL MANAGEMENT OF ACCIDENTALLY EXPOSED EMPLOYEES

As soon as an unexpected exposure is suspected, management should undertake an investigation to determine the dose to the employee. If a dose is established, an injury is sustained, or contamination occurs, then the appointed doctor or occupational health service should be informed.

External exposures

The majority of unexpected exposures are determined to be false alarms, such as the improper use of a dosemeter, and no further action is required. However, once the dose is deemed to have been received, the appointed doctor or occupational health service must be informed. The investigation should include the dose estimates from all types of available dosimetry. It is convenient to divide exposures into three categories of increasing doses.

Doses close to the dose limits

normally, such doses do not require any special clinical investigations or therapy. The role of the occupational health personnel is to counsel the overexposed employee that the exposure is unlikely to produce adverse health effects.

Doses well above the dose limits

Where the exposure is significantly higher, but below the threshold for deterministic effects, the prime role of the occupational physician is to advise the employee of the risks. Then they need to determine whether biological dose indicators, such as lymphocyte counts and chromosome aberration assays, are needed to confirm the dose estimates. Normally, no further action is required other than counselling.

Doses at or above the threshold for deterministic effects

If the assessed external doses are around the threshold for deterministic effects, therapeutic action may need to be undertaken. In order to make this decision, the overexposed employee needs to be examined clinically and any abnormal findings or symptoms recorded. Haematological examination will need to be undertaken in order to monitor the clinical course of the overexposure. If the exposure is severe enough to lead to the acute radiation syndrome, early transfer to a designated hospital is essential.
The occupational physician should institute the initial investigations and treatment of the early symptoms. Immediate life-threatening injuries, such as fractures and burns, must be treated as a priority before transfer to a hospital.

The clinical management of such highly exposed individuals is dealt with below.

**Internal exposures**

Where the exposure is internal in origin (internal contamination), the employee should be removed temporarily from the workplace to prevent any further exposure, even when the dose is expected to be close to, but below, the dose limit. This action will allow more accurate dose estimates from sequential counting either of the body, an organ or body fluids.

High exposures may warrant interventional therapy to accelerate the excretion of radionuclides. Such therapeutic measures might include the administration of chelating agents to enhance the excretion of transuranic radionuclides, as for example in lead poisoning, forced diuresis for high doses from tritium intakes and pulmonary lavage for some inhaled plutonium compounds. For plutonium internal contamination intravenous administration of diethylene triamine pentaacetic acid (DTPA) will enhance excretion by chelation. Incidents involving radionuclides, such as plutonium, can only occur in specialist industries and they usually hold supplies of DTPA.

Medical procedures are not without risk and should only be undertaken when the expected benefit from saving the future dose from the incorporated radionuclide (committed dose) outweighs the risk of the intervention. Many of these therapeutic procedures would be undertaken only at a major hospital, for example lung lavage for a large inhalation of plutonium.

The occupational physician should be prepared to administer the first dose of chelating agents (such as DTPA for transuranic radionuclides) or give stable iodine (see under Additional aspects of treatment of internally contaminated casualties, p. 638) for radio-iodine uptake.

**External contamination**

Where an employee has been externally contaminated, decontamination, by simple washing, should be undertaken as quickly as possible. Significant skin contamination with β-emitting radionuclides can result in radiation burns if not treated quickly. It should be remembered that thermal burns could complicate skin decontamination and both may need to be treated simultaneously. The only justification for delay would be the immediate treatment of life-threatening physical injuries.

It is emphasized that a contaminated casualty will not represent a hazard to the physician or attending staff wearing standard medical dress, such as a gown, gloves and simple face mask.

Some radionuclides may be absorbed through the skin depending on their chemical form, and can lead to internal contamination. This is particularly true where skin contamination occurs with tritiated water and with some compounds of iodine and caesium.

**Return to radiation work**

Exposures which do not approach deterministic levels need not affect an employee’s fitness for further radiation work. An employee should be advised by the physician on the level of the increased risk for stochastic effects. Where their own actions contributed to an overexposure, consideration should be given by management to retraining before return to work. Return to work after internal contamination may be delayed until an adequate dose assessment has been made.

Where there is partial body overexposure which produces deterministic effects, for example, in industrial radiography where the source is handled producing skin and deep tissue hand damage, the employee should be advised on the future risks involved not only in radiation work (e.g. the stochastic risks), but also on future manual work involving exposure to cold and other physical agents, such as chemicals.

**Medical records of overexposures**

The medical record should be as complete as possible. It should contain details of all examinations, treatment and advice. It will also require copies of any dose reconstruction or assessment performed by health physics staff.

**MEDICAL ASPECTS OF A MAJOR RADIATION ACCIDENT**

The overall medical role will involve those responsible for the management and treatment of casualties, the provision of public health information, advice on the health hazards of ionizing radiation and the application of any public health countermeasures.

**Treatment of casualties**

It is likely that most non-essential personnel would be evacuated from a nuclear site as soon as an emergency was declared and before any serious release or irradiations could occur and so an accident, for example to a nuclear reactor, should not result in many casualties. At the Chernobyl accident, however, there was no warning and there were many casualties. Casualties can be considered under three headings.

**Conventional injury**

These could arise from events, such as fires or steam leaks, or follow incidents and panic.

**External irradiation**

Personnel bringing the plant under control or attempting to save life, and injured individuals immobilized close to the reactor or plant, could receive significant doses of whole body external radiation.
Health surveillance

Contamination

Personnel exposed, either within the plant or in the open, to a radioactive cloud would become externally contaminated. In addition, the radioactive cloud, which could comprise fission products or actinides, could be swallowed and, without respiratory protection, inhaled with resultant internal contamination.

Radiation accident casualties, no matter what level their contamination, will not present a significant hazard to appropriately trained and equipped medical teams. Assessment of radiation exposure and contamination levels or actual decontamination procedures must never take precedence over life-saving medical procedures.

Externally irradiated casualties

Following a nuclear accident, individuals suspected of being exposed to high doses of external penetrating radiation should be managed according to Table 53.6.

HLA, human leukocyte antigen.

Internal exposure to contamination

Once in the body, the hazards depend on (1) the elements concerned, for example iodine to thyroid, radium and strontium to bone; (2) the chemical form, for example tritiated water absorbed more rapidly than tritium gas;

CONTAMINATED CASUALTIES

External exposure to contamination

Patients exposed to high levels of contamination may suffer the effects of skin irradiation from the β- and γ-emitting isotopes. This was a significant problem at Chernobyl mainly in those who were watch keepers on duty and in the emergency personnel (fire-fighters). Skin lesions were also a serious problem in people contaminated by caesium in Goiânia, Brazil. Overall medical management requirements for contaminated casualties are shown in Table 53.7.

Internal exposure to contamination

Once in the body, the hazards depend on (1) the elements concerned, for example iodine to thyroid, radium and strontium to bone; (2) the chemical form, for example tritiated water absorbed more rapidly than tritium gas;
Ionizing radiations

(3) the solubility, generally soluble substances are more hazardous than insoluble ones. Alpha emitters are the most hazardous isotopes when incorporated. Particle size is important in inhalation, smaller particles penetrating deeper into the lungs than larger ones and overall the stay time in body (effective half-life) which is determined by a combination of the radioactive decay or half-life \( t_{1/2} \) (physical) and the biological half-life \( t_{1/2} \) (biol):

\[
\text{Formula: } t_{1/2}^{\text{effective}} + \frac{t_{1/2}^{\text{biol}} \times t_{1/2}^{\text{physical}}}{t_{1/2}^{\text{biol}} + t_{1/2}^{\text{physical}}}
\]

The overall management aspects of treating internally contaminated patients are shown in Table 53.8. Examples for accelerating the decporporation of some isotopes in internally contaminated patients are shown in Table 53.9.

ADDITIONAL ASPECTS OF TREATMENT OF INTERNALLY CONTAMINATED CASUALTIES

Once radionuclides have been incorporated, the treatment principles are to reduce absorption and deposition in critical organs (e.g. thyroid for iodine and bone for plutonium) and enhance excretion. Administration of stable iodine, which is normally in the form of potassium iodate tablets, may block significant uptake of radio-iodine in the thyroid gland, but late administration does not enhance excretion. The normal dose of potassium iodate for an adult is 200 mg orally, but the blocking efficacy depends on early administration (ideally when an accident is threatened and before a release occurs) with approximately 50 per cent effectiveness if administered six hours after the exposure.59,60

**KEY FACTORS FOR HOSPITAL STAFF AND FACILITIES**

Protection of medical staff

All paramedical and medical staff involved in the handling and treatment of contaminated patients should wear simple protective clothing consisting of overalls, surgical rubber gloves, boots or overshoes (operating theatre dress) and a face mask or respirator. A simple gown and mask would be adequate if other clothing was not available.

Designated treatment areas

Treatment areas should be clearly demarcated from adjacent clean areas and have adequate space to allow an initial triage and resuscitation and then space for decontamination and treatment. Wherever possible, only decontaminated casualties should be allowed into the clean areas of the hospital. Monitoring of patients for radioactive contamination should take place at a suitable barrier between clean and dirty areas.

Areas designated to receive contaminated casualties must have an adequate water supply for decontamination and consideration should be given to control of ventilation systems to prevent spread of contamination.

BASIC PLAN FOR THE HANDLING OF CASUALTIES FOLLOWING A NUCLEAR REACTOR ACCIDENT

Reception centre

The plant operators and other personnel within the immediate vicinity will normally evacuate to a designated reception centre taking their casualties with them where possible.
in accordance with their detailed plans. These plans are usually required by the national legislation, such as the Ionizing Radiations Regulations in the UK\textsuperscript{56} or recommended by the International Atomic Energy Agency. The initial medical triage should be undertaken by the most experienced medical staff member available, which could be a first-aider. This triage should identify any personnel requiring immediate despatch to a hospital without any radiation or contamination assessment.

### Hospitals

Local plans to deal with accidents should include a designated hospital where radiation or contamination casualties should be taken. Where possible, these should be National Health Service providing assistance within the National Arrangements for Incidents involving Radioactivity (NAIR). This applies to Great Britain (England, Scotland and Wales) only. If the hospital designated to receive the radiation and contamination casualties is not the nearest accident and emergency unit, the local plan should also include the use of that unit to receive uncontaminated casualties. While the plan should include the transfer of radiation and contamination casualties to the specialized hospitals, it must also include instructions to direct casualties requiring immediate life-saving treatment to the nearest unit whatever the patient’s radiation exposure status.

### CLINICAL TREATMENT OF RADIATION INJURIES

Periodically, consensus treatment conferences on the treatment of radiation injuries have been held.\textsuperscript{61} At the last held in Geneva in 2009,\textsuperscript{62} it was agreed that four main medical factors determined the treatment, which interlink: sepsis, marrow aplasia, gastrointestinal injury and cutaneous injury. The consensus publication has an excellent summary for the treatment of radiation casualties. If conventional injuries are present, then the patient is deemed to have a combined injury and the prognosis is worse. The World Health Organization (WHO) has set up a worldwide Radiation Emergency Medical Preparedness Assistance Network (REMPAN). Physicians who need advice or assistance should contact WHO at Geneva, who can then suggest suitable therapies and arrange for the nearest REMPAN Centre to give direct advice.

### CLINICAL CARE OF RADIATION CASUALTIES

#### General

- Experience from many accidents has shown that the heterogeneous nature of the exposures tends to confound both the clinical and pathological picture, so that estimating the scale of the radiation damage and exposure is difficult.
- The early treatment of conventional injuries is the main factor that determines survival in patients who have been accidentally irradiated.

- Casualties on admission can be classified into four treatment categories: mild, moderate, severe and lethal.
- Stating specific dose ranges for these categories is not possible, primarily because of the difficulty in converting an exposure to a meaningful tissue dose; however, equivalent whole body dose ranges would be $<2$, $2–5$, $5–10$ and $>10$ Gy, respectively.
- The most reliable prognostic guides for treatment in the early stage are the change in absolute lymphocyte counts and cytogenetics, levels of blood cells, which will give a good estimate of dose.
- The degree of radiation-induced marrow aplasia (reversible or irreversible) may not be known for days because of the uncontrolled nature of the exposure and the likelihood that it was non-uniform and heterogeneous.
- Assessment of the dose, while important, is secondary to the treatment.
- Reliable triage and good clinical care based on comprehensive biological data will ensure the best chance of recovery, provided some critical stem cells survive the radiation exposure (see Table 53.10).
- Professional help may be necessary to treat psychological problems accompanying radiation accidents.

### Sepsis

- The suppression of bone marrow activity will reduce the resistance to bacterial and viral infections.
- For febrile neutropenic casualties blood, urine and faecal samples for cultures need to be taken on admission.
- Patients need to be started on broad-spectrum antimicrobials and these should be given until the patient is afebrile.
- Experience has shown that fungal lung infections can be the cause of late deaths, when all the other radiation effects have been stabilized.
- Early use of antifungal agents and gamma globulin for viral infections is essential.

### Marrow aplasia

- Following a suspected high radiation exposure, initial patient assessment should be based on dosimetric testing (biological, physical), daily full blood counts, viral titres (e.g. cytomegalovirus, human immunodeficiency virus), human leukocyte antigen subtyping for possible bone marrow transplantation and the administration of haematopoietic growth factors (colony-stimulating factors, such as G or GM-CSF) (see Table 53.10).
- Particular care is needed if the patient has other injuries, such as pulmonary infections, burns or smoke inhalation.
- Subsequent supportive therapy might include platelet transfusions particularly if surgery is indicated for other injuries. Other treatments might include the use of thrombopoietic drugs.
- Bone marrow transplants should only be given if an autologous donor is available.
Gastrointestinal
- Vomiting should be controlled by use of effective anti-emetics, e.g. ondansetron. This relaxes the gut and reduces mechanical damage of lining of the small intestine. Anti-emetics also help to reduce fluid loss.
- Diarrhoea should be treated with fluids and electrolytes and efforts should be made to improve host defences by appropriate nutritional support.

Cutaneous
- Remove all clothing as soon as possible, bathe very gently in lukewarm water, use acetic acid or ion exchangers if surface contamination is thought to be soluble caesium, and only remove contamination mechanically from soles of feet or palms of hands.
- Later treatments might include use of topical creams, systemic acitretin and $\gamma$-interferon. These have been found to be helpful in treating the chronic skin damage seen in the Chernobyl firemen.

Combined injury
- Radiation injury is not immediately life-threatening and initial care should address the associated conventional injuries, for example, thermal burns and wounds.
- After stabilization, radioisotope decontamination should be performed before emergency surgery, definitive care and treatment of radiation injuries.
- Collection of biological samples during the resuscitation stages will supplement the initial data collected during triage.
- Ideally, definitive care should immediately follow resuscitation.
- Management of soft tissue wounds requires alternative ways to close wounds, for example, biological wound coverings and skin grafts.
- Surgical correction of life-threatening and other major injuries should be carried out as soon as possible (within 36–48 hours); elective procedures should be postponed until late in the convalescent period (45–60 days) following haematopoietic recovery.
- Treatment of thermal burns should include early excision of potentially septic tissue and closure of the wounds, preferably by skin grafting.
- Radiation burns and thermal burns should be treated differently, especially when using surgery, which should be delayed in the case of radiation burns (see Table 53.7).

ACCIDENTS AND RADIATION RISK

In any radiation accident, the workforce would take countermeasures to protect themselves. This would involve sheltering or considering evacuation. Similar actions may be necessary for the public. Workers and public would also be advised not to eat open foodstuffs. National authorities usually set the dosimetric criteria for taking these actions based on ICRP recommendations in case of a nuclear power plant accident, where radio-iodines might be released and inhaled or ingested. Reducing doses to the thyroid can be effective by taking stable iodine tablets (see under Additional aspects of treatment of internally contaminated casualties, p. 638). Prophylactic iodine was issued to the workforce at Chernobyl and to most of the population in Poland immediately after that accident and no adverse side effects were reported. The failure to implement adequate early countermeasures against iodine contamination in the former Soviet Union in the immediate aftermath of the Chernobyl accident has resulted in over a 100-fold increase in the incidence of childhood thyroid cancer in the affected republics. The Chernobyl accident showed that accident contingency plans need to be exercised regularly and that the decontamination of casualties needs to be carried out as soon as possible.

Ionizing radiation is a highly emotive subject and a radiation accident can cause widespread concern in a workplace. Individual perceptions of risk, knowledge of medical effects of radiation and the best methods of communicating these effects to people is important. The former Chief Medical Officer at the Department of Health in the UK, has made some tentative proposals on the language of risk. Many facets of life affect perceptions, attitudes and behaviour. Changes in society also have affected attitudes and acceptability of different risks. Radiation risks from occupational exposures are low when compared with many other occupations or activities (Figure 53.1). Determining acceptable levels of risk is central to the process of setting occupational and public dose limits. However, if the degree of risk that society is prepared to accept changes, then the need for robust epidemiological and molecular biological studies to underpin the risk estimates and, inter alia, dose limits is emphasized.

Key points

- Natural radiation and radioactivity are all around us and humans have evolved in that environment.
- The man-made use of radiation in medicine and industry, and for nuclear power has shown that high doses are lethal and early (deterministic) effects are visible and can be life-shortening.
- Latent (stochastic) effects particularly cancer are well documented and risk estimates, based on the study of occupationally and medically exposed cohorts, are reasonably robust.
- Legislation to control radiation exposures at work by defining dose limits is based on these risk estimates.
- Occupational exposures below the dose limits will prevent deterministic effects and reduce the risk of stochastic effects to an acceptable level, although all doses should be kept as low as reasonably practicable.
- The acceptability of risk by the public may change.

FURTHER READING ON MEDICAL TREATMENT OF CASUALTIES

Non-ionizing radiation and the eye

MICHAEL E BOULTON AND DAVID H SLINEY

INTRODUCTION

Visual deterioration, whether through disease or excessive exposure to non-ionizing radiation (generally referred to as light damage), is often severely debilitating. Any reduction of normal vision which affects our everyday functions can place a considerable socioeconomic burden on the family and government agencies. Light damage, though less common in recent years due to improved protective measures and health and safety at work, can still result as a complication of occupation. Anyone believed to have suffered occupational light damage should be referred to a doctor for a medical opinion.

WHAT IS NON-IONIZING RADIATION?

The electromagnetic radiation spectrum has been divided into a number of frequency regions. The most useful divisions are between ionizing (x-rays, gamma (γ) rays and cosmic rays) and non-ionizing radiation (ultraviolet (UV) radiation, visible, infrared radiation, radiofrequency waves).1 The division between ionizing and non-ionizing radiation is generally considered to be at wavelengths around 1 nm in the far UV region. Non-ionizing radiation is that part of the electromagnetic spectrum which does not have sufficient energy to ionize matter, but can excite atoms by raising their outer electrons to higher orbitals, a process which may store energy, produce heat or cause chemical reactions (photochemistry). The wavelengths of non-ionizing radiation of major importance to the eye are grouped under the following headings:

- Ultraviolet: 100–400 nm (wavelength)
- Visible: 380–760 nm
- Infrared: 760 nm–1 mm
- Microwave: 1 mm–1 m

The natural, and major source, of these wavelengths is sunlight which has a broad emission ranging from far UV (200–280 nm) to far infrared (3000–10 000 nm). However, it should be noted that the eye is not normally exposed to the far UV component of the spectrum since this solar component is blocked by the atmosphere. In addition to sunlight, there is an ever-increasing amount of man-made candescent and incandescent sources which cover the full non-ionizing radiation spectrum. Details of the source and wavelength of non-ionizing radiation reaching the eye are given in Table 54.1.

BASIC PRINCIPLES OF VISION

Visual perception results from a series of optical and neural events; visible radiation arriving at the eye is focused by the cornea and lens creating a retinal image which is then converted by photoreceptors to nerve impulses which are conducted to the visual area of the cerebral cortex. The light pathway to the retina (consisting of cornea, aqueous, lens and vitreous) is almost completely transparent to all

Modified from Ref. 2.
wavelengths of visible light (although transmission characteristics do vary with age).\(^2\) In considering the basic principle of vision, we will briefly describe the anatomy of the eye and phototransduction. A more comprehensive review of these areas can be acquired from a variety of general texts.\(^3\)–\(^6\)

**Ocular anatomy**

The eyeball is situated in the anterior part of the orbital cavity, towards the roof and to the temporal side. The eyeball is not completely spherical being made up of the segments of two spheres; the anterior segment, the transparent cornea, occupies about one-sixth of the whole surface, while the opaque posterior segment, the sclera, occupies the remainder of the exterior surface. Anatomy textbooks classically consider the eye to consist of three layers: (1) the fibrous tunic (cornea and sclera), (2) the vascular or uveal tunic (choroid, ciliary body and iris) and (3) the retina (neural retina and retinal pigment epithelium) (Figure 54.1a). Within lie the internal media, aqueous humor, lens and vitreous. Since this chapter concentrates on ocular light damage, the following description of ophthalmic anatomy will concentrate on those tissues which lie on the optic axis.

Figure 54.1 (a) Cross-section of an eyeball. (b) Cross-section of the retina.
CORNEA

Microscopically, the cornea consists of five distinct layers:

1. the epithelium
2. Bowman's layer
3. the stroma
4. Descemet's membrane
5. the endothelium.

The corneal epithelium

The corneal epithelium which is located at the front of the eyeball and is protected by the tear film, is a non-keratinized stratified epithelium five to six cells deep.

Bowman's layer

Bowman's layer is an acellular basement membrane consisting of interwoven collagen fibres which is located immediately beneath the epithelium. The membrane is about 10 μm thick and forms a strong attachment site for the basal cells of the epithelium.

The stroma

The stroma forms about 90 per cent of the corneal thickness. This transparent, avascular structure consists of between 200 and 250 flattened lamellae with each lamella consisting of collagen fibres lying parallel to one another and embedded in a glycosaminoglycan matrix. The lamellae are arranged in a definite pattern with collagen fibres in alternate layers, often being at right angles to one another. Interspersed between the flattened lamellae are stromal fibroblasts (often referred to as ‘keratocytes’). The transparency of the cornea is dependent upon the thickness of the collagen fibres, their arrangement into parallel patterns and the constant separation between fibrils. Disease or trauma can cause the loss of the regular stromal structure culminating in corneal opacification.

Descemet's membrane

This is a thin elastic basement membrane (8–10 μm thick) located between the stroma and the corneal epithelium.

The corneal endothelium

The corneal endothelium is a monolayer of flattened polygonal endothelial cells whose major role is to control the normal hydration of the cornea.

The cornea is avascular, but is extensively innervated with nerve fibres derived from the ophthalmic division of the trigeminal nerve.

AQUEOUS

The aqueous is a colourless, transparent liquid whose composition includes protein, glucose, electrolytes and oxygen which is generated at the ciliary processes. The aqueous enters the anterior chamber via the pupil whence it supplies nutrients to the avascular cornea and lens and removes waste substances as it flows out of the anterior chamber into the canal of Schlemm.

LENS

The lens is a biconvex structure situated between the vitreous and the back of the iris. The lens is composed of three major parts:

1. an elastic capsule that envelopes the entire lens;
2. the lens epithelium which is a monolayer of cuboidal cells which are attached to the posterior surface of the anterior capsule;
3. the lens fibres which constitute the majority of the lens and are high in the protein crystallin which provides the focusing power of the lens.

Opacification of the lens, usually resulting from the degeneration of the lens fibres, is referred to as cataract. The lens is held in position by radially arranged suspensory ligaments, termed ‘zonules’, which connect the ciliary processes and the lens capsule.

VITREOUS

The vitreous is a colourless, transparent gel which occupies the majority of the posterior chamber. It consists of 99 per cent water, collagen fibrils, hyaluronan, soluble proteins and salts.

RETINA

The retina extends from the vitreous base towards the optic nerve covering the whole of the eye cup. It functions to capture an ocular light image and to transduce it into a pattern of electrical signals for processing into a visual image in the brain. The retina can be divided into two layers:

1. the neural retina
2. the retinal pigment epithelium.

The neural retina

The neural retina contains three zones of neurons, named in the order which they conduct impulses, the photoreceptor cells, the intermediate neurons and the ganglion cells (Figure 54.1b). The photoreceptor cells are located in the outer retina adjacent to the retinal pigment epithelium. Two types of photoreceptor are present, rods (specialized for vision in dim light and do not recognize colour) and cones (specialized for colour vision and visual acuity). The photoreceptors consist of an inner and outer segment and it is the outer segment, abutting the retinal pigment epithelium which contains the light-sensitive pigment rhodopsin. The inner segments project into the inner retina where they synapse with inner retinal neurons which in turn synapse with the retinal ganglion cells. The ganglion axons exit through the optic nerve head and send
nerve impulses to the visual cortex. In addition, the neural retina also contains supporting glial cells and the retinal vasculature.

The retinal pigment epithelium

The retinal pigment epithelium is a single layer of polarized hexano-cuboidal cells located beneath the neural retina and separated from the choroid by Bruch’s membrane (Figure 54.1b). These cells contain melanin (an absorber of stray light), form the outer blood retinal barrier (controlling the supply of nutrients to the photoreceptors) and maintain the integrity of photoreceptor outer segments by ingesting the spent tips of photoreceptor outer segments.

At the posterior pole of the eye, approximately 3 mm lateral to the optic disc, is a shallow depression in the retina which forms the centre of the macula. The macula is an oval yellowish area approximately 5.5 mm in diameter. The yellowish colouration of the macula is caused by the macular pigment which principally consists of the carotenoid xanthophyll. The fovea is a depression in the centre of the macula and is about 1.5 mm in diameter. The floor of this depression, about 0.35 mm in diameter, is called the ‘foveola’. The depressed area is formed by the nerve cells being displaced peripherally, leaving only densely packed photoreceptors in the centre. There are no blood vessels and no rod photoreceptor cells in the foveola, i.e. this is an all-cone region of the retina. The macula is anatomically adapted to permit light to have greater access to the photoreceptors than elsewhere in the retina and explains in part why this is the area of the most acute vision.

In addition to the ocular structures which lie on the optical axis, the eye is also made up of:

- the sclera – the outer, opaque, fibrous coat constituting the posterior 83 per cent of the outer surface of the eye;
- the iris – a contractile diaphragm which forms a central aperture, the pupil, which controls the amount of light entering the eye and impinging on the retina;
- the ciliary body – an annular portion of the uvea extending from the ora serrata to the root of the iris which provides the necessary muscular changes for accommodation and produces the aqueous fluid;
- the choroid – predominantly a vascular structure whose principal function is to nourish the retinal photoreceptors and pigment epithelium; this tissue contains melanocytes whose melanin granules absorb light and xenobiotics.

Phototransduction

Within picoseconds after an image is formed on the retina, photons are absorbed by the light-sensitive pigment rhodopsin, the chromophore is isomerized and the protein portion becomes activated. The photoexcitation of rhodopsin triggers a rapid chain of molecular events within the photoreceptor outer segments which results in the closure of ion channels such that the receptor potential takes the form of a hyperpolarization and a decrease in the rate of neurotransmitter release. The generator potentials produced by the photoreceptor cells induce signals in both bipolar neurons and horizontal cells which are transmitted as a partially processed excitatory visual signal to the ganglion cells. The ganglion cell axons connect via the optic nerve and optic chiasma to the visual areas located in the occipital lobes of the cerebral cortex.

BASIC MECHANISMS OF LIGHT DAMAGE IN TISSUES

While optical radiation is essential for visual perception it can also, given the appropriate conditions, produce tissue damage. Such damage, although generally considered detrimental to visual function, can be of considerable therapeutic value if used appropriately. Radiation damage is thought to occur via at least one of three fundamental processes: mechanical (or ionization), thermal and photochemical (Figure 54.2). It should be noted that although this broad classification is used for simplicity, light damage often results from more than one of these processes through a continuum of photoinduced events.

Mechanical damage

Mechanical damage results from extremely short wavelength light exposures (nanosecond or less) at high irradiance levels causing sonic transients or shock waves that mechanically disrupt the tissue. The injury may be due to ionization where electrons are stripped from the outer orbitals of atoms resulting in a plasma. In the eye, such mechanical damage is normally associated with radiation originating from Q-switched or mode-locked lasers.

Thermal damage

Thermal damage can occur if incident energy is trapped or absorbed in a substrate molecule resulting in a significant increase in temperature. A rise in temperature of 10°C or more in the retina is considered sufficient to cause coagulative tissue damage. Such damage usually occurs

Figure 54.2 The mechanisms of light-induced retinal damage related to exposure duration. Modified from Ref. 9.
at longer wavelengths than for mechanical damage with exposure duration usually between 10^-6 and 10^-3 seconds and is dependent on the absorption of light by specific chromophores. The retina contains a number of chromophores which readily absorb visible light, i.e. melanin, blood, xanthophyll and lipofuscin. Typical sources of thermal energy are xenon arc and laser photocoagulators, the extent of tissue damage being dependent on exposure time. The depth of penetration is dependent on wavelength, e.g. optical radiation from argon lasers (457–524 nm) is primarily absorbed at the retinal pigment epithelium, while that from the krypton red (around 650 nm) and diode lasers (790–830 nm) is absorbed by the choroid, as well as the retinal pigment epithelium.

**Photochemical damage**

This has been the most extensively studied form of light damage owing to its ability to cause damage under ambient conditions and its potential role in ocular pathologies (e.g. cataract and age-related macular degeneration). Photochemical damage is brought about by prolonged exposure (seconds to years) to the more energetic short wavelengths of light, such as blue and UV, which, when absorbed by a chromophore, lead to an electronic transition of the substrate to an excited state with a potential for causing tissue damage.

Although photochemical damage is reported to occur in most ocular structures, it has been most studied in the lens and the retina. The interactions of endogenous, as well as exogenous, biomolecules with UV radiation has demonstrated that the major UV absorbers in the lens are free or bound aromatic amino acids, as well as numerous age pigments and fluorophores. Photochemical changes in the lens appear to be cumulative and certainly contribute to ageing changes and the development of cortical cataract. Retinal photochemical damage is currently classified as either type 1 or type 2 on the basis of animal studies. Type 1 damage is caused by prolonged exposure (hours or days) to low irradiances, which at threshold result in damage to the retinal photoreceptors. The action spectra of type 1 damage corresponds reasonably with the absorption spectrum of the visual pigments thus supporting the view that these pigments are the prime chromophores responsible for the generation of type 1 damage. By contrast type 2 damage is considered to originate in the retinal pigment epithelium and appears to correlate with relatively higher retinal irradiances than for type 1 damage delivered over shorter time spans (seconds to minutes). However, current evidence suggests that prolonged exposure to low retinal irradiances can result in cumulative damage similar to that of type 2 (see Chronic light damage, p. 654). Ham and colleagues measured the action spectrum of type 2 damage and reported that its sensitivity increased with decreasing wavelength, a feature which led to this type of damage being referred to as ‘blue light damage’. Melanin in the retinal pigment epithelium has been proposed as the major chromophore, although more recent evidence suggest that the age-pigment lipofuscin which accumulates within retinal pigment epithelium cells with age may be the primary chromophore in man.

**LIGHT ABSORPTION BY OCULAR TISSUES**

Visual perception results from a response to visible radiation (400–780 nm) reaching the retina. The light pathway to the retina is almost completely transparent to all wavelengths of visible light (although transmission characteristics do change with age). However, these ‘transparent’ tissues do have the ability to absorb varying amounts of non-ionizing radiation normally present in the environment. Thus, the various structures of the eye can also be considered as a consecutive series of spectral filters with each component absorbing exclusive wavelengths and preventing/reducing the likelihood of retinal photodamage (Figure 54.3). Table 54.1 provides details of spectral domain, wavelength, non-ionizing radiation sources, absorption site and type of light damage for different ocular tissues.

All non-ionizing radiation below approximately 295 nm is cut off by the cornea and does not reach the lens. The cornea is thus capable of absorbing the UV-C (100–280 nm) and the short wavelengths in the UV-B between 280 and 295 nm. It should be noted that the cornea is only exposed to UV-C from artificial non-ionizing radiation sources since this solar component is blocked by the atmosphere. The lens absorbs strongly in the long UV-B (300–315 nm) and the full UV-A (315–400 nm); appreciable irradiances of UV-B and UV-A reach the retina only in aphakic eyes. Both the cornea and the lens absorb in the infrared (1400–10 000 nm). Neither the aqueous nor the vitreous demonstrates any significant absorption of radiant energy

---

**Figure 54.3** The penetration/absorption of ultraviolet, visible and infrared radiation by the different structures of the eye.
under non-pathological conditions. Thus, the light reaching the retina is the so-called ‘visible component’ of the electromagnetic spectrum (380–760 nm). The most obvious absorber in the retina is the visual pigment which has a broad band absorption across the whole of the visible spectrum. In addition, the retina contains a number of chromophores which readily absorb visible light:

- the broad band absorbers melanin and lipofuscin – absorption increases with decreasing wavelength and thus these chromophores have been implicated in blue light damage to the retina;
- haemoglobin which has absorption properties between 400 and 600 nm;
- macular pigment which strongly absorbs between 400 and 530 nm – this spectral absorption may protect the macula from potential blue light damage.

It should be noted that the absorption characteristics of different ocular tissues vary with age, e.g. the yellowing of the lens increases its absorptive characteristics between 300 and 400 nm with end absorptions extending to 500 nm.

A final point that should be emphasized is that the combined refractive powers of the cornea and lens can increase the light intensity reaching the fovea.

**Ocular Light Damage**

Although light is essential for vision its absorption by various tissues can result in tissue damage (Figure 54.4). As discussed earlier, dependent on wavelength, irradiance energy and exposure duration, three different types of light damage can be identified: ionizing, thermal and photochemical. The damaging effect of non-ionizing radiation can be broadly divided into acute and chronic depending on the immediacy of the response, type of damage and the ability of the damaged tissue to recover.

**Acute Light Damage**

Ultraviolet damage most commonly occurs in the superficial structures of the eye and is caused by excessive exposure to UV light (e.g. photokeratitis, photoconjunctivitis). There is usually a latent period of up to 12 hours following UV exposure before damage to ocular tissues becomes apparent. The adverse effects of UV are related to the duration, intensity of the exposure and the degree of penetration (i.e. UV-A will reach the lens, while the majority of UV-B is absorbed by the cornea). By contrast, light in the visible spectrum will usually affect the retina (e.g. solar retinopathy, welding arc maculopathy). Infrared damage is discussed under Damage by infrared and microwaves, p. 654.

**Photokeratitis and photoconjunctivitis**

The acute damage to ocular tissues by exposure to excessive UV is well documented and usually affects the corneal (photokeratitis) and conjunctival (photoconjunctivitis) epithelia. This damage is photochemical and is most commonly caused by exposure to UV-A, B and/or C. The acute inflammatory reaction of the superficial part of the cornea (and conjunctiva) to UV was originally termed ‘photophobia’. One of its forms (snowblindness, photokeratitis) was first described in 1722, although the condition became more common and better recognized after the introduction of the electric arc furnace and lighting in 1879. Epithelial damage is observed within 8–12 hours of exposure. The

![Figure 54.4](image-url)
photochemical changes induce a painful (foreign body sensation), red, photophobic profusely lacrimating eye with pronounced blepharism, all manifestations of inflammatory keratoconjunctivitis (e.g. arc-eye, flash-eye, ophthalmia electra, snowblindness, exposure from sun lamp/sunbeds). Resolution takes between two and seven days, depending on the severity of the burn and the patient may be advised to lubricate the eye with antibiotic ointment (e.g. chloramphenicol) and take analgesics during the recovery period which involves the proliferation and migration of healthy epithelium to replace the damaged cells.

Despite the normal use of protective goggles, the most common industrial cause of damage is from welding arcs. It should be noted that damage can be cumulative; short exposures are additive within a period of 24 hours. Individuals receiving repeated exposure to UV radiation over extended periods (e.g. welders, those inhabiting snowy regions) can develop chronic blepharoconjunctivitis (with loss of elasticity of the conjunctiva and band degeneration of the cornea), as well as playing a role in the pathogenesis of pterygia, pinguecula and act as a trigger for recurrent corneal erosion.

**Ophthalmic instruments**

Powerful light from ophthalmic instruments used for diagnostic and therapeutic purposes has been reported to cause iatrogenic phototoxicity in some patients. To date, there have been no confirmed reports of occupational risk from the use of these instruments in either the clinic or operating theatre. However, there is a potential occupational risk from ophthalmic lasers. This will be discussed in more detail (see Lasers, p. 652).

**Solar retinopathy**

Solar retinopathy is a well-recognized form of acute light damage caused by direct or indirect viewing of the sun. Duke-Elder reports that solar retinopathy has been recognized since the time of the ancient Greeks; Socrates advised that ‘a solar eclipse should be only observed by looking at its reflection in water’. Galileo injured his eye while viewing the sun through his telescope. As detailed by De La Paz and D’Amico, the most common cause of solar retinopathy is the direct viewing of a solar eclipse, but photic retinopathy has also been described in association with direct sun gazing by sunbathers and patients with psychotic disorders, religious festivals, military personnel and the use of hallucinogenic drugs, such as lysergic acid diethylamide (LSD).

Retinal damage is considered to be photochemical since sunlight exposure is insufficient to raise the retinal temperature by 10°C provided macular choroidal blood flow is maintained. The patient complains of blurred central vision immediately or soon after (usually within minutes) and the damage is usually, but not always, bilateral. The fundus presents initially with a yellow spot at the fovea which after several days changes to a reddish area with surrounding pigmentation change (Figure 54.5). There is a marked drop in visual acuity with a central scotoma. By two weeks, a red, well-circumscribed lamellar hole (100–200 μm diameter) often with a larger area of retinal pigment epithelium mottling is apparent. Visual acuity usually improves to near normal by six months, although a slight-to-moderate loss in visual acuity may persist in some individuals. A very small central red spot may remain throughout life. Oral corticosteroids have been advocated as a treatment for acute lesions with severe visual loss, but their efficacy remains unproven.

**Figure 54.5** Photographs of solar retinopathy. The fundus photograph shows pigmentary disturbance at the fovea and the angiogram confirms a focal window defect in the pigment epithelium at the fovea. Image provided by Professor D McLeod, Manchester, UK.
Welding arc maculopathy

Photic retinopathy may occur, due to photochemical damage by the blue light component of the welding arc, to individuals welding without goggles. In general, patients present with a decrease in vision which occurs immediately or soon after the injury; fundus appearance and visual recovery resemble those described for solar retinopathy (see Chapter 44, Welding).

Laser

Laser is an acronym for Light Amplification by the Stimulated Emission of Radiation. Lasers are sources of non-ionizing radiation that can operate in the UV, visible and infrared region of the electromagnetic spectrum. The light emitted has a unique combination of spatial coherence (i.e. all the waves are in step), monochromaticity (one colour or narrow wavelength range) and usually high collimation. Furthermore, the emission may be continuous wave or pulsed for either long or short (Q-switched) duration.

The known effects of acute light damage to ocular tissues are exploited in preventive ophthalmology. Optical breakdown damage from Q-switched or mode-locked lasers are important procedures in iridotomy and posterior capsulotomy. Photoreactive keratectomy is now a standard procedure in Europe for the correction of refractive error less than 4 dioptres, as well as becoming fashionable for the treatment of high myopia and is routinely undertaken using an Excimer laser emitting in the UV-C region of the spectrum. Providing irradiance, exposure time, pulse rate and beam alignment are optimal, the operation is successful, however, poor quality control can result in corneal fibrosis and opacification. Argon, krypton and diode lasers are routinely used in retinal scatter photocoagulation to induce the regression of subretinal and preretinal vessels in conditions such as proliferative diabetic retinopathy.

Lasers are commonly used both in the industrial (e.g. drilling, cutting, welding, communication) and military (e.g. rangefinders, tactical target designators, night vision) settings and there have been numerous reports of accidental exposure resulting in immediate loss of central vision. Depending on the type of laser, damage occurs by either a thermal or mechanical mechanism. In the case of retinal damage, a gliotic scar develops and a paracentral or central scotoma may persist. Lasers are divided into four major classes depending on the potential safety hazard. These classes are defined by British Standard BS/EN/IEC 6082:2007 and ANSI Z136.1: 2007.

- Class 1 – non-hazardous lasers; (i) the output is so low the laser is inherently safe or (ii) the laser is part of a totally enclosed system. A class 1M laser product is safe to view without optical aids, but otherwise is potentially hazardous.
- Class 2 – low power visible continuous wave and pulsed lasers which, whether repetitively pulsed or continuous wave lasers, are not hazardous within the eye’s aversion response (i.e. ≤0.25 second). Normally only procedural controls such as not directly pointing the laser at the eye are required. Class 2M laser products pose the same risk if viewed without optical aids, but otherwise are potentially hazardous to view with telescopes.
- Class 3 – divided into class 3R and class 3B. Class 3R – low to medium power lasers where the risk is minimal largely because of the extremely low probability of the pupil being large, of all the beam energy entering the eye and the eye accommodated to focus the beam to a minimal spot. Nevertheless, the eye may be exposed technically to levels up to five times the maximum permissible exposure (MPE). Hazard can be controlled by relatively simple procedures (e.g. use of beam stops and ensuring that beam paths are not at eye level). The only documented injuries from this type of laser have occurred from intentional direct-beam exposure. Class 3B – medium power lasers where the viewing beam either directly or by specular reflection is hazardous, but diffuse reflections are almost always safe. Hazard can be controlled by the use of beam enclosures, beam stops (ensuring that beam paths are not at eye level) and, if needed, laser eye protection.
- Class 4 – high power lasers which are not only a hazard from direct viewing and from specular reflections, but also from diffuse reflections. The direct beam may also be a skin and fire hazard. Their use requires extreme caution.

Most laser accident experience comes from careless use of lasers in the research laboratory, with fewer in industry and military applications. A review of the accident data suggests that at least one type of laser is responsible for the majority of accidental injuries that result in a significant visual loss: the Q-switched neodymium: YAG (Nd:YAG) laser which emits invisible, near-infrared radiant energy at 1064 nm. Although a continuous wave (CW) laser causes thermal coagulation of tissue, a Q-switched laser having a pulse of only nanoseconds duration disrupts tissue by thermomechanical processes. A visible or near-infrared laser can be focused on the retina, resulting in a vitreous haemorrhage (Figure 54.6). Despite macular injuries and an initially serious visual loss, the vision of many patients recovers surprisingly well. Others may have severe vision loss. Corneal injuries resulting from exposure to reflected laser energy in the far-infrared account for surprisingly few reported laser accidents. The explanation for this accident statistic is not really clear. However, with the increasing use of lasers operating at many new wavelengths, the ophthalmologist may see more accidental injuries from lasers. Not all laser incidents result in injury, and temporary visual effects are now also of concern.

As discussed, the eye is particularly vulnerable to injury in the retinal hazard region from 400 nm at the short-wavelength end of the visible spectrum to 1400 nm in the near-infrared part of the spectrum. In this spectral
band, a collimated beam can be focused to a 15–20 μm
diameter retinal spot (i.e. much smaller than the diameter
of a human hair). Because of the great brightness of a laser,
its radiant energy can be greatly concentrated when
focused (e.g. upon the retina) compared with the rays from
conventional light sources which are much less bright. The
gain in beam irradiance from cornea to retina is approxi-
mately 100,000 times in the visible spectrum. Hence, a
corneal beam irradiance of 1 W/cm² becomes 100 kW/cm²
at the retina. Vision loss can vary from temporary after-
images to a permanent blind spot (scotoma) or even total
loss of vision in an eye.1,44,49

Diffuse reflections of laser beams are normally safe to
view, since the energy is dissipated upon reflection into all
directions and the resulting image on the retina is that of
an extended source. However, under special conditions, it
is a realistic possibility to produce a hazardous diffuse
reflection.50 This can result from a diffuse reflection of a
Q-switched (1–100 ns) laser in the retinal hazard region.

Colour contrast sensitivity can be reduced in ophthal-
mologists using argon blue-green lasers for retinal photo-
coagulation.28 After argon blue-green laser treatment
sessions, sensitivity was reduced for colours lying along a
tritan colour-confusion line for several hours. This acute
effect was due to spectacular ‘flashbacks’ from the aiming
beam off the surface of the contact lens. In addition, a cor-
relation has been made between the number of years of
laser experience and a chronic reduction in tritan colour
sensitivity. Appropriate safety procedures have now been
introduced following this finding.

Hand-held laser pointers (class 2 or class 3R) have
engendered a considerable degree of concern in many
quarters because of deliberate misuse by the public.
Indeed, in some countries, only class 2 laser pointers are
authorized for use by the general public. Claims in the
media of individuals ‘blinded’ by a laser pointer are almost
universally over-exaggerations and certainly related to
being flash-blinded by the visually bright beam.46

Exposure limits

Occupational exposure limits have been promulgated by a
number of organizations (see list of Health and Safety
directives at end of chapter). In the United States, both
the American Conference of Governmental Industrial
Hygienists (ACGIH) and the American National Standards
Institute (ANSI) have produced a comprehensive set of
exposure limits which apply for pulse durations of 100 fs to
30 ks (eight hours) for wavelengths from 180 nm in
the ultraviolet (UV) to 1 mm in the extreme infrared.
These exposure limits are virtually identical, although
exposure limits are termed ‘threshold limit values’ by
ACGIH and maximum permissible exposure limits in the
ANSI standard Z-136.1.51 On the international scene, the
International Commission on Non-ionizing Radiation
Protection (ICNIRP) published guidelines for limits of
human exposure to laser radiation in 1996. The basic
resource used for the development of the laser exposure
limits was the Environmental Health Criteria Document of
the World Health Organization (1982). The International
Electrotechnical Commission (IEC) and European guide-
lines (EU Optical Radiation Directive) are all based upon
the ICNIRP, ACGIH and ANSI exposure limits. Although
the complete listing of all laser exposure limits is beyond the
scope of this text, Table 54.2 provides a brief summary of
some of the most commonly used limits.

Screening tests

Although not obligatory, some employers undertake a pre-
employment check of a potential employee’s fundus
appearance and visual acuity. This is largely for employer
protection should an employee with a retinal lesion prior
to working with a laser develop reduced vision and enter into
litigation. Routine screening of employees is uncommon,
particularly since small or subthreshold lesions are difficult
Non-ionizing radiation and the eye

Note: To convert exposure limits in mW/cm², multiply by exposure time in seconds, e.g. the He-Ne or Argon EL at 0.1 s is 0.32 mJ/cm².

CHAONIC LIGHT DAMAGE

Chronic light damage has been clearly demonstrated in animal models, but is difficult to prove in man; subclinical photodamage is believed to accumulate through a lifetime, eventually exceeding a threshold at which overt clinical damage is evident. However, to what extent such damage, particularly in the aged population, is primarily due to light exposure or other factors is open to debate. Furthermore, the major source of chronic light exposure has shifted dramatically over the last 50 years. Sunlight used to be the major non-ionizing radiation source; however, fluorescent lighting (and even lighting from light-emitting diodes (LEDs) is now a common feature both at home and in the workplace. Furthermore, computers are now commonplace. Thus, an increasing number of individuals are being exposed to non-ionizing radiation from visual display units in an environment of fluorescent lighting. Only time will tell if these changes in lighting sources will increase or reduce ophthalmic conditions attributable to chronic light exposure.

Sunlight

There are numerous epidemiological studies which have reported an association between chronic light exposure and cataract, pterygium, climatic droplet keratopathy and age-related macular degeneration. The most detailed study of sun exposure and cataract was undertaken on 838 Chesapeake watermen in Maryland and a 60 per cent increase in risk of cortical cataract with a doubling of cumulative sun exposure was noted. This observation was subsequently supported by the smaller study undertaken by Bochow and colleagues. Other less detailed studies have reported that the risk for posterior subcapsular cataract is slightly increased in people with moderate and high light exposures. Surprisingly, no association has yet been noted between light exposure and nuclear cataract. Studies organized by a group at Kanazawa, Japan, have pointed to a strong correlation of nuclear cataract and ambient lifetime ambient temperature; whereas – as in the other studies – cortical cataract was associated with UV exposure. Severe cases of age-related macular degeneration have been shown to have received significantly greater exposures to either blue and/or full spectrum visible light over a 20-year period compared with controls especially in older subjects. However, the role of light in the initiation and progression of early age-related macular degeneration remains a subject for debate. Thus, high levels and chronic exposure of individuals to all or part of the visible light spectrum can manifest as ocular disease later in life.

Fluorescent lights

Many of the animal studies of light damage to the retina have employed fluorescent lamps, and this has given rise to concerns about human exposure to fluorescent lighting. It is important to recognize that the typical light exposure conditions for the test animals employed ring fluorescent lamps such that the animals (rats) could not look in any direction without seeing a bare fluorescent lamp. Under such conditions, where the luminance exceeded that of sunlight reflected from snow, retinal damage resulted after some days of exposure for 12 hours per day. Such conditions simply do not occur in human activity, where such a luminance would preclude seeing and result in almost continued ‘bleaching’ of the retinal pigment. It was necessary to dilate an animal’s eyes in order to obtain this result in primates. There is no evidence of any detrimental effect in humans to date.

VISUAL DISPLAY UNITS

There is a large amount of literature on the viewing of visual display units and the suspected health hazards. Fundamentally, the research over the past two decades shows that while ergonomic (human-factor), refractive and visual comfort problems are real, there is no long-term adverse effect upon the visual system. Sources of infrared (IR) (which is normally invisible to the naked eye) include molten glass, furnaces, acetylene
welding, the sun, various heating appliances, lasers (both commercial and ophthalmic) and military weapons. IR-A damage is predominantly observed in the choroid, retina, iris and lens, while the longer wavelength IR-B and IR-C are absorbed by the cornea and lens but do not reach the retina (Table 54.1). Specific sources of IR-B and IR-C are the erbium and carbon dioxide lasers, respectively. Tissue damage is normally thermal, and in the case of the retina, largely irreversible.

Ocular damage from exposure to IR-A was common in workers involved with furnaces, molten glass or molten metals at temperatures over 1500°C. It was recognized as long ago as 1786 by Wenzel who observed that glass blowers had an increased incidence of cataract. Cataract formation appeared to be more common in the left eye probably due to the tendency for greater exposure to infrared on the left side as a result of common working practice. It was calculated that the temperature of a human lens can increase by 9°C if the eye is exposed to molten glass at 1 foot (0.3048 m) distance for one minute.

Infrared-induced cataract was ‘prescribed’ as an occupational disease in the United Kingdom in 1907 and the subsequent introduction of shields and goggles reduced the incidence of cataract in glass blowers dramatically, such that in 1908 some 20 per cent of workers had cataract while by 1945 only one case was reported in the United Kingdom in a whole year. Subsequently, the bulk of glass production and foundry work has been mechanized, leaving only a small number of workers, especially in craft centres, at risk. However, a significant problem will still exist in developing countries where mechanization and safety procedures are minimal.

Lens damage appears to be cumulative as a posterior cataract begins to develop after a decade or two of working near high intensity infrared sources. Cataract presents with a blurring of vision and associated lens opacities. Clinically, the infrared cataract starts as a cobweb-like opacity which increases in size and density and develops into a saucer-shaped posterior cataract. The opacity will continue to grow and will ultimately form a complete opacity resembling a senile cataract. Treatment is by cataract extraction and intraocular lens implantation. Retinal damage often goes unnoticed since infrared is invisible and the retina has no pain receptors. However, pain may be experienced if the choroid is affected. Damage is thought to result from absorption of energy by melanin in the retinal pigment endothelium and choroidal melanocytes. This can result in a scotoma which, if at or near the fovea, can produce a profound loss of visual acuity. Examination may reveal localized areas of retinal oedema or patches of pigmented disturbance, lesions often not appearing until 48 hours after exposure (fluorescein angiography can be used to identify burn areas not apparent by ophthalmoscopic examination). There is no recognized treatment for this condition.

Flash burns to the cornea may occur by the flashback of large artillery and by the flash of an atomic explosion. These burns which are a combination of infrared and ultraviolet are identical to those caused by other types of thermal exposure. In most flash burns, the blink reflex protects the eyes from damage; however, in some instances the cornea is involved. The condition results in a painful eye which resolves within a few days. Treatment normally consists of topical antibiotics if epithelial defects and cyclopedia for discomfort. In more severe burns, there is corneal thinning, neovascularization and scarring.

**Microwaves**

Microwave radiation is the high-frequency end of the radiofrequency region of the electromagnetic spectrum with a wavelength range of 1 mm to 1 m. Sources of microwaves include household ovens, radar, satellite communication, insect control appliances and surgical diathermy apparatus. It is unlikely that domestic appliances will pose a risk to the individual, but military and civilian radar/communications workers may be at risk of exposure to dangerous levels of microwave radiation during service procedures near the antenna. It has been hypothesized that in some tissues, especially the lens, repeated exposure causes cumulative damage and can manifest as cataract. However, evidence from chronic exposure animal and epidemiological studies have failed to confirm a direct correlation between microwave irradiation and cataract. Acute, accidental exposure of the eyes to microwave radiation may lead to skin burns, conjunctival infection and loss of corneal epithelium, as well as stromal oedema and opacification. Epithelial loss can be managed with topical antibiotics (e.g. chloramphenicol or fusidic acid) and cyclopia (e.g. cyclopentolate), while topical steroids (e.g. prednisolone acetate) may also be considered if stromal damage and inflammation occur (indicated by corneal oedema and opacification). Exposure limits vary from approximately 1 to 10 mW/cm² in different standards and with animal ocular injury thresholds being in the order of 100 mW/cm². More recent studies by Kues et al. suggest that short-pulse exposures at 2.45 GHz may produce effects at lower average power densities. Individuals usually recover within two weeks, although some stromal haze could persist for more than 12 months.

**PHOTOSENSITIZATION**

Photosensitizers, often given as drugs, can contribute to light-induced ocular damage. Two groups of compounds, phenothiazines and psoralsens, have been clearly identified as intraocular photosensitizing agents, capable of causing photochemical damage to the choroid, retina and lens in man, as well as experimental animals. 8-Methoxypsoralen (8-MOP) is a typical example of such a photosensitizer which is used in the photodynamic therapy of psoriasis and other skin diseases. Interaction between 8-MOP and the lens or retina results in the photobinding of the dye to these...
tissues. The phototoxic side effects of psoralen plus UV-A therapy (PUV-A) in patients on oral 8-MOP were evaluated in a large prospective study over five years. No significant dose-dependent increase in the risk of cataract formation was found in the group of patients receiving PUV-A therapy and using protective glasses constantly for 24 hours after therapy to block out UV-A and hence prevent photobinding. Lens opacities have been reported to occur within months in patients who did not use eye protection for 24 hours after PUV-A treatment. However, photosensitizers such as verteporfin, have been used to abolish or regress pathological blood vessels associated with age-related macular degeneration. Verteporfin is a light-activated drug used in photodynamic therapy that preferentially locates to new blood vessels and when activated by light in the presence of oxygen, generates highly reactive, short-lived reactive oxygen radicals that cause endothelial cell damage.  

**PROTECTION AGAINST LIGHT DAMAGE**

The eye is well adapted to protect itself against acute optical radiation (ultraviolet, visible and infrared radiant energy) injury from ambient sunlight. It is protected by a natural aversion response to viewing bright light sources that normally protects against injury from viewing sources such as the sun, arc lamps and welding arcs, since this aversion limits the duration of exposure to a fraction of a second (about 0.25 s). However, sources rich in ultraviolet radiation without a strong visual stimulus can be particularly hazardous. One can force oneself to stare at the sun, a welding arc or a snow field and thereby suffer a temporary loss of vision, which in some cases may be permanent. In the industrial setting, when bright lights appear low in the field of view, the eye’s protective mechanisms are less effective, and hazard precautions are particularly important.  

**Safety standards**

Safety standards for arc welding have long existed and specify eye protectors, curtains and barriers. Safety standards for lasers are also well developed worldwide; most following the general equipment and user guidance in IEC 60825-1:2007. Lasers are grouped into several hazard classes and so labelled by manufacturers; the user then follows certain specified control measures based upon the laser class. However, standards for lamp safety are actually more recent. In the United States, the Illuminating Engineering Society of North America (IESNA) issued photobiological safety standards for lamps and lighting systems for the first time in 1996 and lamp groups are placed in risk groups somewhat similar to laser hazard classes. Since then, this approach has been followed in the joint standard CIE-S009 of the International Commission on Illumination (the CIE) and in standard IEC-62471:2006 of the International Electrotechnical Commission (IEC).

**Eye protector design and standards**

The design of eye protectors for welding and other industrial optical sources (foundries, steel and glass manufacture, etc.) began at the beginning of this century with the development of Crooke’s glass. Eye protector standards which evolved later followed the general principle that since infrared and ultraviolet were not needed for vision, those spectral bands should be blocked as best as possible by the then currently available glass materials. Figure 54.7 illustrates the wide variety of design from spectacles to goggles and full-face welding helmets.

The empirical standards for eye protective equipment were tested in the 1970s and shown to have large safety factors for infrared and ultraviolet when the transmissions factors were tested against current occupational exposure limits, whereas the protection factors for blue light were just sufficient. Some standards’ requirements were therefore adjusted. Table 54.3 summarizes recommended eye protectors for different types of optical sources. Laser protective eyewear was developed after occupational exposure limits had been established, and specifications were drawn up to provide the optical densities (a logarithmic measure of attenuation factor) that would be needed as a function of wavelength and exposure duration for specific lasers. Although specific laser eye protector standards exist in Europe, guidelines for laser eye protection are provided in the American National Standard ANSIZ136.1 and ANSIZ136.7 in the US.
Human exposure limits

From knowledge of the optical parameters of the human eye and the radiance of a light source, it is possible to calculate irradiances (dose rates) at the retina. Exposure of the anterior structures of the human eye to ultraviolet radiation may also be of interest; and the relative position of the light source and the degree of lid closure can greatly affect the proper calculation of this ultraviolet exposure dose. For ultraviolet and short-wavelength light exposures, the spectral distribution of the light source is also important.

A number of national and international groups have recommended occupational exposure limits for optical radiation (i.e. ultraviolet, light and infrared radiant energy) (see list of Health and Safety directives at end of the chapter). Although most such groups have recommended exposure limits for UV and laser radiation, only one group has recommended exposure limits for visible radiation (i.e. light). This is the American Conference of Governmental Hygienists who, as previously mentioned, refer to its exposure limits as threshold limit values, and these are issued yearly, so there is an opportunity for a yearly revision. They are based in large part on ocular injury data from animal studies and from data from human retinal injuries resulting from viewing the sun and welding arcs. The threshold limit-values also have an underlying assumption that outdoor environmental exposures to visible radiant energy are normally not hazardous to the eye, except when fixating the sun or in very unusual environments such as snow fields and deserts.

Optical radiation safety evaluation

Since a comprehensive hazard evaluation requires complex measurements of spectral irradiance and radiance of the source, or very specialized instruments and calculations, this is rarely done by occupational hygienists and safety engineers. Instead, the eye protective equipment is mandated by safety regulations in hazardous environments. Research studies have evaluated a wide range of arcs, lasers and thermal sources in order to develop broad recommendations for practical, easier-to-apply safety standards.30

Protective filter materials

ULTRAVIOLET AND INFRARED PROTECTION

Almost all glass and plastic lens materials block ultraviolet radiation below 300 nm and infrared radiation at wavelengths greater than 3000 nm (3μm), and for a few lasers

and optical sources, ordinary impact-resistant clear safety eyewear will provide good protection (e.g. clear polycarbonate lenses effectively block the 10.6 μm CO₂ wavelength). However, absorbers such as metal oxides in glass or organic dyes in plastics, must be added to eliminate UV-A and UV-B up to about 380–400 nm, and infrared beyond 780 nm to 3 μm. Depending upon the material, this may be easy, or very difficult or expensive, and the stability of the absorber may vary somewhat. Filters that meet ANSI Z87.1 must have the appropriate attenuation factors in each critical spectral band.

FOUNDRY AND GLASS INDUSTRY EYEWEAR

Spectacles and goggles designed for ocular protection against infrared radiation generally have a light greenish tint, although the tint may be darker if some comfort against visible radiation is desired. Such eye protectors should not be confused with the blue lenses used in the steel and foundry operations where the objective is to visually check the temperature of the melt; these blue spectacles do not provide protection, and should only be worn briefly.

FIREFIGHTING

Firefighters may be exposed to intense near-infrared radiation, and apart from the crucially important head and face protection, infrared attenuating filters are frequently prescribed. Here, impact protection is also important.

ULTRAVIOLET RADIATION PROTECTION

A number of specialized UV lamps are used in industry for fluorescence detection and for photocuring of inks, plastic resins, dental polymers, etc. Although UV-A sources normally pose little real risk, these sources may either contain trace amounts of hazardous UV-B or pose a disability glare problem (from UV-A fluorescence of the crystallin lens); UV filter lenses with very high attenuation factors are widely available to protect against the entire UV spectrum with either glass or plastic lenses. A slight yellowish tint may be detectable if protection is afforded to 400 nm. Of paramount importance in these types of eyewear (and for industrial sunshades) is peripheral protection. Side-shields or wrap-around designs are important to protect against the corneal effect (focusing of temporal, oblique rays into the nasal equatorial area of the lens (where cortical cataract frequently originates).

LASER EYE PROTECTORS

The objective of laser eye protective filters is to transmit as much visible light for seeing while at the same time blocking the laser wavelength(s) of concern. The protective factor used for laser eyewear is termed optical density (OD). The OD is a logarithmic expression for attenuation factor, e.g. a protection factor of 1000 (10³) is an OD of 3.0, and a protection factor of one million (10⁶) is an OD of 6.0. Since most lasers emit powers or energies of the order of thousands to millions of times the maximum permissible exposure limit, optical densities of 4–6 are most typical. The ANSI standard Z136.1 Safe use of lasers provides detailed methods for determining the appropriate eyewear and ANSI standard Z136.7 Testing and labelling of laser protective equipment provides extensive technical detail. Although some eyewear vendors and laser safety promoters have argued for very robust filters of coated glass to withstand extremely high beam irradiances of many kilowatts per cm², this is overkill, and polycarbonate laser protective lenses are quite adequate (the skin will be severely charred at much lower irradiances). Polycarbonate has superior burn-through characteristics compared with other plastics and is also superior to all other lens materials for industrial impact protection.

At present, prescription lenses in laser filter materials are only available on a limited basis for glass lenses, but there are a number of companies which supply cover goggles for laser protection. The Laser Institute of America in Orlando, FL is a useful source of information on laser safety and laser eye protectors.

Welding filters

Infrared and UV radiation filtration is readily achieved in glass filters with additives such as iron-oxide, but the visible attenuation determines the shade number, which is a logarithmic expression of attenuation. Normally a shade 3–4 is used for gas welding (goggles), and 10–14 for arc welding and plasma arc operations (helmet protection required). The rule of thumb is that if the welder finds the arc to view, adequate attenuation is provided against ocular hazards. Supervisors, welders’ helpers and other people in the work area may require filters with a relatively low shade number (e.g. 3–4) to protect against welder’s photokeratitis (arc-eye). In recent years, a new type of welding filter, the autodarkening filter has appeared on the scene. Regardless of the type of filter, it should meet ANSI Z87.1 and Z-49.1 standards for fixed welding filters specified for the dark shade.

AUTODARKENING WELDING FILTERS

Autodarkening welding filters represent an important advance in the ability of welders to produce consistently high-quality welds more efficiently and ergonomically. Considering the total welding process, the welder formerly had to lower and raise the helmet or filter each time an arc was started and quenched. The welder had to work blind just prior to striking the arc. Furthermore, the helmet is frequently lowered and raised with a sharp snap of the neck and head which can lead to neck strain or more serious injuries. Faced with this uncomfortable and cumbersome
procedure, some welders frequently initiate the arc with a conventional helmet in the raised position – leading to ‘welder’s flash’ (arc-eye or photokeratitis). Under normal ambient lighting conditions, a welder wearing a helmet fitted with an autodarkening filter can see well enough with the eye protection in place to perform tasks such as aligning and fixturing the parts to be welded, precisely positioning the welding equipment and striking the arc. Then, in the most typical helmet designs, light sensors detect the arc flash and direct an electronic drive unit to switch a liquid crystal filter from a light shade to a preselected dark shade. The aforementioned drawbacks of fixed shade filters are largely eliminated by autodarkening filters which explains the widespread popularity of these newer systems.

Questions have frequently been raised whether there are hidden safety problems with the new autodarkening filters. For example, can after-images (flash-blindness) result in impaired vision in the workplace? Do the new types of filters really offer equivalent or better protection than conventional fixed filters? The answer to the second question is Yes, but not all autodarkening filters are equivalent. Filter closure speeds and light and dark shade values vary, as does the weight of each unit. The temperature dependence of performance, variation of shade with electrical battery degradation, the ‘resting state shade’ and other technical factors vary depending upon each manufacturer’s design. These are being addressed in new standards.

Since adequate filter attenuation is afforded by all systems, the single most important attribute specified by the manufacturers of autodarkening filters is the speed of filter switching. Current autodarkening filters vary in switching speed from 1/10th second (0.1 s) to faster than 1/10 000th second (100 µs). Buhr and Sutter72 have indicated a means of specifying the maximum switching time, but their formulation varies relative to the time-course of switching. Switching speed is crucial, since it gives the best clue to the really important (but unspecified) measure of how much light will enter the eye when the arc is struck compared with when wearing a fixed filter of the same working shade number. If too much light enters the eye for each switching during the day, the accumulated light energy dose produces transient adaptation and complaints about eye strain, etc. Current products with switching speeds of the order of 10 ms or less will provide adequate protection against photoretinitis. However, the shortest switching time of the order of 30–100 µs (0.03–0.1 ms) has the advantage of reducing ‘transient adaptation’ effects.71,73 Transient adaptation is the visual experience caused by sudden changes in one’s light environment which may be accompanied by discomfort, glare and temporary loss of detailed vision.

Simple check tests are available to the welder short of extensive laboratory testing. Suggest to the welder to simply look at a page of detailed print through each autodarkening filter. This will give an indication of its optical quality. Next, try striking an arc while observing it through each filter being considered for purchase. Fortunately, one can rely on the fact that light levels which are comfortable to view will not be hazardous. The UV radiation and IR filtration should be checked in the manufacturer’s specification sheet to make sure that the unnecessary bands are filtered out. A few repeated arc strikings should give the welder a sense of whether discomfort will be experienced from transient adaptation, although a one-day trial would be best.

The resting or failure state shade number of an autodarkening filter (e.g. if the battery fails) should provide 100 per cent protection of the welder’s eyes for at least one to several seconds. Some manufacturers use a dark state as the ‘off’ position and others use an intermediate shade between the dark and the light shade states. In either case, the resting state transmittance for the filter should be appreciably lower than the light shade transmittance to preclude a retinal hazard. In any case, the device should provide a clear and obvious indicator to the user when the filter is switched off or when a system failure occurs. This will ensure that the welder is warned in advance when the filter is not switched on or is not operating properly before beginning to weld. Other features, such as battery life, performance under extreme temperature conditions, etc. may be of importance to certain users.

CONCLUSIONS

Although technical specifications can appear to be somewhat involved for eye protectors against optical radiation sources, safety standards exist which specify shade numbers, and these standards provide a conservative safety factor for the wearer. However, should damage occur the recipient should be immediately referred to a doctor for a medical opinion.

Key points

- Excessive non-ionizing radiation can damage the eye.
- Damage is usually to the cornea or retina and can result in visual deterioration.
- Users exposed to acute or chronic non-ionizing radiation should be aware of exposure limits, safety standards and the appropriate eye protection.

NATURE OF ELECTRIC AND MAGNETIC FIELDS

Electricity use has grown throughout the industrialized world since the first public power station began operation in London on January 12, 1882. Electricity is generated and usually transmitted as alternating current (ac) in the United States at 60 cycles per second, or 60 Hertz (Hz), and in Europe at 50 Hz.

Electricity is generally considered safe, but it is not completely without hazard. For example, in the United States each year there are about 1100 deaths attributed to electric shocks. Approximately three-quarters of these deaths occur from unsafe operation of electrical appliances in the home and the remainder are from accidents in the workplace. However, the subject of clinical treatment of electric shocks and burns resulting from direct contact with electrical conductors is beyond the scope of this section, which considers health effects postulated from exposure to electric and magnetic fields associated with the delivery and use of electricity.

Electric and magnetic fields are ubiquitous in modern societies. The magnitude of electric fields, measured in kV/m, is directly proportional to line voltage, while magnetic fields, measured in tesla (T) or microtesla (μT), are determined by the magnitude of the electric current. These fields are found around every electrical conductor, motor and appliance. In office buildings, computers and copy machines are common sources of magnetic fields. Power distribution facilities and large motors used to drive building air conditioning systems can also contribute significantly to the magnetic field environment. In factories, high magnetic fields are encountered near large electric machines, electrical heating equipment and other high current-carrying devices.

Measurement of 50–60-Hz electromagnetic fields (EMF) is easily carried out with hand-held field meters. However, extreme variability of fields, both in space and time, make exposure assessment and the development of proper exposure surrogates of past exposures difficult. This is further complicated by the lack of knowledge regarding what aspects of exposure are biologically relevant and what might constitute a dose.

OCCUPATIONAL EXPOSURES

Occupational EMF exposures are considerably higher than non-occupational ones, which are usually in the 0.01–0.3 μT range (Figure 55.1). Occupational exposures have been studied most extensively in the electric utility industry. Average exposures have been found to be higher in electrical occupations than in other occupations, such as office work, ranging from 0.4–0.6 μT for electricians and electrical engineers to approximately 1.0 μT for power line workers. Welders have the highest average exposures at 3.7 μT. Average measurements or arithmetic means, however, can be strongly influenced by a few high measurements. Geometric means, which are not thus influenced, are much lower. Geometric means are 0.2–0.3 μT for electricians and electrical engineers, 0.4 μT for power line workers and 0.6 μT for welders.

Much less is known about exposures in non-electrical occupations. Few data, if any, are available for many jobs
and industrial environments. Of note in the few surveys conducted are high exposures among railway engine drivers (about 4 μT) and seamstresses (about 3 μT). The best information on work exposures among the general population is available in a survey conducted by Zaffanella and Keaton. The survey included 525 workers employed in a variety of occupations. The largest geometric mean (0.16 μT) for exposure to magnetic fields during work occurred in electrical occupations and in service occupations. Technical, sales and administrative support positions had a geometric mean of 0.11 μT; managerial and professional specialty occupations had 0.10 μT; and precision production, craft and repair occupations and operators, fabricators and labourers had a geometric mean 0.09 μT. At 0.05 μT, farming, forestry and fishing occupations had the lowest geometric mean. Work exposures were often significantly higher and more variable than other exposures; people spent significantly more time, for example, in fields exceeding 16 mG estimates for the US population.

**Figure 56.1** Length of time during different periods with field exceeding 16 mG estimates for the US population.

**ACUTE EFFECTS IN HUMANS**

Electric fields can be detected as a slight tingling of the hair at field strengths of 5–10 kV/m. Electrical workers may also be affected by microshocks which can be experienced by a person touching a conducting object in an elevated electric field greater than about 2 kV/m. Imperceptible contact current flows into the person’s body as long as it remains in contact with the conductor. Microshocks have been suggested as the source of certain effects in cells and tissues, such as chromosomal anomalies. It should be noted, however, that there is no substantial evidence implicating microshocks as harmful beyond their nuisance effects (see under Neurobehavioural and neurodegenerative effects, p. 669).

There is evidence that certain animals and organisms (e.g. birds, bacteria) can detect and be guided by the Earth’s static magnetic field and very low frequency ac fields (<10 Hz). Humans cannot sense time-varying magnetic fields of 50–60 Hz, except at very high field strengths (on the order of 3–5 mT). At this field strength, humans perceive visual flashes of light, i.e. magnetophosphenes, which are transient and not thought to produce any permanent retinal lesions. Extremely high fields may result in nerve stimulation.

In the past, exposures to ambient EMF have been thought to be without biologic effects. The first suggestion that exposures might be detrimental to health arose from studies conducted in the Soviet Union in the early 1960s. These studies focused on utility workers, particularly substation employees. Studies of these employees found an excess of symptoms such as sleeplessness, headache and upper respiratory distress. Investigations of the general health of electrical workers in several western countries have failed to confirm these findings. Indeed, in evaluations of health between electrical workers and comparison groups, no differences were found based on the response to a survey questionnaire of people in whom field measurements had been made.

Some experimental studies suggest that electric and magnetic fields can, under certain exposure conditions, produce physiologic effects in human volunteers. Changes in heart rate, heart rate variability, cognitive function and evoked cerebral potentials were observed to be slightly affected by exposures to EMF. These observations, however, were not confirmed unambiguously in later studies.

**LONG-TERM HEALTH EFFECTS**

The first publication linking EMF to human cancer appeared in 1979. The paper reported an association between childhood cancer and presumed residential exposure to EMF, originating from neighbourhood power lines. This observation spurred a number of epidemiologic studies which examined the effect of occupational exposure to EMF on cancer development. The focus of this chapter is on occupational epidemiologic studies of workers with potential exposure to EMF.

The health effects that have received the most attention are cancer, reproductive effects, neurobehavioural and neurodegenerative conditions and cardiovascular diseases.

**Cancer**

**EPIDEMIOLOGIC STUDIES**

The study of the hypothesized association of EMF exposure with human cancer has mostly followed these two lines of investigation: cancer among children whose exposure to EMF is residential in origin, and cancer among workers in broadly defined electrical occupations whose exposure to EMF presumably occurs at the workplace. Based on epidemiologic studies, childhood leukaemia risk appears to
double at average residential exposure levels above 0.3–0.4 μT. \cite{12,13} Studies of residential exposure in adults and biological effects from EMF are largely negative thus far. Detailed discussion of the studies of residential exposures is outside the scope of this chapter, for a review, see Ref. 28.

Occupational studies of EMF have employed several designs such as proportionate mortality, case–control and cohort analysis. The occupational groups studied included the following categories of workers: linemen, substation workers, welders, electricians, motion picture projectionists, electronic assemblers and electrical engineers. Unfortunately, the definition of electrical workers in these studies is broad, varies considerably among investigations and does not always reflect a high EMF exposure. More recent and better quality studies have assessed magnetic field exposures through job–exposure matrices (JEMs) populated with personal measurements of time-weighted average (TWA) magnetic fields. JEMs for electric utility workers\cite{14,15} and for the general population\cite{16,17} have been constructed from extensive full-shift measurements. These data are combined with activity records to calculate the TWA and other metrics, such as time above a threshold, that summarize a worker’s exposure.

A major limitation of magnetic field JEMs is that occupation is not the main determinant of exposure. A person’s occupational exposure depends on the performed job tasks, field sources encountered during work, the average strength of sources and the proportion of time spent at different locations relative to sources. Consequently, measured exposure varies widely among individuals within the same occupations.\cite{18} Furthermore, JEMs based on contemporaneous measurements may not properly represent historical exposures.

Several improvements to JEMs have been tried. Miller developed a JEM that classifies exposure measurements by location as well as by job.\cite{19} Renew et al.\cite{20} assessed exposures of power station workers with a magnetic field model that takes account of the engineering design, layout and operational history for each power station. Results from this model were combined with data on the proportion of time spent in specific plant areas for each job and with occupational history to give individual exposure values. Good agreement was found between modelled and measured exposures. This approach had the added advantage of reconstructing historical exposures. While this approach is valuable for power plant occupations with fixed working locations, exposures for transmission and distribution workers are still best assessed by JEMs.

Elevated electric field exposures occur only where there are unshielded, high-voltage conductors and therefore do not normally occur in indoor facilities, such as power stations or factories. Moderate-to-high levels (0.1 to >1 kV/m) are found only near high-voltage transmission lines or exposed, energized busbars in substations. In these limited environments, adequate estimates of TWA electric field exposures can be obtained from spot measurements or computer modelling.\cite{21}

A brief summary of the numerous studies investigating occupational EMF exposures and several cancers is presented below. Leukaemia and brain cancer, and, more recently, breast cancer have received the most attention, although many of the breast cancer studies focused on residential exposures. Also, occupational exposures to electric fields have re-emerged as an issue of potential importance.

Because of the large number of occupational studies of EMF and leukaemia and brain cancers, specific study references which have been included in meta-analyses are omitted below. Reference should be made to Kheifets et al.\cite{22–24}

**LEUKAEMIA**

The risks of leukaemia associated with occupational exposure to magnetic fields are generally low. A meta-analysis of occupational epidemiologic studies suggested an excess of all leukaemias with a risk estimate of 1.18 (95 percent confidence interval (CI) 1.12–1.24),\cite{22} with slightly higher risks for the various leukaemia subtypes. Although most studies reported a small elevation in risk, the apparent lack of a clear pattern of exposure to EMF substantially detracts from the hypothesis that magnetic fields in the work environment are responsible for it. These findings were not sensitive to assumptions, influence of individual studies, weighting schemes or modelling. Some evidence of publication bias was noted.\cite{23} A pooled analysis of large cohort studies of electric utility workers showed similar weak but positive associations between occupational magnetic field exposure and adult leukaemia. More recent cohort studies of electric utility workers in the United Kingdom and Denmark showed no elevation in leukaemia risk in association with occupational magnetic field exposure (Figure 55.2).

A recent update to the previous meta-analyses on occupational EMF and adult leukaemia collected and evaluated all relevant 1993–2007 publications.\cite{24} Combining the new and past studies leads to a small overall increase in risk of 17 per cent for all leukaemia with little indication of heterogeneity. A more detailed look indicates somewhat higher risk increases for specific leukaemia subtypes (an excess ranging from 15 to 37 per cent), but the excess is largely limited to the previous analysis with newer studies providing little indication of risk. Additionally, while in the past analysis the highest estimate was obtained for chronic lymphocytic leukaemia now the highest risk appears for acute lymphocytic leukaemia.

Improvements in study quality have not clarified the relationship between occupational EMF exposure and leukaemia. While recent studies represent substantial improvements over earlier research, each has unique limitations. The most recent studies do not point to strong biases or confounding in the earlier studies. However, so little is known of the risk factors for adult leukaemia that confounding from an as yet unidentified risk factor remains a possibility. Also, the lack of an exposure–response relationship and the inconsistencies in results from different studies makes it difficult to conclude that
occupational EMF exposure is a risk factor for adult leukaemia. Large increases in adult leukaemia risk in association with occupational EMF exposure, however, are unlikely based on the available results.

**BRAIN CANCER**

Similarly, there is a small but significant increase in brain cancer risk associated with estimates of potential workplace magnetic field exposure (relative risk (RR) = 1.21, CI 1.11–1.33). While most studies reported a small elevation in risk, there was considerable heterogeneity in the results. Pooled risk estimates (based on inverse-variance weighted pooling) decreased over time. The findings of this meta-analysis were not affected by inclusion of unpublished data, influence of individual studies, weighting schemes or model specification. A pooled analysis of large utility cohort studies showed a weak-positive association between occupational exposure to EMF and adult brain cancer. More recent electric utility cohort studies from Denmark and the United Kingdom observed no increases in brain cancer risk. An update to the earlier meta-analysis for brain cancer leads to an overall 14 per cent increase in risk for brain cancer and an 18 per cent increase for glioma, with some presence of heterogeneity.

While some studies reported a slight elevation in risk for adult brain tumours among people in electrical occupations, the lack of a dose–response relation in some studies and the lack of knowledge of other risk factors for brain tumours which could be confounding variables limit our ability to reach conclusions about the risks for adult brain cancer from occupational exposure to EMF. Similar to leukaemia, however, large increases in the risk of adult brain cancer in relation to occupational EMF exposure may be excluded on the available epidemiologic results (Figure 55.3) and previously observed risk patterns are not strengthened by new and better quality data.

**BREAST CANCER**

Numerous studies have examined cancer in electrical occupations, with many considering breast cancer as one of the outcomes. These studies were motivated by a specific, biologically based hypothesis, which proposed that magnetic field exposure suppresses melatonin production at night and that reduced melatonin levels would result in an...
increased risk of breast cancer. Male breast cancer is very rare and most of the studies were not based on sufficiently large populations, so estimates of risk for male breast cancer were often not included in the tables of results unless an excess risk had been observed. This makes it difficult to evaluate the risk of male breast cancer. Although several reports were suggestive of a positive association, the more recent large studies of electrical workers did not identify any excess of male breast cancer.

Few occupational studies of electrical workers included sufficient numbers of females to address the potential association of occupational EMF exposure and female breast cancer. Although some studies supported a possible association between EMF exposure and oestrogen receptor-positive breast cancer among premenopausal women, other studies did not. Most recently, a very large and well-designed occupational case–control study of Swedish women using a sophisticated female-occupation specific job–exposure matrix found no increase in breast cancer risk with exposure to magnetic fields. Available epidemiologic results, overall, do not provide support for an association between occupational exposure to EMF and breast cancer.

OTHER CANCERS

Sporadic reports of elevated risks for other cancers, such as malignant melanoma, non-Hodgkin’s lymphoma, testicular cancer and prostate cancer, have appeared in the literature but these have been inconsistent and none has been sufficiently strong to warrant further discussion here. Overall, epidemiologic results do not indicate that occupational EMF exposure may be a risk factor for these types of cancers.

ELECTRIC FIELDS

Magnetic, rather than electric, fields have been identified as the exposure of potential interest in most epidemiologic studies. In addition to the plethora of well-known difficulties in measuring magnetic field exposures today and extrapolating them to workers who held similar jobs in the past, measuring electric field exposure presents unique difficulties. Electric fields are perturbed by conducting objects, such as humans and their surroundings. The interaction of the subject with the field affects the reading of a field meter placed on the body. The field that is recorded by the instrument is therefore very dependent on where the device is worn, the posture of the subject and the relative location of sources of fields. This makes measurements of the electric fields difficult to perform and interpret, often yielding relative, as opposed to absolute, values of exposure for different individuals. Because most of the exposure assessments in the occupational environments have focused on magnetic, rather than on electric fields, little is known about the reliability and validity of electric field measurements. However, reanalyses of two cohorts of the Canada–France study and of a study in Los Angeles County considered electric...
field exposure (the original focus of these studies was magnetic fields).

In the first, Miller et al. reported an association of all leukaemias and leukaemia subtypes (but not for brain cancer) with increasing electric field exposures. The primary effect occurred when both electric and magnetic field exposures were considered together. In contrast to these results, the second reanalysis found no evidence of an increased risk of leukaemia and some evidence of an increased risk of brain tumours among utility workers exposed to electric fields. Finally, a limited reanalysis of data from Los Angeles County did not find an association between leukaemia and electric field exposures in a variety of occupations. The two further analyses of the Ontario portion of the Canada–France electric utility worker study found an increased risk of leukaemia and non-Hodgkin’s lymphoma with elevated exposures to electric fields.

Due to the inconsistency of results and the special difficulties in assessing electric field exposure, there is currently little research studying possible associations between electric field exposure and cancer.

**SUMMARY OF EPIDEMIOLOGIC RESEARCH**

In summary, over 100 occupational studies have examined magnetic fields as a potential risk factor for a variety of cancers. A few of these studies also considered electric fields as a risk factor and one investigated the combination of electric and magnetic fields appearing together. These studies have varied widely in the design, types of study subjects, methods of exposure assessment, outcomes considered and quality.

Of the many cancers and exposures examined, a weak positive association exists between occupational exposure to magnetic field and leukaemia and brain tumours; the epidemiologic literature is consistent with either no association or a small association for these cancers. Based on epidemiologic results, overall, breast cancer is not likely to be related to magnetic field exposure.

The likelihood of positive findings due to chance alone is difficult to evaluate. Many of the studies were not specifically designed to test the EMF hypothesis, but rather were secondary analyses of existing data collected for other purposes. Biases are undoubtedly present in many or all of the epidemiologic studies. However, the magnitude and direction of biases in the studies of EMF are not well understood. These potential biases vary from study to study and over time some sources of bias have been largely eliminated, while others remain.

EMF exposure is an uncertain risk factor for the cancers studied based on the small to modest elevation in risk reported in some studies, general lack of a dose–response relationship, possible uncontrolled confounding, and inconsistencies among the studies in specific cancers and in exposures identified as most important. As the methodology of studies improved, the estimates of risk have become lower, making it unlikely that a large risk is being missed.

**LABORATORY STUDIES**

No biophysical mechanisms operating at low levels have been identified, in particular: effects below 5 T are implausible, at about 50 T, no specific mechanism has been identified, but the basic problem of implausibility is removed. Above about 500 T, there are established or likely effects from accepted mechanisms.

As a whole, laboratory research does not support EMF exposure as a carcinogenic agent. Multiple studies have failed to show those cellular or tissue findings usually associated with the transformation of normal cells into neoplastic cells. For example, with certain rare exceptions, EMF has not been shown to be mutagenic, clastogenic or teratogenic, nor has any mechanism been established for weak to moderately strong fields.

A review of animal models for carcinogenicity concluded that long-term continuous exposure to magnetic fields in the range of 2–5000 T is not likely to result in carcinogenesis in rats or mice. Based on available evidence, a weak promoting effect of EMF under certain exposure conditions cannot be ruled out. Most of the studies addressing promotion and progression, however, were negative.

The absence of laboratory evidence of EMF as a cancer-initiating agent has led to some speculation and evaluation of EMF as synergetic with other agents. Juutilainen et al. reviewed effects of such co-exposures in cell culture and short-term animal studies. The results of this analysis showed a high percentage of positive studies, suggesting that EMFs do interact with other physical and chemical exposures. All studies on apoptosis and embryotoxicity were positive while it was not the case for genotoxicity. Most of these studies on combined effects used magnetic fields of 100 T or higher.

Overall, the majority of animal and in vitro studies have found no evidence of genotoxic effects of extreme low frequency (ELF) magnetic fields at field strengths relevant to human exposure.

**Reproductive effects**

Reports of the effects of EMF on human reproductive outcomes, particularly in the occupational setting, are fewer than those of cancer. While there are a number of reports linking some forms of adverse reproductive outcome to occupational EMF exposure, overall, the body of evidence does not support an association between occupational exposure and reproductive outcomes, such as miscarriages or intrauterine growth retardation. Among occupationally exposed populations, a variety of effects has been examined.

**PREGNANCY OUTCOMES AND VIDEO DISPLAY UNIT USE**

The potential influence of occupational EMF exposure on reproduction has been examined among women working with video display units (VDU). Initial concern was based on reports of several clusters of spontaneous abortions and congenital malformations among VDU operators.
Subsequently, several epidemiologic studies provided very limited or no evidence of an association between VDU use and spontaneous abortion or other adverse pregnancy outcome. A study by Goldhaber et al. offered some evidence that extensive work with VDUs had a detrimental effect on pregnancy outcome. However, the results of this study did not show consistent increases in risk with either extent of VDU use or particular job categories. Moreover, both recall and information biases could explain the study findings. With the exception of the study by Schnorr et al., all of these investigations did not involve any measurements of fields produced by VDUs. EMF exposures from VDUs in the Schnorr study were found to be similar to the exposures encountered in the home.

CONGENITAL MALFORMATIONS

Studies of congenital malformations among offspring of VDU operators have also been negative, although most of the studies were small and thus did not have the ability to detect small risks. Furthermore, laboratory studies and appropriate animal models employing VDU signals have not found adverse reproductive effects.

Only a small number of studies looked at paternal occupational exposure to magnetic fields and malformations among the offspring of males exposed to EMF. In 1983, Nordstrom et al. used a written questionnaire to examine reproductive outcomes among Swedish workers employed in high voltage switching facilities. He reported an increase in a variety of malformations. Two more recent studies found no consistent pattern in the relationship between paternal exposure and congenital malformations. While some type of anomalies showed a positive association, others showed negative association with paternal occupational exposure.

Animal studies of possible teratogenic effects of EMF exposure have been conducted with electric and magnetic fields separately at several intensity levels. They have found no association with VDU exposure.

PARENTAL EXPOSURE AND CANCER IN THE OFFSPRING

Childhood leukaemia

Early studies were concerned with childhood leukaemia as a possible consequence of parental exposure. No association was found in any of 24 studies conducted, or in a secondary analysis of a major childhood cancer study in Denver. A 1991 investigation reported an increased risk with maternal exposure to non-ionizing radiation, but not specifically EMF, during pregnancy. Paternal (but not maternal) exposure was associated with an increased risk of childhood leukaemia in one study and for male offspring (but not female) in another one. Thus, findings for childhood leukaemia and parental exposure do not show any consistency.

Brain tumours

Eight case–control studies examined the occurrence of childhood brain tumours or neuroblastoma among the children of fathers whose work presumably exposed them to EMF. As in most occupational studies, exposure assessment was based on job title. Elevated relative risks (above 2.0) reported in two of the studies were not confirmed in later studies. Selective reporting in earlier reports may account for the discrepancy. More recent analyses of childhood brain tumour studies found no association.

In summary, there is little evidence to implicate occupational EMF exposure in the adverse pregnancy outcomes. However, because of methodological problems such as the potential for omission of early miscarriages, recall bias and the fact that the level of EMF exposure under study was not substantially different from the background level, additional studies designed to address these issues may be necessary to resolve this question definitively.

Neurobehavioural and neurodegenerative effects

A number of studies have focused on two categories of possible neurobehavioural effects in occupationally exposed populations: generalized neurasthenic effects and suicide. As a result of the early observations of Soviet scientists on depressive symptoms, several psychologists and industrial physicians conducted studies of such symptoms and found no effects. Other investigators have examined suicide as a possible effect of EMF exposure and while some studies found an increased suicide risk, it has not been consistently confirmed in other occupational studies.

Although the findings do not appear to produce a strong evidence of neurobehavioural effects in humans, there is some evidence of behavioural effects in animal studies. For example, learning ability in laboratory animals exposed to EMF was impaired. Furthermore, some evidence that EMF might influence the secretion of melatonin suggests that both neurobehavioural and circadian effects in occupationally exposed human populations deserve further evaluation.

A series of studies investigated the potential relationship between occupational magnetic field exposure and neurodegenerative diseases, most notably Alzheimer’s disease (AD) and amyotrophic lateral sclerosis (ALS). These investigators also suggested biological pathways that might be responsible for the association.

In summary, there is little evidence to implicate occupational EMF exposure in the adverse pregnancy outcomes. However, because of methodological problems such as the potential for omission of early miscarriages, recall bias and the fact that the level of EMF exposure under study was not substantially different from the background level, additional studies designed to address these issues may be necessary to resolve this question definitively.
Cardiovascular effects

The first epidemiologic study specifically examining the association between occupational magnetic field exposure and cardiovascular diseases was motivated by a hypothesis suggesting that magnetic fields reduce heart rate variability which in turn results in acute cardiovascular events. In support of their hypothesis, Savitz et al. found an increase in risk for death due to acute myocardial infarction and arrhythmia, but not due to chronic heart disease. The hypothesis was supported by the initial findings in a human volunteer study which showed an effect of magnetic field exposure on heart rate variability, and by several prospective cohort studies which suggested that reductions in some components of heart rate variability are associated with increased risk for heart disease, overall mortality rate in survivors of myocardial infarction and sudden cardiovascular death. Most of the epidemiologic studies with rigorous and varied designs which followed showed no effect. In a detailed review and analysis of the totality of evidence, Kheifets et al. conclude that the weight of evidence speaks against an aetiological relation between magnetic field exposure and cardiovascular disease. The potential for interference with implanted medical devices, such as pacemakers, needs to be considered in the case of very high electric and magnetic fields. All patients with pacemaker and defibrillators should be informed of the potential problems that could be associated with exposure to magnetic field. Interference of electric and magnetic fields is usually temporary and moving away from the source will alleviate the response. Advice to patients with these devices is to consult their cardiologist and the device manufacturers if concerned about potential EMF interference.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is now widely used in clinical medicine and new applications with the potential fields of 10 T and higher are being developed. These imaging devices produce static, time-varying magnetic and radiofrequency fields. While the patient is exposed to all of these fields, technicians and other occupational personnel are exposed mostly to the static fields. Occupational exposure during construction and testing of these devices may result in exposure levels above 1 T. Field strengths very close to the machine during typical use may be as high as 10 mT. This field decreases to 1 mT at 3 m from the machine where a technician may stand for a few minutes. Farther away at the operating console, the technician is exposed to a considerably lower field level. The development of interventional magnetic resonance techniques will increasingly involve the exposure of staff involved in clinical procedures during real-time MRI scanning and at much higher levels. From the available scientific data and the magnitude of measured fields, it is unlikely that the health of operators is affected by their exposure to these magnetic fields, but studies capable of rigorously addressing this issue have not been conducted. There are some contraindications for using MRI for individuals with metal implant and pacemakers or who have had operations involving metal aneurysm slips or metal sutures. In addition, caution is indicated for patients who are pregnant and infants.

Exposure guidelines

Exposure standards are based on studies that provide information on the health effects of EMF, as well as the physical characteristics and the sources in use, the resulting levels of exposure and the people at risk. Exposure standards generally refer to maximum levels to which whole or partial body exposure is permitted from any number of sources. This type of standard normally incorporates safety factors and provides the basic guide for limiting personal exposure. There are two main international standards or guidelines: the International Commission on Non-Ionizing Radiation Protection (ICNIRP) and the Institute of Electrical and Electronic Engineers (IEEE). Additionally, many national authorities have developed their own guidelines, which often adopt or modify ICNIRP guidelines. The European Union’s directive to limit occupational exposure to EMF in its member countries, and which was based on ICNIRP guidelines, was introduced in 2004. Its implementation, however, was recently delayed for four years due to concerns that proposed guidelines for occupational MRI exposures are overly cautious and would prevent researchers and practising physicians from using the most recent generations of MRI technology.

Acute effects on the nervous systems form the basis of international guidelines. None of the guidelines consider potential long-term effects, such as cancer, to be sufficiently established to serve as a basis for standards. In particular, exposure limits are based on the acute effects on electrically excitable tissues, particularly those in the central nervous system (CNS). The current ICNIRPlimits for workers are 10 kV/m and 500 T μ for 50 Hz and 8.3 kV/m and 420 μT for 60 Hz. The IEEE exposure levels are 20 kV/m and 2710 μT at 60 Hz. The differences in the guidelines, derived independently by the IEEE and the ICNIRP, result from the use of different adverse reaction thresholds, different safety factors and different transition frequencies, i.e. those frequencies at which the standard function changes slope.
The occupationally exposed population consists of adults who are generally exposed under known conditions and are trained to be aware of potential risks and to take appropriate precautions. By contrast, the general public comprises individuals of all ages and of varying health status and may include particularly susceptible groups or individuals. Therefore, typically, exposure limits for the general public are lower by a factor of 5 than occupational exposure limits or exposures in the ‘controlled environments’, as they are referred to in some guidelines.

CONCLUSIONS

A large body of epidemiologic literature examined the potential health effects of residential and occupational magnetic field exposure. A number of national and international expert panels uniformly concluded that an association between residential exposure and childhood leukaemia development provides the strongest evidence. This relationship, however, cannot be considered causal since alternative explanations, such as bias, could not be excluded with certainty. Lack of a plausible biophysical mechanism and lack of evidence showing carcinogenic effects of magnetic fields in laboratory studies also weakens the argument for a causal effect. This uncertainty of the nature of the observed relationship is reflected in the classification of power-frequency magnetic field exposure as a possible human carcinogen (group 2B) by the International Agency for Research on Cancer and World Health Organization.28,85

Previous epidemiologic evidence also suggested an association between occupational magnetic field exposure or work in electrical occupations and adult leukaemia and cancer of the brain. However, the inadequate quality of exposure assessment, small elevations in risk, general lack of a dose–response relationship, possible uncontrolled confounding and inconsistencies among the studies in specific cancer types and exposures identified as the most important made the interpretation of the data difficult. Furthermore, more recent studies, presumably of better quality, have not strengthened this association – thus real risk increases for these and other cancers, including breast cancer, are unlikely. The data that are available do not meet the criteria of known occupational carcinogenic agents, i.e. EMF does not function either as a mutagen or a complete carcinogen.

An increase in risk of ALS among workers in electrical occupations should be investigated further. The evidence, however, remains weak, and it is unclear what aspects of the workplace exposure (magnetic fields, small electric shocks or some other confounders), if any, are responsible for the observed association. Risk increases in cardiovascular diseases in relation to occupational magnetic field exposure are unlikely in light of the current scientific literature.

Electricity use has grown throughout the industrialized world since the first public power station began operation. Today, the developing nations look to electricity as the means of providing jobs and improving lifestyle. Yet, concern over adverse health effects from electric and magnetic fields generated by electric power delivery and use has been a concern since the 1960s. Much has been learned from the many years of research on EMF and the many studies that have been published to date. It is clear that EMF do not pose a large public health or occupational hazard. The widespread use of electricity justifies research designed to resolve the remaining uncertainties.

Key points

- Exposures to extremely low frequency electric and magnetic fields (ELF, EMF) are widespread and highly variable in many work environments.
- Acute effects on the nervous systems form the basis of international ELF guidelines. None of the guidelines consider potential long-term effects, such as cancer, to be sufficiently established to serve as a basis for standards – mainly due to a lack of generally accepted mechanism or replicated laboratory evidence below guideline limits.
- Although a small risk increase for leukaemia and brain cancer from occupational exposures cannot be entirely excluded, the lack of a clear exposure–outcome pattern suggests that magnetic fields as presently measured are by themselves not responsible. No consistent indication of an association has been found for other cancers, including breast cancer.
- The evidence speaks against an aetiologic role for EMF exposure in cardiovascular disease.
- Among the major neurodegenerative disorders, amyotrophic lateral sclerosis (ALS) has been most strongly and consistently related to electrical occupations, thus warranting further investigation. Multi-country collaborative studies of ALS are needed to clarify this relationship.

Radiofrequency fields

GABOR MEZEI AND LEEKA KHEIFETS

**RADIOFREQUENCY EXPOSURE**

Radiofrequency fields (RF) are a segment of the non-ionizing part of the electromagnetic spectrum. RF frequencies range from a few kHz to several hundreds of GHz. During the past few decades, we have witnessed tremendous advancement and proliferation of technologies using RF energy, and people in all societies are increasingly exposed to various sources and frequencies in the RF range. The public may be exposed to RF produced by AM and FM radio and television broadcast antennae, navigations systems, cordless telephones, wireless local area networks, and increasingly by mobile phone base stations and mobile phone handsets. Occupational exposures to RF may be experienced while operating and maintaining radio and television broadcasting and telecommunications systems. Additional significant sources of occupational RF exposures are dielectric heaters used for heating, sealing and melting vinyl and other materials and from military and civilian use of radar systems. In the medical field, exposures can occur from the use of magnetic resonance imaging (MRI), diathermy or electrosurgery. Workers in the electric utility industry may also be exposed to RF from antennae located on or near electric utility facilities. RF exposure in the far fields (at least several wavelengths away from the antenna) is typically measured as power density in W/m² or mW/cm². In near fields (close to the source of exposure relative to wavelength), exposure to RF is measured as electric and magnetic fields, in V/m and A/m, respectively. Since the actual amount of exposure a person receives from an RF field is also dependent on many factors, such as body size, grounding state of the person and frequency, uniformity and polarization of the field, in addition to field intensity, the internal exposure is typically expressed as specific absorption rate (SAR), in W/kg. Measurement of RF exposures of individuals and human populations appears to be even more complicated than that of extreme low frequency (ELF) due to potential distortions from other objects and bodies. In addition, communication technology is rapidly changing, which further complicates exposure assessment. Meters capable of capturing personal exposures have only recently been developed and are yet to be implemented in large-scale epidemiologic studies. In the RF studies, the lack of details about sources and exposures is still a major obstacle and extensive measurement studies within occupational groups are lacking.

**ACUTE EFFECTS**

Exposure to RF radiation induces heating in body tissues and imposes a heat load on the whole body, thus thermal mechanisms are accepted and prevention of excessive heating (above 1°C) serve as a basis for most international guidelines. Exposure to very high intensity microwave beam can result in skin erythema and burns through tissue heating due to direct energy absorption. High RF may also interfere with pacemakers and other implanted medical devices. Direct contact with or very close proximity to an RF source, through an electric arc, may result in severe burns which tend to heal poorly. The lens of the human eye, due to lack of circulation and inefficient mechanisms to eliminate thermal energy, is known to be sensitive to heat. Therefore, heating due to high RF exposure could result in cataract. Observational studies in human populations, however, did not suggest that long-term, low-level RF exposure is associated with cataract development. Many different effects at low RF energy, thought to be
non-thermal in nature, have been reported in recent studies. Generally, it is thought that such interactions are unlikely to be biologically significant at the RF levels below guidance values, but much of the ongoing research focuses on the search for non-thermal mechanisms.

**Exposure guidelines**

RF exposure guidelines are currently based on avoiding the risk to health that results from localized rises in tissue temperature and from the physiological stress engendered by excessive whole-body heat loads. An SAR of at least 4 W/kg is required to result in an increase of 1°C in the tissue temperature. Present guidance on occupational exposure is based on restricting the RF-induced whole body SAR to less than 0.4 W/kg (a safety factor of 10); a heat-load sufficiently small that its contribution to other possible heat loads, generated from hard physical work and/or imposed by high ambient temperatures, can be neglected. Basic restrictions on localized SARs, averaged over any 10 g of contiguous tissue, are 10 W/kg in the head and trunk and 20 W/kg in the limbs. These are intended to restrict local tissue temperature rises to acceptable levels. Guidance on public exposure incorporates an additional safety factor of five, reducing the basic restrictions to 0.08 W/kg for the whole body and to 2 W/kg for localized exposures. Temperatures are derived from dosimetric calculation and thermal modelling. SARs are also related to external field values via dosimetric calculation.1,2

Of note are recent calculations indicating that for the frequencies in the GHz range far field waves, the whole body SAR is substantially larger for short subjects.5,6

**Cognitive and neurobehavioural effects**

Cognitive and neurobehavioural effects may result in occupational safety hazards if workers’ judgement is impaired. Several studies examined potential cognitive effects of RF exposure from mobile phones in humans in laboratory settings. Earlier studies by Preece et al.7 and Koivisto et al.8 showed shortening reaction times in various cognitive tests but no impairment in overall accuracy. The effects were seen for analogue but not for digital phones. It was hypothesized that these effects were thermal effects due to local tissue heating. Later replication attempts, however, did not show consistent and statistically significant cognitive or neurobehavioural effects.9–12 Nevertheless, electroencephalogram (EEG) changes, effects on regional cerebral blood flow and on sleep have been repeatedly reported in association with RF exposure from mobile phones in human laboratory studies.13–17 The clinical significance of these EEG changes, however, are unclear. As human laboratory studies have been generally conducted at levels generally assumed to be too low to induce significant heating, if robust and replicable effects are identified this will have broad implications for our understanding of the plausibility of non-thermal RF effects in general.

**CHRONIC EFFECTS**

**Cancer**

**EPIDEMIOLOGIC STUDIES**

Several epidemiologic studies examined potential long-term effects, most notably cancer development, in association with RF exposure from various sources. Among cancer types, brain cancer and leukaemia were addressed most extensively in the literature. These epidemiologic studies are generally grouped into three categories based on the source of RF exposure: exposure from occupational sources, residential exposure from radio and television broadcast antennae, and exposure from use of hand-held mobile phones. Only the first type of epidemiologic studies investigated directly the potential health effects of occupational RF exposure and is the focus of this section. Additionally, mobile phone studies are also briefly discussed here because mobile phones produce relatively high exposures to the head and are increasingly part of many occupational environments.

Available case–control studies generally examine specific types of cancer and presumed occupational RF exposure in the general adult population, while cohort studies typically focus on well-defined groups of people exposed to a specific source through their work or hobby. All studies suffer from major methodological weaknesses. None of the studies included RF exposure measurements and exposure classification is often based on job title alone. In addition, no or only limited control for confounding has been made in these studies.

**Occupational case–control studies**

Two studies, conducted in the United States, showed a small increase in the risk of brain tumours in association with assumed occupational exposure to RF.18,19 One of them investigated brain tumours among US Air Force personnel, and assessed exposure through job title and reports of exposure incidents above permissible limits.18 Based on 230 cases and 920 controls, a small but statistically significant risk increase was observed (odds ratio 1.4, 95% confidence interval (CI) 1.0–1.9). The other study compared 435 deaths due to brain cancer to 386 deaths due to other causes identified through death certificates.19 Exposure was assessed based on job titles ascertained through interviews with relatives of the deceased subjects. The study reported a risk increase for brain tumours with assumed occupational exposure with RF (odds ratio 1.6, 95% CI 1.0–2.4); the risk increase, however, was only seen with RF in electrical or electronics occupations and not with RF in other occupations. A third case–control study of occupational RF exposure and brain cancer, recently conducted in Germany included 366 glioma
and 381 meningioma cases. A slight, statistically not significant, increase in risk was observed for both glioma and meningioma. The odds ratios and 95% CI were 1.2 (0.7–2.2) and 1.4 (0.7–2.9), respectively. When the analyses were restricted to the exposure for more than ten years, the observed odds ratios further increased. Finally, in an Australian occupational epidemiologic study of RF exposure and glioma risk, exposure was estimated for 416 cases of glioma and 422 controls based on job titles linked to a job-exposure matrix (JEM) from a study in Finland. No increased risks were observed for self-reported exposure, exposure based on expert assessment or exposure based on JEM.

Both male and female breast cancers were investigated in case-control epidemiologic studies. Demers et al. compared potential exposure to occupational RF of 227 male breast cancer cases to that of 300 controls. Based on seven cases, the authors reported a three-fold but statistically not significant risk increase among radio and communications workers. A 1995 US case-control study compared possible exposure to RF based on job titles from death certificates of women who died of breast cancer to that of women who died of other causes. The authors found no trend in breast cancer risk with either likelihood or level of occupational RF exposure.

Ocular melanoma was examined in two case-control occupational epidemiologic studies. The first of these studies examined 221 cases of ocular melanoma and 447 controls, and obtained exposure information through interviews on a large number of chemical and physical agents. The authors reported a roughly two-fold risk increase of ocular melanoma for subjects ever exposed to microwave or radar through their occupations (odds ratio 2.1, 95% CI 1.1–4.0). A German case-control study of 118 cases of ocular melanoma and 475 controls found a three-fold risk increase with occupational exposure to radio set or mobile phones, but no risk increase with occupational exposure to radar units. The authors acknowledged that methodological limitations of the study may have contributed to the observed inconsistent pattern of associations.

A case-control study of testicular cancer relying on two methods for exposure assessment also reported inconsistent results; while with self-reported RF exposure, the risk appeared to increase three-fold, with RF exposure determined through job titles no risk increases were observed.

A study of 694 cases of non-Hodgkin’s lymphoma and the same number of controls in Australia investigated RF and other occupational exposures based on a Finnish JEM. Based on very small numbers, the authors observed a three-fold, but statistically non-significant risk increase in the upper tertile of RF exposure (odds ratio 3.2, 95% CI 0.6–15.9).

**Occupational cohort studies**

Szmigiel et al. reported statistically significant risk increases with RF exposure for several cancer types of the haematopoietic and gastrointestinal systems and the brain among Polish military personnel based on information obtained from service records. These observations, however, were later attributed to methodological limitations of the study rather than actual risk increases.

Two studies that evaluated cancer mortality among US Navy personnel and veterans in relation to potential radar exposure showed no risk increases for cancer in general, or for leukaemia or brain cancer risks in particular. Although a statistically significant risk increase was seen for non-lymphocytic leukaemia in one of the studies, it was only observed in one of the three highly exposed occupations in that study, and was conflicting with the results from the other study.

Milham examined mortality among about 67000 registered amateur radio operators in California and Washington states. Statistically significant increases were observed in acute myeloid leukaemia and cancers of other lymphatic tissue. Statistically decreased risks were also observed, however, for cancers of the respiratory tract and the pancreas.

Occurrence of cancer was investigated in a cohort of about 2600 Norwegian female radio and telegraph operators. Statistically significant risk increases were observed for breast and uterine cancers; no other types of cancer showed elevated risks. This risk increase may also be explained by potential confounding by shift work. Shift work has recently been classified as a probable human carcinogen by the International Agency for Research on Cancer (IARC).

Among operators of RF sealers in a small Italian manufacturing plant, a non-significant increase in cancer mortality and overall mortality was observed. The results, however, were based on very small numbers.

An excess risk for melanoma and testicular cancer was also found among police officers in Ontario. No information was available on radar use (potential source of RF exposure) in this study.

Researchers at McGill University in Montreal and Institut National de la Santé et de la Recherche Medicales in Paris examined cancer incidence in a cohort of about 170000 workers at two electric utility companies in Quebec and France. They assessed exposure to pulsed electromagnetic fields (PEMF) based on a JEM that was developed based on extensive full-shift measurements using meters calibrated to measure exposure in the 5–20-MHz range. Characteristics of detected fields are unclear because the meters used to measure them were very sensitive to fields at frequencies other than those originally intended by the manufacturer. The authors reported a statistically significant risk increase for lung cancer in the highest exposure category of PEMF. The apparent risk increase persisted even when adjustments were made for various potential confounding variables. Although adjustments were made for exposure to cigarette smoke, a potent lung carcinogen, they may have been incomplete because information on smoking was incomplete. Findings were not confirmed in several follow-up analyses of existing data. Limitations of these follow-up analyses include suboptimal exposure assessment (as they had to use a JEM from the original work) and no information on smoking. Improved assessment of relevant exposures in the workplace,
as well as better information on cigarette smoking, may clarify inconsistencies in these studies.

Cancer mortality of about 200,000 workers of a US wireless-communication products company was examined over a 20-year period by Morgan et al. Exposure to RF was assessed by a qualitative JEM. An expert panel categorized job titles into one of four categories (background, low, moderate, high). No excess risk was found for any type of cancer when the high exposure group was compared to either the background and low exposure groups, or the general population. The validity of the exposure assessment has not been assessed as no measurements were included.

Mobile phone studies

Most epidemiologic studies of mobile phone use examined tumours of the head and neck, mostly brain tumours and tumours of the acoustic nerve. Some of these studies relied on billing records from mobile phone companies to determine use and estimate exposure. This method is often constrained by limited access to billing records and is prone to exposure misclassification due to people sharing phones, using more than one phone, using company phones and switching carriers. Other studies assess exposure based on number and duration of calls, and duration of use in years as reported by study participants. Additionally, type of phone, urban/rural environment and use of hands-free devices can also be assessed in the interview-based studies. The main limitation of this exposure assessment method is the potential for recall bias, which might be particularly important for outcomes with impaired brain capacity. Both exposure assessment methods tend to be limited by lack of information on other factors greatly influencing RF exposure (e.g. signal strength, relative position of antenna, etc.). A novel exposure assessment method incorporating interviews, records and measurements is needed.

Most notable of the mobile phone epidemiologic studies is the ongoing Interphone study, which is a multinational population-based case–control study of mobile phone use and cancer of the brain (glioma and meningioma), the acoustic nerve and the parotid gland among adults in 13 countries. Exposure is assessed by computer-assisted interviews of subjects using standardized structured questionnaires on aspects of mobile phone use, demographic characteristics and exposure to potential other risk factors, such as ionizing radiation and smoking. The study overall will include more than 2700 glioma cases, about 2400 meningioma cases, about 1100 cases of acoustic nerve tumour and about 100 cases of parotid gland tumour. The overall Interphone results are yet to be published. Combined results available from five countries suggest no overall association between regular mobile phone use and tumours of the brain and the acoustic nerve. Subset analyses, however, suggest the possibility of a slight increase in the risk of glioma and, particularly, of acoustic nerve tumours among long-term users (more than ten years). The relatively small number of cases among long-term users, however, does not allow firm conclusions.

In summary, the currently available epidemiologic literature does not provide sufficiently convincing evidence to link RF exposure to brain cancer or other types of cancer. Due to severe limitations in RF exposure assessment and other methodological problems in most occupational RF and mobile phone use epidemiologic studies, the available epidemiologic evidence is also insufficient to rule out any potential effects. Most of the non-cancer outcomes are yet to be properly investigated.

LABORATORY STUDIES ON CARCINOGENICITY

Several two-year bioassays with rodents, such as Sprague–Dawley rats, Fischer rats and mice, were conducted to study the potential carcinogenic effect of long-term, daily RF exposure in typical mobile phone frequency ranges (0.8–1.6 GHz). The exposure systems in most cases were set up to achieve SAR levels of 1–2 W/kg in the brain and about a magnitude lower (0.1–0.4 W/kg) averaged over the whole body. The results of these studies, overall, do not suggest that RF exposure, at these levels, are associated with increased incidence of brain tumours or other tumours.

Similar long-term exposure studies with rodents genetically susceptible to tumour development (e.g. transgenic mice) were also conducted to investigate the effect of RF exposures on cancer development. Although two initial studies showed increased development of lymphoma and mammary tumours, these results were not reproduced in later replication studies. Other rodent studies combined exposure to RF fields with known carcinogenic agents, such as ENU and DMBA. These studies, overall, do not suggest that RF exposure modifies the effects of other carcinogenic agents.

Most genotoxicity studies in animals and cell cultures showed no effect when examining mutation, DNA and chromosome damage, or cytogenetic effects. Positive findings in individual studies could not be replicated independently, and most of these observations may be explained by thermal effects.

REPRODUCTIVE EFFECTS

A number of experimental studies examined possible teratogenic effects of RF exposure among various non-mammalian and mammalian species. Teratogenicity was clearly demonstrated at RF exposure levels that result in maternal body temperature increases of 2°C or more. These exposure levels, however, are well above current guideline limit values. No consistent laboratory evidence is available to suggest non-thermal teratogenic effects at RF exposure levels below guideline values. This research area, however, has received much less attention.

Potential reproductive effects of occupational RF exposure were mostly investigated by epidemiologic studies conducted among physiotherapists using therapeutic microwave or shortwave diathermy. The examined outcomes included delay in conception, miscarriage, stillbirth,
preterm birth, birth defects and change in the offspring sex ratio. Although some of these studies showed increased risks for a few of the examined outcomes, no consistent pattern arose to implicate any specific type of adverse pregnancy outcomes.

Most experimental studies investigating effects of RF exposure on testicular function in rats found no adverse effects, or the decreased sperm parameters were attributed to the effect of hyperthermia. Semen quality was also assessed in several studies among men exposed to RF mostly from military use of radar or microwaves. Some indication of decreased sperm count and density was observed in some of these studies. Two recent cross-sectional studies conducted at infertility clinics showed inverse relationship between semen quality and self-described mobile phone use. Limitations of exposure assessment, the highly selective study population and the cross-sectional design itself preclude any firm conclusions based on these results. Since spermatogenesis is known to be extremely sensitive to heat, some reduction in fertility as a result of low-level RF exposure cannot be ruled out.

CONCLUSIONS

No convincing evidence currently available suggests that occupational RF exposure below current exposure guideline limits results in increased risk of cancer or other adverse health effects. Due to severe limitations in study quality in most epidemiologic studies published to date, with particular deficiencies in exposure assessment, and due to poor current understanding of occupational and other RF exposures, potential adverse health effects cannot be ruled out, either, based on available scientific data.

Key points

- With the rapid advancement of communication technologies, exposure to radiofrequency fields (RF), has increased rapidly both in the general population and in occupational environments.
- Current RF exposure guideline limits are based on avoiding known acute health risks due to local tissue heating and whole body heat loads (thermal effects). No generally accepted mechanism or replicated laboratory evidence exist for non-thermal effects below established guideline limits.
- Current epidemiologic evidence does not point consistently to an increased risk of cancer or other adverse health effects. However, due to severe limitations of available epidemiologic studies and poor understanding of occupational and other RF exposures, potential adverse health effects cannot be ruled out based on available scientific data. Rigorous studies for a variety of outcomes are needed to close this gap.

Introduction

Work-related musculoskeletal disorders (WMSDs) are considered an important source of occupational morbidity. Estimates of the size of the problem and its human and economic costs vary, depending on case definition and the source of the statistics. However, it is believed to represent the largest category of work-related illness in Britain today. The Health and Safety Executive (HSE) estimates that in 2004/5 WMSDs affected a million people and cost society £5.7 billion in direct and indirect costs. Although back pain was the most common complaint (450,000 prevalent cases), disorders of the neck and upper limb were almost as common (375,000 cases).

WMSDs comprise a heterogeneous group of disorders—some well-defined, some ill-defined, whose natural history is for the most part poorly characterized. In some cases the debate concerns whether a recognized clinical entity is actually being described at all; in others it is the epithet 'work-related' that is contentious.

Physicians are most likely to be concerned with the following questions:

1. Which upper limb and neck conditions may be caused or aggravated by work, and which conditions make work difficult to perform?

2. How can such cases be identified clinically and how should they be managed?

3. Who is most at risk? And how can the risk be assessed?

4. What can be done to prevent such problems, and how effective is the intervention likely to be?

Information exists on some of these questions, and this chapter will attempt a synthesis of the available information. However, it will help the reader in interpreting this information to possess some overview of the areas of difficulty and controversy.

The apparently simple question: ‘Which musculoskeletal problems are known to be work-related?’ has proved surprisingly difficult to answer. It is necessary first to state the problem more precisely, for example, to distinguish between exposures that cause a condition, and those that aggravate or accelerate it; and to identify unambiguously the end points of interest (discomfort or disability, accepted rheumatological and orthopaedic conditions or ill-defined regional pain disorders?). In assessing the individual complainant, the clinician would then need to consider several issues that bear on the likelihood of injury or complaint:

- the background level of the disorder and its natural history in unexposed populations (how unusual is its presentation?);
factors personal to the worker (such as age, sex, the individual’s anthropometrics and physical strength, medical history, mental health and threshold for complaint); factors particular to the working environment (e.g. job tasks and ergonomic stressors, workplace psychosocial conditions); and factors arising outside work (such as sport, housework and home craft activities).

He might turn to the epidemiologist for further guidance and would then find that these issues have been studied, to a greater or lesser extent, but that knowledge is incomplete and that its interpretation would be carefully qualified. For example, in general terms, there are data on the prevalence and incidence of complaints in the community, and how these vary by age and sex; many studies describe associations between job title and musculoskeletal complaint, and many others report a link in working groups between mental well-being and upper limb complaint. However, the epidemiologist would point out that most surveys of WMSD have been cross-sectional in design, and may therefore have suffered from the problem of selection bias (for example, those worst affected may have selected themselves out of employment and escaped observation, leading to an underestimate of the problem); also that this study design does not permit the time sequence of events to be observed, and makes it harder to separate cause from effect. (For example, does the association between poor mental well-being and upper limb symptoms stem from a causal relationship, or do anxious and depressed workers simply complain more often than others about their aches and pains?) He would point out that some studies are of pain reports rather than specific diagnoses and that cross comparison is hindered because diagnostic criteria have varied, been ill-defined or not been applied in a uniform or standardized way; and he would say that it has proved difficult to grade the complex biomechanical workplace exposures that combine elements of force, frequency, repetition and movement and then vary them so thoroughly, so that in assessing causality there is scant information on dose–response relationships. The net result is that doctors entertain different views on the relation between work and particular symptom patterns presenting to them.

Two broad groups of musculoskeletal disorders that may be related to work will be considered in this chapter: neck/upper limb pain (Table 57.1) and osteoarthritis. We describe for each principal disorder in turn, its epidemiology, the evidence for its apparent association with work, its clinical presentation and its management. Later in the chapter we consider aspects of detection and prevention, as well as the current path on which research enquiries are headed.

### SHOULDER PROBLEMS

The glenohumeral joint has a greater range of movement than any other joint and this is permitted at the expense of stability. The glenoid fossa is shallow, the capsule is lax and there are no strong traversing ligaments. Stability, therefore, mainly depends on the muscles and tendons of the rotator cuff (supraspinatus, infraspinatus, teres minor and subscapularis), while the deltoid muscle provides a further mechanical support. The joint is protected superiorly by an arch formed by the coracoid process, the acromion and the coracoacromial ligament.

### Epidemiology

Fraying and tearing of the rotator cuff tendons, thickening of the bursae and proliferative changes of the synovium are common age-related phenomena. They are often asymptomatic in life, but may be discovered at post-mortem. However, shoulder pain is also fairly common in community prevalence surveys. Bergenudd et al. reported that 14 per cent of middle-aged men and women in a sample from Malmö, Sweden, had experienced shoulder pain lasting a day or more in the preceding month, and 3 per cent had taken sick leave because of it in the preceding year. A study of 15 268 Stockholm residents reported a point prevalence of shoulder pain of 20 per cent in subjects aged 40–74 years and Dimberg et al. found that 13.1 per cent of workers in an aeroengineering factory had current shoulder pain. Complaints become more common with age, although the Stockholm data suggest a peak around ages
Shoulder problems

55–60 years.9 In the younger age group, there appears to be little difference in prevalence between the sexes, but in the 50s and thereafter men complain more commonly.9

Data on incidence derive principally from the National Morbidity Surveys in General Practice in England and Wales, a general practice-based surveillance system which collects details of consultations in participating practices over a one-year period. The 1981 survey indicated an annual incidence for all shoulder syndromes of 6.6 per 1000 practice-registered patients.10 In the Stockholm survey, a subset of the cross-sectional respondents was interviewed and examined a year on, also providing incidence data: around 1–2.5 per cent had developed a painful shoulder, which included clinically verified restricted movement.9

The peak annual incidence rate occurred in the fifth decade and there was little difference between the sexes.

Occupational studies

Injury appears to arise because of regular impingement of a relatively hypovascular area of the cuff against the acromioclavicular arch, an event that may be aggravated functionally through superior migration of the humeral head in abduction and elevation, or by an acromial spur or degenerative acromioclavicular joint. Studies of blood flow in the supraspinatus muscle11,12 and muscle fatigue13 confirm the importance of postural risk factors in the development of shoulder disorders. Occupational studies have therefore concentrated on working groups who elevate the shoulder repeatedly or for sustained periods at work, such as crop production workers, assembly line and other production workers.

Table 57.2 summarizes some of the older findings, based upon a comparison of occupational titles. Although risk estimates vary, most reports have concluded that there is good evidence of an association between overhead work and shoulder problems. In more recent investigations, exposure contrasts have been defined in terms of work activity, rather than the cruder measure of job title. A number of exposures (e.g. repetitive movements, vibration, high psychological demands) have been studied in this way. Van der Windt et al.,20 in their systematic review, comment that in studies of good methodological quality associations were ‘generally not strong’; while another review by National Institute for Occupational Safety and Health (NIOSH)21 referred to ‘evidence’ (meaning some degree of support) for associations with repeated or sustained shoulder postures with greater than 60° of flexion or abduction, but ‘insufficient evidence’ in relation to vibration and forceful movements. Only recently have prospective studies been undertaken. However, in an Arthritis Research Campaign cohort study of new employees, lifting, carrying, pushing/pulling, monotonous employment and work with the hands above shoulder height were all found roughly to double risks of the relatively softer outcome of new onset shoulder pain during a two-year follow up.22

It should be noted that these studies have mainly investigated the occurrence of rotator cuff tendinitis (defined operationally as localized shoulder pain and tenderness over the humeral head23) or shoulder pain; the relation of other shoulder problems to work activity has not been examined in detail, although they may arise, coexist or become confused with tendinitis, and may certainly contribute to work incapacity when they occur. For this reason, they are described separately under Rotator cuff tendinitis, Calcific tendinitis, Bicipital tendinitis and Shoulder capsulitis (frozen shoulder).

Clinical aspects

ROTATOR CUFF TENDINITIS

Rotator cuff tendinitis (most commonly an inflammation of the supraspinatus tendon), tends to have an insidious onset,
causing a dull shoulder aching or discomfort in the absence of a trauma history. Nocturnal pain is a prominent feature. Pain is felt over the deltoid region, and difficulty is encountered in reaching up, in dressing and in overhead work.

On examination, there may be tenderness over the humeral head and greater tuberosity, and the diagnosis is confirmed by reproducing the pain in resisted movement of the affected tendon. Supraspinatus tendinitis causes discomfort on abduction with a painful arc occurring between 70–120 degrees of abduction.

Chronic rotator cuff tears are often found at autopsy,\textsuperscript{24,25} and in life these tend to be associated with falls on the outstretched hand, as well as overuse, and are noteworthy clinically because of weakness and muscle wasting, and because of the inability to maintain abduction (a positive 'drop off' sign).

Plain x-rays show evidence of calcification in the rotator cuff tendons in 8 per cent of the asymptomatic population over age 30 years,\textsuperscript{26} and sometimes cystic and sclerotic changes at the greater tuberosity insertion. Ultrasound and magnetic resonance imaging (MRI) may be used to demonstrate rotator cuff tears, while arthrography will demonstrate full thickness tears.

**CALCIFIC TENDINITIS**

Calcific tendinitis often arises against a background of chronic shoulder pain on movement and arises at the site of rotator cuff injury and calcification, but it has a clinical pattern distinctive enough to be separately described. Pain is severe, localized to the deltoid area and quite abrupt in onset. Passive and active shoulder movements are greatly limited by pain, and there is extreme tenderness over the humeral head. X-rays reveal well-defined or fluffy calcium deposits in the affected tendon (usually the supraspinatus). The erythrocyte sedimentation rate (ESR) and white cell count are normal. Acute calcific tendinitis is a self-limited process, lasting one to two weeks. Sometimes it occurs spontaneously and not in apparent relation to injury.

**BICIPITAL TENDINITIS**

The long head of the biceps tendon tends to become inflamed as part of a more generalized shoulder problem (such as rotator cuff or adhesive capsulitis), rather than in primary overuse. However, it has occurred following weight lifting, and may well arise occupationally from prolonged repetitive carrying.

Pain occurs over the anterior shoulder, radiates into the biceps and is felt in overhead work and in shoulder extension, abduction and rotation. Tenderness is usually found over the tendon as it passes through the bicipital groove. In Yergason’s test,\textsuperscript{27} pain is provoked over the anterior inner shoulder in resisted active supination of the forearm with the elbow bent at 90°.

**SHOULDER CAPSULITIS (FROZEN SHOULDER)**

The primary form of this condition is characterized by global restriction of glenohumeral movement in all planes in the absence of significant underlying joint disease. It is believed to affect 2–3 per cent of the population\textsuperscript{28} and onset nearly always occurs after the age of 40 years. Classically, there are three phases in the natural history of the condition, each lasting several months: a painful shoulder (phase 1) becomes painful and stiff (phase 2), and then profoundly stiff with slow natural resolution (phase 3). A minority of patients (7–15 per cent) have persistent functional difficulties afterwards.\textsuperscript{29,30}

The onset is insidious, with pain in the deltoid area increasing gradually until sleep is disturbed. In the adhesive phase, there is equal restriction of active and passive glenohumeral movement in a capsular pattern (external rotation more than abduction, more than internal rotation). The aetiology of the condition is poorly understood and a particular relation with work has not been demonstrated thus far.

**Management of shoulder problems**

A Cochrane review by Green et al.,\textsuperscript{31} in summarizing the evidence base on management of shoulder problems, found that certain physical therapies (exercise, laser therapy, ultrasound, pulsed electromagnetic field therapy) offered some benefit over placebo in certain disorders (e.g. rotator cuff disease, adhesive capsulitis, calcific tendinitis), but that more robust conclusions were undermined by small studies with weak statistical power and other methodological limitations. This information gap notwithstanding, a number of treatment options have gained currency in clinical practice.

The treatment of rotator cuff tendinitis is often difficult. Rest and modification of aggravating activities are necessary to prevent the problem becoming chronic. Initial treatment should be directed at reducing inflammation by means of physical therapy (for example, ultrasound) and a non-steroid anti-inflammatory agent. If symptoms fail to settle within three weeks, a subacromial injection of corticosteroid is useful. Once pain has eased and normal shoulder movements have been restored, a muscle-strengthening exercise programme should be instituted, concentrating on rotator cuff exercises. Failure to respond to a conservative programme within a year or so is a reasonable indication for surgical repair of the rotator cuff and release of acromial impingement.

Many therapies have been tried to modify the natural history of adhesive capsulitis of the shoulder joint. The mainstay of treatment remains intra-articular corticosteroid injection during the early phase when pain is the most prominent clinical complaint. During the phase of movement restriction without pain, it has been difficult to demonstrate the efficacy of any modality of treatment...
(including injection therapy, physiotherapy and anti-inflammatory drugs). Carefully directed corticosteroid injections also comprise the mainstay of treatment for a number of other shoulder problems, including acromioclavicular joint dysfunction, bicipital tendinitis and subacromial bursitis.

NECK PROBLEMS

Epidemiology

Neck pain is extremely common. According to studies from Finland and Canada, two-thirds of adults experience neck pain at some time,6,32 in adults aged 25 years and over from the Netherlands the 12-month period prevalence was 31 per cent, with a point prevalence of 21 per cent and a prevalence of chronic symptoms (lasting more than three of the past 12 months) of 14 per cent;33 a study from the UK estimated the prevalence of neck pain lasting greater than one week in the past four weeks in adulthood to be about 14 per cent;34 and three studies from Sweden variously estimated a prevalence of chronic neck pain (more than three or more than six months) of 14–23 per cent.35–37

Prevalent neck pain, including chronic neck pain, is reported more often by older subjects, with a peak sometimes described in mid-life. Chronic neck pain, like back pain, is episodic and recurrent, with many individuals shifting their status over time. Thus, for example, in one study from Saskatchewan,38 the 12-month cumulative incidence of new symptoms was 14.6 per cent among those free of neck pain at baseline, but disabling pain developed rarely, in only 0.6 per cent of the cohort. However, among subjects with neck pain initially, only a third enjoyed a complete resolution a year on, a further third reported persistence, almost 10 per cent experienced an aggravation of symptoms and a fifth had recurrent episodes of discomfort.

Pathogenesis of neck pain

The cervical spine is the most mobile and least stable section of the spine. Pain may arise from vertebrae, intervertebral discs, articulations or the complex system of ligaments and muscles. Unfortunately, although the International Association for the Study of Pain (IASP) recognizes some 60 sources of neck pain, the origin of symptoms is often unclear. Clinical and radiographic features are a weak guide to pathogenesis: tender points, restricted neck movement and degenerative changes on x-ray can be seen in the absence of neck pain.39,40 In the general population, signs and symptoms correlate along a continuum with no distinct clustering suggestive of separate diagnostic entities.40,41

In the absence of clearer clinical pointers to pathogenesis, approaches to the classification of neck pain have varied. The diagnostic outcomes most often studied in occupational research are cervical spondylosis, cervical syndrome, tension neck syndrome and thoracic outlet syndrome, while the most popular classification schemes are those by Waris et al.,42 Viikari-Juntura43 and Ohlsson et al.44

Occupational studies

Neck complaints do appear to show an association with occupation, with lower incidence rates in office workers than in manual workers.45 Four categories of neck problem have been particularly considered in surveys: cervical spondylosis, cervical syndrome, tension neck syndrome and thoracic outlet syndrome.

CERVICAL SPONDYLOSIS

This condition is characterized by degenerative changes in the intervertebral discs (particularly of the lower cervical spine) with the development of osteophytes and spurs. These changes are commonly accompanied by osteoarthritic change in the facet and neurocentral joints. The diagnosis of cervical spondylosis is often made on clinical grounds, but can be made with certainty only by the finding of typical changes on radiographs of the cervical spine. Cervical spondylosis is common from middle adult life and onwards, so that by the age of 65 years nearly everyone (90 per cent) will show radiographic evidence of the disease, irrespective of their occupational history. Some patients complain of stiffness, creaking and pain in the neck (which sometimes radiates to the occiput, shoulders and arms and is made worse by movement of the cervical spine), but many with similar radiographic evidence of disease do not. This lack of consistency between the symptoms and radiographic features of cervical spondylosis is a source of diagnostic difficulty. For these various reasons, surveys aimed at defining the extent and clinical significance of cervical spondylosis in different populations must be of limited value when based simply on the radiographic appearances of the cervical spine and/or symptom questionnaires. Radiographically verified cervical spondylosis has been found to occur significantly more commonly in meat carriers, dentists and miners than other groups.45

CERVICAL SYNDROME

Cervical syndrome is said to be present when pain in the neck coincides with symptom radiation along the distribution of a spinal nerve root. Some authorities also require limitation of neck movement and pain provoked by test manoeuvres before making the diagnosis. Although separately defined, this syndrome most probably arises from nerve root entrapment secondary to degenerative changes in the cervical spine. There have been relatively few studies of cervical syndrome in the occupational setting, and no compelling evidence of work-related risk.
TENSION NECK SYNDROME

Tension neck syndrome (TNS) is reported in Scandinavian and American studies of occupation, but is not described in standard textbooks of rheumatology and orthopaedics, and not widely recognized in the UK. However, it most closely corresponds to a regional pain disorder of the neck–shoulder area. It has been defined as a constant feeling of fatigue or stiffness in the neck associated with other subjective symptoms (such as neck pain or headache) and tender spots, palpable hardenings and neck muscle tightness.23

Such clinical patterns have been described in excess in assembly line workers,46 data entry operators,47 scissor makers,18 lamp assemblers48 and other groups, with reported risk ratios of 2.3 to 7.3. In keeping with this literature, a recent systematic review49 found ‘moderate’ evidence that neck pain with palpation tenderness (TNS) and mixed neck–shoulder disorder (predominantly TNS) were causally related to repetition at the shoulder and neck flexion allied with repetition, but only limited evidence in relation to other factors, such as hand–wrist repetition and static loading in the absence of repetition. In the high quality Danish Project on Research and Intervention in Monotonous Work (PRIM) health study50 – which involved pain-staking reconstruction of work tasks, videotape analysis of rates of repetition and proportion of time spent with the neck in various postures, and prospective blinded standardized assessment of outcome – strong exposure–response gradients were seen with the physical risk factors investigated, and odds ratios were raised by two- to three-fold in those whose jobs typically involved >15 versus 0 shoulder movements per minute or with the neck flexed >20° for at least two-thirds of the time.

Various mechanisms have been suggested for occupationally related TNS, including local muscle ischaemia, disturbed muscular microcirculation and sensitized pain receptors, but no specific pathological lesion has been identified. It seems plausible that tasks involving dynamic loading and tension of the shoulder and neck muscles produce such symptoms, but less clear whether they constitute a defined, discrete WMSD. (This may be a semantic point for occupational physicians who are interested in good ergonomic practice and worker comfort.)

THORACIC OUTLET SYNDROME

A constellation of neurological and vascular features ascribed to entrapment of the brachial nerve plexus and subclavian vessels by a cervical rib or congenital fibrous band. The frequency of this condition is highly contentious – some orthopaedic authors regard the syndrome as very rare in the general population, whereas others describe large panels of successfully treated patients.51 A similar divergence of opinion exists in occupational medicine: some authorities have described high prevalences of the condition in assembly line workers (14–44 per cent),52 while others have reported risk ratios of 2.3 to 7.3. In keeping with this literature, a recent systematic review49 found ‘moderate’ evidence that neck pain with palpation tenderness (TNS) and mixed neck–shoulder disorder (predominantly TNS) were causally related to repetition at the shoulder and neck flexion allied with repetition, but only limited evidence in relation to other factors, such as hand–wrist repetition and static loading in the absence of repetition. In the high quality Danish Project on Research and Intervention in Monotonous Work (PRIM) health study50 – which involved pain-staking reconstruction of work tasks, videotape analysis of rates of repetition and proportion of time spent with the neck in various postures, and prospective blinded standardized assessment of outcome – strong exposure–response gradients were seen with the physical risk factors investigated, and odds ratios were raised by two- to three-fold in those whose jobs typically involved >15 versus 0 shoulder movements per minute or with the neck flexed >20° for at least two-thirds of the time.

Various mechanisms have been suggested for occupationally related TNS, including local muscle ischaemia, disturbed muscular microcirculation and sensitized pain receptors, but no specific pathological lesion has been identified. It seems plausible that tasks involving dynamic loading and tension of the shoulder and neck muscles produce such symptoms, but less clear whether they constitute a defined, discrete WMSD. (This may be a semantic point for occupational physicians who are interested in good ergonomic practice and worker comfort.)

Management

The management of cervical pain syndromes is predominantly non-surgical. Acute exacerbations of neck pain are managed with a soft cervical collar, an eight-week course of combined analgesic and anti-inflammatory therapy and a physiotherapy programme. The physical therapy should include the use of heat pad, neck exercises, ultrasound/short-wave diathermy and massage. Traction and transcutaneous electrical nerve stimulation (TENS) are helpful in controlling brachial root irritation. Manipulative therapy and acupuncture may assist in selected resistant cases. The principal indication for structural imaging (MRI or computed tomography (CT)) is objective neurological deficit. If severe foraminal encroachment or myelopathy is discovered, surgical decompression may become necessary.

ELBOW

The elbow joint actually comprises a compound synovial joint with articulation between the ulnar notch and the trochlea of the humerus, and also between the radial head and the humeral capitellum. In consequence, a large variety of movements are possible, including flexion of 150°, pronation of 75–80° and supination of 85–90°. Apart from epicondylitis and olecranon bursitis, soft tissue problems of the elbow are uncommon.

Epidemiology

Epicondylitis is a pattern of pain at the origins of the extensors of the fingers and wrists on the lateral epicondylo (lateral epicondylitis), or at the origin of the flexors on the medial epicondyle of the humerus (medial epicondylitis). Lateral epicondylitis (tennis elbow) is about seven times more common than medial epicondylitis (golfer’s elbow). The point prevalence of elbow pain has been reported at 11–13 per cent in aeroengineering workers4 and textile workers3 and in a population survey the period prevalence of elbow pain during the previous year was 7 per cent in 40–50 year olds and 14 per cent in those over 50 years.54 However, clinically verified epicondylitis is less common: among the textile workers only 2 per cent had tender as well as painful elbows3 and in a Swedish community survey that included clinical examination the prevalence in 31–74 year olds was...
2.5 per cent. Clinical epicondylitis reaches a peak prevalence and incidence in the fifth decade of life, and becomes increasingly less common after the age of 50 years. It more commonly affects the dominant hand. Although 40–50 per cent of tennis players have the condition, less than 5 per cent of cases arise from the sport.

Aetiology

Lateral epicondylitis is believed to arise principally from overexertion of the finger and wrist extensors – in repeated hand dorsiflexion or in alternating forearm pronation and supination. In those cases coming to clinical attention, there is often a history of unaccustomed, forceful, repetitive use.

However, the pathological lesion remains a point of debate, and there have been at least 25 suggested causes. The most widely held theory is that macroscopic or microscopic tears occur between the common extensor tendon and the periosteum of the lateral humeral epicondyle, and such tears have been identified in surgical procedures, but not consistently enough to resolve the argument.

Occupational studies

Over 20 epidemiological studies have examined workplace physical risk factors and their relation to epicondylitis. A major review by NIOSH found 'insufficient' evidence for associations with repetition and postural factors when considered individually, and only weak evidence in relation to forceful work, but the evidence was considered 'strong' when these factors existed in combination. As examples of the evidence base, in three cross-sectional surveys comparing meat cutters, sausage makers and packers with workers in less strenuous jobs, Viikari-Juntura et al. found that elbow symptoms were 1.6–1.8 times more common in the exposed groups, but the prevalence of clinically verified epicondylitis was identical (0.8 per cent). Dimberg et al. reported a higher prevalence in aircraft factory workers (7.4 per cent), but found no difference between white- and blue-collar workers. McCormack et al. described a relative risk of 1.5 in packers and sewers compared with knitters, a moderate excess of clinical epicondylitis has been described in a cross-sectional survey of public gas and water workers with long-term exposure to strenuous elbow work and Luopajärvi et al. described a similar-sized effect when women packers were compared with non-cashier shop assistants, but these differences are comparatively modest and the confidence intervals for the risk estimates were compatible with chance.

In 1997, when the review was written, just one cohort study had been published, with strongly positive findings: an incidence rate 7–10 times higher in meat cutters and sausage makers (designated as jobs with high force and repetition) relative to other workers. Ten years on, the evidence base is scarcely more extensive, although one case–control and one cohort study point in the same direction. Haahr et al. compared work exposures in 267 cases and 388 referents, recruited from Danish general practices and found associations with various activities performed for three-quarters or more of the time versus never/almost never – namely, arms lifted in front of the body (odds ratio (OR) 4.0 for women), hands bent or twisted (OR 7.4 for women, 3.2 for men), same movements of the arm (OR 3.7 for women) and work requiring precise movements (OR 5.2 for men). In France, where workers have routine statutory medicals, Leclerc et al. reported that jobs that involved repetitive turning and screwing doubled the risks of incident epicondylitis after allowing for other factors.

Clinical aspects

The hallmark of lateral epicondylitis is slow onset pain and tenderness over the lateral epicondyle. The pain is reproduced by resisted dorsiflexion of the wrist with the elbow extended. Grip is impaired and this may limit working ability. In medial epicondylitis, the pain and tenderness (which are medially located) are often less prominent. Pain is reproduced over the medial epicondyle by resisted palmar flexion of the wrist. Investigations are generally unhelpful and unnecessary.

Management

Many treatments have been proposed, though not all have been validated. Placing the arm in a sling or plaster cast may help, but recovery often requires six weeks of immobility. A wrist splint (to prevent wrist dorsiflexion) sometimes provides symptomatic relief. Pulsed ultrasound has been shown to be efficacious, while up to 90 per cent of subjects respond to local injection of corticosteroids. In resistant cases, surgery may be required as a last resort. After conservative treatment relapse is fairly common (18–50 per cent within six months), especially in manual workers such as mechanics and builders. In a case series of 88 workers visiting an occupational health department, splint therapy combined with indomethacin was compared with cortisone therapy; neither duration of absence from work, nor recurrence rate differed between the treatment groups.

It is said that lateral epicondylitis resolves spontaneously in eight to twelve months, but in one rheumatology clinic a majority of sufferers were still symptomatic at the one year stage.

TENOSYNOVITIS AND PERITENDINITIS

There is some confusion in the literature about the appropriate terminology for this lesion. Some authors draw a
distinction between inflammation of the tendon sheath of the wrist (tenosynovitis), the paratendon at the muscle–tendon junction rather further up the arm (peritendinitis), and the tendon itself (tendinitis), but such a distinction is not often drawn in the classification criteria adopted in occupational and community surveys. For this reason, we use the terms interchangeably in this account.

Epidemiology

In the US National Health Interview, 20 per 1000 adults reported that a doctor had told them they had ‘tendinitis’, while in the UK Primary Care Study for 1981, the incidence of tenosynovitis, tendinitis, synovitis and bursitis combined was 10.9 per 1000 persons per year. The incidence was more common in women than men at all ages, and peaked in middle age.

Occupational studies

There have been several cross-sectional surveys of hand–wrist tendinitis in the workplace. In a recent systematic review, elevated relative risks (RRs) were found in four studies of assembly and packing – one in the shoe industry (prevalence ratio (PR) 3.7), one in automobile workers (PR 2.5), one of assembly line packers (PR 4.1) and one of meat packers (RR 36). In addition, two positive surveys were found of meat cutters. A longitudinal study by Kurppa et al. found an incidence rate ratio of 13.9, while an odds ratio (OR) of 3.1 was reported in a smaller investigation by Roto et al. The first of these studies also indicated a high RR (24.1) in women making sausages. Finally, in a cross-sectional study that examined risks by physical activity, jobs that combined high force and high repetition carried a 29-fold greater risk of tendinitis than those lacking such features.

Clinical aspects

The tendons most frequently involved are the radial extensors of the wrist and the long abductor and short extensor of the thumb. The flexor tendons are affected far less often.

TENOSYNOVITIS OF THE WRIST (DE QUERVAIN’S DISEASE)

Tenosynovitis of the wrist (De Quervain’s disease) is characterized by pain on movement, localized to the tendon sheaths in the wrist and reproduced by resisted active movement. Pain is centered on the radial aspect of the wrist and thumb base, and particularly aggravated in grasping and employing the pinch grip. Typically symptoms appear following return to work after a long lay off, or following a change to unfamiliar work requiring new, rapid movements. For example, many cases occurred in the 1940s when people were required as part of the war effort to undertake unaccustomed work in factories and in agriculture. Initially, a dull aching is experienced, but continuation of the work can give rise to severe pain. In the classical case, a sausage-shaped swelling is present on the radial side of the lower part of the dorsal surface of the forearm, proximal to the radial styloid process. The swelling, which is generally about 4 cm long, is tender and crepitus is often palpable and audible over it, sometimes extending up the forearm. Local redness and warmth may occur. In the less florid case, the diagnosis may be confused with osteoarthritis of the thumb base, but radiological assessment assists in this differential diagnosis.

The treatment consists of local heat, non-steroidal anti-inflammatory drugs (NSAIDs), and wrist and thumb immobilization by thermoplastic splinting. In patients with severe or persistent pain, one or more local corticosteroid injections can be helpful, giving complete and lasting relief in about 70 per cent of patients. Surgical decompression of the first extensor compartment (with or without tenosynovectomy) is indicated in those with persistent symptoms lasting longer than six months.

TRIGGER FINGER

Trigger finger is the result of tenosynovitis affecting the flexor tendons of the finger or thumb. The consequent fibrosis and constriction impair the tendon’s motion at the first annular pulley, which overlies the metacarpophalangeal joint. The most common cause of trigger finger is said to be overuse of the hands in repetitive gripping activities. Management consists of modification of hand activity, local heat treatment, gentle exercises and NSAIDs as required. One or more corticosteroid injections to the affected flexor tendons cure the majority of patients. Surgical transection of the fibrous annular pulley is rarely required.

The evidence of benefit in these various treatments usually relates to short-term improvement, and there is clearly a need to demonstrate their longer-term benefit in controlled trials of adequate design. Such trials should reflect the occupational environment in which the pain syndrome developed and the effect of ergonomic interventions instituted during the trial period.

CARPAL TUNNEL SYNDROME

As it passes through the carpal tunnel into the wrist, the median nerve lies immediately beneath the palmaris longus tendon and anterior to the flexor tendons. Conditions that decrease the size of the carpal tunnel or increase the volume of structures contained within it, tend to compress the median nerve against the transverse ligament which bounds the tunnel’s roof. Such circumstances can arise traumatically, congenitally or due to systemic or inflammatory effects (for example, diabetes mellitus, rheumatoid arthritis, acromegaly, hypothyroidism, pregnancy and tenosynovitis).
Epidemiology

The symptoms, signs and nerve conduction abnormalities of carpal tunnel syndrome (CTS), can arise separately, or in combination. Estimates of prevalence and incidence therefore vary according to the chosen case definition. In a large Dutch population survey that took as its definition sensory disturbance in the median nerve distribution occurring at least twice a week, generally waking the patient from sleep, and associated with neurophysiological abnormalities, the point prevalence was estimated at 0.6 per cent in men and 8 per cent in women. In clinically diagnosed CTS occurred with a prevalence of 1.1 per cent in textile workers and 2.1 per cent in other industrial workers. The crude incidence rate is reported to be one per thousand person years in hospital diagnosed patients, and around two per thousand person years in UK primary care (unpublished data from the Royal College of General Practitioners).

Obesity and short stature appear to be independent risk factors for CTS. In case reports, pregnancy, the oral contraceptive pill, the menopause, hysterectomy and breast feeding have all been linked with the syndrome, although epidemiological evidence is contradictory. The condition is often bilateral and symptoms tend to be worse in the dominant hand.

Occupational studies

The relation between CTS and worker activities has been investigated repeatedly. For example, a review by Hagberg et al. in 1992 identified 15 cross-sectional studies and six case-control studies that met high quality criteria for case ascertainment. In the cross-sectional studies, the prevalence of CTS between different occupational groups varied from 0.6 to 61 per cent. Particularly high prevalences and odds ratios were reported in grinders, grocery store workers, frozen food factory workers and platers. The authors concluded that repetitive and forceful gripping were major risk factors for occurrence of the syndrome. Silverstein et al. classified the occupation of 652 workers from seven different industries according to the degree of force and repetition required, and found, compared with low force–low repetition jobs, that both high force and high frequency increased the risk moderately (odds ratios 1.8 and 2.7, respectively), but that the combination of high force and high frequency resulted in an odds ratio of more than 15.

The strongest associations in case-control studies have been with use of vibratory tools and with activities that frequently flex or extend the wrist (Table 57.3). The link with vibratory exposure has also been described in industry-specific surveys, notably among foresters and grocery store workers, frozen food factory workers and platers. The authors concluded that repetitive and forceful gripping were major risk factors for occurrence of the syndrome. Silverstein et al. classified the occupation of 652 workers from seven different industries according to the degree of force and repetition required, and found, compared with low force–low repetition jobs, that both high force and high frequency increased the risk moderately (odds ratios 1.8 and 2.7, respectively), but that the combination of high force and high frequency resulted in an odds ratio of more than 15.

body of evidence that highly repetitious flexion and extension of the wrist can more than double risks of CTS, and recently this association has been accepted for compensation purposes within the terms of the UK State Industrial Injuries Benefits Scheme.

It should be remembered that case-control studies, like cross-sectional surveys, are susceptible to well-recognized biases. The association with a particular exposure may be spuriously inflated by recall bias, or by the effect of disease on work (if the decision to consult relates especially to difficulty in getting the job done). In CTS investigations, however, the studies have been in broad agreement. The more classically specific the case definition, the stronger the association with physical risk factors. Furthermore, it can be demonstrated experimentally that extreme flexion and extreme extension of the wrist increase the pressure in the carpal tunnel sufficiently to impair blood perfusion of the median nerve, so that epidemiological and physiological investigations provide a coherent view of causation.

Clinical aspects

The history is typically one of gradual onset of numbness and tingling in the median nerve distribution of the hand. Strenuous use of the hand usually aggravates symptoms, although this may not become apparent until several hours after the activity. Night-time pain commonly disturbs sleep and patients often hang the affected hand over the side of the bed in an effort to gain relief. Many sufferers also complain of progressive weakness and clumsiness in their hands and tend to drop things.

Tinel’s test (percussion over the flexor retinaculum reproducing paraesthesiae over the median nerve distribution) is positive in about three-quarters of sufferers, and Phalen’s test (sustained complete flexion of the wrist for 1 minute producing symptoms over the median nerve distribution) is positive in a similar proportion. In one large case series, clinical impairment of sensation could be demonstrated over the median nerve in a quarter of cases, and thenar atrophy in a fifth.

The most important diagnostic test is nerve conduction. A slowed sensory nerve conduction velocity across the carpal tunnel and a prolonged distal motor latency support the diagnosis. Electrodiagnostic tests are often quoted as the gold standard, but even the most sensitive latency tests confirm no more than 90 per cent of ‘classical’ clinical cases.

Management

The specific treatment of carpal tunnel syndrome depends to a large degree on whether there is an identifiable cause of the entrapment. Conservative measures may suffice when symptoms are of short duration. Electromyographic determinations repeated over time may help the clinician determine the correct therapeutic approach. Other measures which are known to be of benefit include splinting, local corticosteroid injection, the use of anti-inflammatory drugs and, ultimately, surgical release.

CHRONIC UPPER LIMB PAIN

In describing upper limb disorders, different physicians have used a variety of terms in a variety of ways. For some, ‘work-related upper limb disorders’, ‘cumulative trauma disorders’ and ‘repetitive strain disorders’ are synonymous, and describe collectively the full range of recognized and ill-defined disorders arising (or appearing to arise) from frequent, forceful overuse of the upper limb at work. For others, repetitive strain injury (RSI) refers to a particular diagnosis made by exclusion, i.e. chronic upper limb pain ascribed to overuse at work, for which no clinical diagnosis can be made. Inevitably, confusion has ensued among doctors and especially in medical litigation.

The problem can be illustrated by reference to some topical cases that have attracted publicity. In 1981, an enquiry over upper limb complaints in an Inland Revenue office accepted that complaints, such as lateral epicondylitis and tenosynovitis, could sometimes arise from the use of the visual display unit (VDU). In December 1991, Judge Byre found in the High Court that two British Telecom keyboard operators had RSI that had been induced by the nature of the work (at least 10 000 depressions per hour with a bonus for higher totals) and long hours in constrained postures on defective seating (the complaints were diagnosed as tenosynovitis and epicondylitis). In 1994, a legal secretary received an award for tenosynovitis provoked by periods of intense typing. By contrast, in 1993 Judge Prosser, dismissed the complaints of a Reuters journalist, concluding that ‘RSI did not exist’. Such a ruling plainly does not disprove the existence of well-established entities, like lateral epicondylitis and tenosynovitis, and the debate is really on two different fronts: (1) how often such specific complaints can arise from work activity and (2) whether there is a condition of chronic upper limb pain which presently defies clinical diagnosis, and which may be caused by work. Information on these questions has been tainted by studies that have drawn no distinction between potentially dissimilar clinical end points.

In this chapter we have attempted to draw a clearer distinction. The term RSI in the text that follows refers to chronic upper arm pain for which no diagnosis can be made and which has been ascribed to occupational overuse.

Epidemiology

It has proved difficult to define the epidemiology of a condition for which no clear definition and no validated or accepted diagnostic criteria exist. Routinely collected statistics tend to involve umbrella classifications that make it
Table 57.4  Incidence rates of compensated repetitive strain injury (RSI) by industry in Australia, 1985–86 (adapted from Gun99).

... work in surveys than can be explained by known physical risk factors from the workplace. By the 1990s, the compensation rate in Australia had declined to a more normal level without any reduction in occupational physical demands. Similar transient epidemics have been seen in other countries and other time periods: in Japan, an epidemic of ‘occupational cervicobrachial disorders’ was reported between 1958 and 1982 and an epidemic of writer’s cramp occurred among male clerks in the British Civil Service in 1830. In the Japanese outbreak, the workers who most frequently complained were typists and keyboard operators, punchcard operators and telephone operators (10–28 per cent of people claimed to be affected in some of the occupational groups98). As a result, the Japanese Ministry of Labour introduced guidelines that restricted working time at the keyboard to no more than five hours a day and the maximum number of key strokes to 40,000 per day, and this was followed by a fall in the frequency of complaints.99 Another crop of upper limb complaints developed in the Inland Revenue Department of the British Civil Service in 1981.

The time variation in these various data sets suggests that psychosocial variables play an important part in the presentation and recognition of the condition, if not also in its development.

**Clinical aspects**

Miller et al.100 have described a series of 200 consecutive patients referred for specialist opinion with suspected RSI in whom no other specific diagnosis could be made. In 75 per cent, the onset of pain was gradual, beginning as localized distal pain, but more diffusely spread by the time of clinic attendance. Nearly all of the patients described paraesthesiae and 73 per cent described subjective swelling of the limb. The dominant hand was more commonly affected, but bilateral disease was also common. Anxiety, irritation, mood change, fatigue and sleep disturbance were nearly always present. Clinical signs were generally absent, although most of the patients described tenderness at multiple sites.

In this respect, RSI has many similarities with fibromyalgia, a chronic musculoskeletal disorder of uncertain cause characterized by chronic widespread pain and multiple tender points. Fibromyalgia sufferers also tend to complain of fatigue, sleep disturbance, stiffness and paraesthesiae, and the clinical similarity between these two conditions has led to the suggestion that RSI is a fibromyalgia variant.100,101 Fibromyalgia is fairly common, affecting around 1–2 per cent of the population, 102,103 5–8 per cent of hospital attendees104 and 14–20 per cent of patients referred to a rheumatology clinic.105,106 The diagnostic criteria of the American College of Rheumatologists requires the pain of fibromyalgia to be present for at least three months in all four quadrants of the body and axial skeleton, with tenderness at 11 of 18 defined examination points.107 The
key point of clinical distinction is that fibromyalgia, pain and tender points occur in the trunk and lower limbs, as well as in the arm, shoulder and neck.

It has been suggested that RSI is a condition of pain amplification leading to abnormally low cutaneous pain threshold (allodynia), muscle stiffness and vasomotor changes. However, these ideas remain largely untested. Clinical and some epidemiological observations suggest that personality, emotional state, health beliefs, culture and psyche are important too, and pessimism about recovery is a poor prognostic indicator in arm pain sufferers, even when account is taken of case severity.\textsuperscript{108}

No standard scheme exists to classify case severity in suspected cases of RSI, but the Australian Occupational Repetitive Strain Injuries Advisory Committee of the New South Wales Government of Industrial Relations proposed a three-stage clinical grading scale. The first stage was characterized by aching and tiredness occurring at work but settling overnight. In stage 2 disease, symptoms failed to settle overnight and disturbed sleep, a condition that could persist for several months. Finally, in stage 3 disease symptoms persisted at rest, prevented even light duties and were persistent over months or years. The relation between this proposed clinical grading scheme and the various specific and non-specific disorders that may be encountered in practice remains unclear.

Management

These aetiological components suggest and support a biopsychosocial approach to treatment. A structured rehabilitation programme including graduated exercises, behavioural approaches to pain control, analgesic medication and assistive devices, such as short-term splinting, may achieve dramatic benefits in the small number of severely affected patients. In this subgroup, there is otherwise a very low probability of returning to gainful employment.

DUPUYTREN'S CONTRACTURE

Dupuytren's contracture is a nodular proliferation of fibrous tissue of the palmar fascia which leads to contracture and permanent flexion of the fingers (especially the fourth and fifth fingers) of one or both hands.

Epidemiology

Dupuytren's contracture is a common condition. In northern Europe, for example, it affects about 10 per cent of men aged over 65 years. The condition is more common in men than women, and the prevalence increases with age.\textsuperscript{109}

The condition is frequently bilateral. In a recent case-control study, the condition was found to be independently associated with cigarette smoking and alcohol consumption.\textsuperscript{100} It is also known to be more common in patients with diabetes and epilepsy.

Occupational studies

The relation between Dupuytren’s contracture and acute or cumulative traumatic injury is controversial. Case reports exist of Dupuytren’s contracture arising soon after an acute injury to the hand, such as a penetrating wound, crush injury or fracture,\textsuperscript{111} although epidemiological studies have not been conducted so far to investigate the association more formally. The relation between Dupuytren’s contracture and chronic cumulative trauma has been reviewed recently by Liss and Stock.\textsuperscript{112}

Bennett\textsuperscript{113} observed a standardized morbidity ratio of 1.96 for Dupuytren’s contracture among bagging and packing plant workers as compared with the expected age-adjusted prevalence from an earlier survey, and an odds ratio of 5.5 compared with workers from the local plant who did not undertake these activities. While Mikkelsen\textsuperscript{114} reported a sex-adjusted odds ratio of 3.1 for heavy versus light manual work in a population-based sample from Norway, however, the literature is comparatively sparse.

The relation with use of vibrating tools has been investigated more extensively. Thomas and Clarke\textsuperscript{115} observed that Dupuytren’s contracture was twice as common in 500 men claiming vibration-induced white finger than in 150 controls admitted to hospital for elective surgery. An Italian case–control study\textsuperscript{116} reported an odds ratio of 2.3 for exposure to vibration at work after adjustment for alcohol. In another Italian investigation, Bovenzi \textit{et al.}\textsuperscript{117} observed an increased frequency of Dupuytren’s contracture among quarry drillers and stone carvers compared with stone workers who performed manual work but were not exposed to vibration (odds ratio 2.6, 95 per cent CI 1.1–6.2). Other researchers, by contrast, have failed to observe such an association.\textsuperscript{112}

In summary, there is some evidence that Dupuytren’s contracture may arise from occupational activities and this evidence is strongest for exposure to hand-transmitted vibration. The relation between Dupuytren’s contracture and other manual work is uncertain at present.

OTHER SOFT TISSUE RHEUMATIC CONDITIONS

Two other categories of complaint that may be related to repetitive physical activity are recognized (prescribed) for state compensation under the UK Department for Work and Pensions (DWP)’s Industrial Injuries Disablement Benefits (IIDB) provisions:

- cramp of the hand or forearm ‘due to repetitive movements’;
The ‘beat’ conditions – subcutaneous cellulitis of the hand (beat hand) and subcutaneous cellulitis or bursitis of the knee (beat knee) or elbow (beat elbow).

The epithet ‘beat’ has been removed in a recent revision of IIDB terminology. Carpal tunnel syndrome in vibrating tool users and tenosynovitis are also prescribed.

**Writer’s cramp, telegraphist’s cramp, twister’s cramp or craft palsy**

This is said to be a condition of occupations that involve a great deal of handwriting, typing or other repetitive movement of the hand or arm. According to Department for Work and Pensions examiners’ guidelines, it manifests as symptoms of spasm, tremor and pain in the hand or forearm (Focal dystonia) brought about by attempts to perform a familiar repetitive muscular action, and occurs in the absence of physical signs or detectable abnormalities on investigation. Many physicians would question whether such an entity exists as a defined disease. The time course and chronicity of disease is not clearly defined, and it would appear difficult in practice to distinguish this condition from transient occupational discomfort or chronic non-specific upper limb pain. Despite these uncertainties, around 120 new cases undergo assessment each year for prescription purposes.

**The beat conditions**

These are a more clearly recognized group of disorders. Repeated use of picks, shovels and hand tools in miners, quarrymen and labourers has sometimes been associated with a subcutaneous cellulitis of the hand with associated pain, tenderness, redness and swelling (beat hand) which may leave some residual disability. A sterile bursitis (beat knee) may sometimes arise in work that entails prolonged kneeling, such as coal mining, plumbing or carpet fitting. A similar disorder may arise at the elbow (beat elbow), although its association with occupational activity has been less clearly defined. It is assumed in each of these conditions that repeated physical trauma, friction and pressure are causal factors. It is not known how commonly these complaints occur, but nearly 200 new claims per year are assessed by DWP special medical boards in connection with them.

**OSTEOARTHRITIS**

**Epidemiology and clinical features**

Osteoarthritis (OA) is probably the most common joint disorder in the world. In western populations, radiographic evidence of OA occurs in the majority of people by the age of 65 years, and in about 80 per cent of those aged 75 years and over. The disorder is second only to ischaemic heart disease as a cause of work-related disability in men over 50 years of age.

OA is defined as focal loss of articular cartilage with variable subchondral bone reaction. There is incomplete concordance between these pathological features and radiographic or clinical characteristics of the disorder. However, the difficulties encountered in using a pathological definition for epidemiological studies of OA have led to the widespread use of radiological and clinical markers. The radiographic features conventionally used to define the severity of OA include joint space narrowing, osteophyte, subchondral sclerosis, cyst formation and abnormalities of bony contour. These radiographic features can be incorporated in rating scales at the commonly affected joint sites (for example, the hand, knee and hip), permitting standardized grading of disease severity. The two clinical sequelae of OA that are most relevant are joint pain and functional impairment.

The development of OA at any joint site depends upon a generalized predisposition to the condition, and biomechanical abnormalities that act at specific joints. Individual risk factors that may be associated with a generalized susceptibility to the disorder include obesity, a family history and hypermobility. Those that reflect local biomechanical insults include trauma, abnormalities of joint shape and physical activity, including work.

**Occupational studies**

**KNEE OSTEOARTHRITIS**

The four major non-occupational risk factors for knee OA are obesity, knee injury, meniscectomy and the presence of Herberden’s nodes. Evidence has accumulated in recent years that risk is also increased by work that entails prolonged or repetitive knee bending, squatting, kneeling and load bearing with the knee flexed. These data fall into four categories: (1) comparisons of the prevalence of knee OA in different occupational groups, (2) assessment of the risk of knee OA in different occupations, (3) case–control studies in which general assessments of activity level in the workplace are compared in patients with knee OA and controls and (4) more detailed case–control studies in which a history of specific activities in the workplace is obtained.

Observational studies on the prevalence of symptomatic or radiographic knee OA in different occupational groups date back over 40 years (Figure 57.1). In 1952, Kellgren and Lawrence found that the prevalence of moderate to severe radiographic knee OA was almost six times greater among miners than clerical workers. Later studies in dockers and civil servants, painters and concrete workers and shipyard workers and clerks, all confirmed that the risk of knee OA is greater among men involved in heavy manual labour.
These observations have been extended by a register-based Swedish cohort study, in which the risk of knee OA coming to arthroplasty in various occupational groups was compared with the baseline population risk. Men employed as firefighters, farmers and construction workers presented significantly more often for surgery. Among women, there was a significant excess among cleaners. The risk estimates for these occupations varied from 1.4 to 3.0. These observations agree with the findings of three case–control studies of knee OA in the United States, the Netherlands and Sweden. When workplace activity was classified as heavy or light, the cases in all of these studies were between two and three times more likely to have been engaged in heavy activity occupations before the occurrence of knee OA. However, the risk estimates in all three studies failed to attain statistical significance.

Perhaps the most compelling evidence linking knee OA with occupational activity comes from two population-based surveys in the United States. In an analysis of cross-sectional data from the HANES I study, radiographic OA of the knee at age 55–64 years was three times more common in people whose jobs were judged likely to entail knee bending. In a follow-up study of 1400 men and women from Framingham, the risk of radiographic knee OA was highest in subjects whose earlier jobs were classified as both physically demanding and likely to involve bending of the knees.

In each of these studies, data on knee use in the workplace was obtained by extrapolation from job title rather than through direct questioning about workplace activity, but two British population-based case–control studies of knee OA examined specific occupational activities in some detail. Cases with symptomatic knee OA from a defined population in Bristol were compared with age- and sex-matched controls who had no evidence of knee pain or radiographic abnormality. A lifetime occupational history was obtained, as well as details of specific workplace physical activities (kneeling, squatting, stair climbing, walking, standing, heavy lifting, sitting and driving). The risk of symptomatic knee OA (after adjustment for body mass index and the presence of Heberden’s nodes) was significantly increased among men and women whose major previous occupation had entailed prolonged squatting (greater than 30 minutes daily), prolonged kneeling (greater than 30 minutes daily) and repeated stair climbing (greater than ten flights daily). There was no increase in risk associated with prolonged walking, standing, sitting or driving. Regular heavy lifting (25 kg daily) was not independently associated with an increase in risk, but subjects whose occupations involved heavy lifting and repeated knee flexion in combination had a substantial increase in risk (Figure 57.2). Jobs frequently reported by the cases as involving squatting or kneeling included teaching and nursing in women and steel erecting, electrical maintenance, roofing and other construction work in men. It was estimated from the data that around 5 per cent of all symptomatic knee OA might result from occupations involving repetitive knee use. Extrapolation from the Framingham study suggests an even greater attributable risk.

A second British case–control study by Coggon et al. compared patients listed for surgical treatment of knee osteoarthritis among various occupational groups.
osteoarthritis with age- and sex-matched controls from the same communities. After statistical adjustment for body weight, history of knee injury and the presence of markers of Heberden’s nodes, risks were more than doubled in subjects kneeling or squatting at work for more than one hour per day over at least one year and raised 1.7-fold in those lifting weights of ≥25 kg more than ten times per week for at least a year. There was also an association with occupational climbing of ladders and stairs in men (odds ratio 2.3), but not in women. Even greater risks were reported from work that entailed both kneeling/squatting and heavy lifting (OR relative to neither activity 2.9 in men and 4.2 in women).

The balance of evidence thus favours occupational physical workload as a risk factor for knee OA, with risks being notably high in workers with non-occupational risk factors, such as morbid obesity.

**HIP OSTEOARTHRITIS**

The risk factor profile for hip OA is somewhat different from that for knee OA. There is a weaker association with obesity, hip injury and Heberden’s nodes\(^{118,120}\) and a greater influence from developmental disorders of the hip joint, such as congenital dislocation of the hip, slipped upper femoral epiphysis and Perthes’ disease.

Data on the relationship between specific work activities, such as heavy lifting, and the risk of hip OA are not currently available. However, some studies have compared the occurrence of hip OA according to occupational title. Strong evidence has emerged that one such occupation – farming – is associated with high rates of the disorder.\(^{134}\) Early studies from France, Norway and Sweden suggested that farmers had higher rates of total hip arthroplasty for OA than other occupational groups. In the large Swedish cohort study, which included 250 000 people in the blue-collar occupations,\(^ {126}\) the relative risk for hip arthroplasty among farmers was 3.8 (95 per cent CI, 2.9–3.9). However, farmers may seek treatment more often than other occupational groups, not because they have a higher incidence of the disorder, but because they are more handicapped by it when it occurs. This issue may be addressed by population-based radiographic studies comparing the prevalence of hip OA in farmers and other workers. In a British study\(^ {134}\) comparing men from a defined population aged 60–75 years who had ever been in farming with a group of controls who had spent their entire careers in clerical work, the prevalence of moderate/severe radiographic hip OA (defined as a minimal joint space <1.5 mm) was found to be 18 per cent in the former group, as compared with 2.4 per cent in the controls. This gave a summary odds ratio for hip OA among the farmers of 7.8 (95 per cent CI, 1.8–33.8), a risk estimate comparable with a Swedish study in which 15 000 agricultural workers were asked about previous hip radiography: 565 men and 151 women had had such examinations and the prevalence of hip OA in male farmers was increased more than ten-fold compared to the male population of similar age.

The evidence on farmers has proved sufficiently compelling for hip OA in farmers to be added to the list of prescribed diseases recognized for Industrial Injuries Disablement Benefit in the UK. However, the precise risk factors for hip OA in farmers have not been defined with certainty and it is not known whether an excess risk also exists in other heavy manual workers, such as construction workers and labourers. In a second British case–control study,\(^ {135}\) the risk of hip OA was found to be related to occupations that entailed regular heavy lifting (for example, the daily moving of weights greater than 25 kg by hand), prolonged standing and walking over rough ground, but the magnitude of risk associated with these exposures was much lower than that found in farmers, and further research is warranted.
Management

The goals of management in hip and knee osteoarthritis are to control pain, minimize disability and educate the patient about the disorder and its therapy. The medical modalities of management currently available are shown in Table 57.5 and can be divided into non-pharmacological and pharmacological components.

The role of exercise in knee and hip osteoarthritis has been widely reviewed. Three randomized control trials in patients with knee OA have demonstrated that strengthening of quadriceps muscle with isometric or isotonic exercises was associated with significant improvement in quadriceps strength, knee pain and function, when compared with controls. Recent data suggest that exercise regimens, particularly those incorporating hydrotherapy, have similar benefits at the hip.

Proper use of a stick (in the hand contralateral to the affected knee or hip) reduces loading forces on the limb and is associated with decreased pain and improved function. In addition, patients may benefit from shoe inserts to correct abnormal biomechanical problems arising from angular deformity at the knees. Although trial data are not available, the wearing of shock-absorbing shoes with insoles is believed to be of benefit. Finally, the use of lightweight knee braces may be helpful in patients with tibiofemoral disease, especially if complicated by lateral instability. Education also plays a central role.

Several studies have found that obesity is a major risk factor for the development and progression of knee OA, and in one study, weight loss was associated with lower odds of developing symptomatic disease. Overweight patients with OA of the lower limb joints, especially those being considered for arthroplasty, should be encouraged to participate in a comprehensive weight management programme, including dietary counselling and aerobic exercise.

Pain relief is the main indication for drug therapy in OA. No drugs are available presently that reverse the structural or biochemical abnormalities of the disorder, but chondroprotective agents have been studied in animal models of OA and may become available in the future for human use.

Traditionally, non-steroid anti-inflammatory drugs have been the agents of choice for pain relief. Recently, however, because of concerns about their possible deleterious effects on articular cartilage metabolism, questions about the role of synovial inflammation in natural disease progression and recognition of the greater risk of toxicity from prolonged therapy, the central role of these agents in the treatment of OA has been questioned. Randomized controlled clinical trials suggest that anti-inflammatory agents offer no advantage over paracetamol in simple pain relief, whereas the adverse effects of paracetamol are substantially less than for long-term NSAID use, so paracetamol should be the analgesic agent of first choice in OA. However, anti-inflammatory agents can be used in short courses among patients who have polyarticular disease with synovial inflammation.

In individuals with knee OA who do not respond to oral analgesics or who do not wish to take systemic therapy, topical analgesics or even capsaicin cream can be effective. Finally, patients who do not respond satisfactorily to these modalities may benefit from open or closed tidal knee irrigation with saline.

The response to surgical intervention in osteoarthritis of the hip and knee is dramatic. Pain is the most important single reason for surgery. When pain becomes intolerable or unmanageable by medical means, operative treatment should be considered. Other reasonable indications for surgery include progressive loss of movement, increasing deformity, complications such as sudden locking of the knee and progressive disability and dependency.

RISK FACTORS FOR WORK–RELATED MUSCULOSKELETAL DISORDERS AND INTERVENTION STUDIES

A basic hypothesis exists that WMSDs are caused or aggravated by forceful, repetitive and awkward movements with insufficient rest or recovery time. The evidence from case reports, workplace surveys and a mixed bag of formal epidemiological investigation points in this direction, although, as indicated earlier, evaluation is not straightforward.

A better gold standard might be high-quality blinded randomized control trials, to show that removal of a given exposure reduced the incidence of a given upper limb disorder in a target population. However, in practice some serious methodological challenges arise in mounting such trials – in blinding (where it may be possible to disguise the intervention from the clinician assessing outcome, but not from the participant), in randomization (which is most conveniently allocated at the factory, workshop or plant level), in standardized approach to diagnosis (a common omission), and in implementation (fear of litigation limits the number of employers willing to experiment, there being a bias towards solutions proposed on the basis of ergonomic theory and enforced by regulatory authorities). The evidence that has accrued so far is rather sparse.

However, three recent randomized trials in computer keyboard users suggest that the challenge is now being taken up. Gert et al.136 monitored the incidence of neck–shoulder complaints in workers randomized to receive an ergonomically adjusted workstation or the usual set-up. No important difference was found. By contrast, Aarás et al.137 found a decrease in shoulder pain in parallel with a reduction in trapezius loading in a small group of female data workers, after instituting a training programme with more ergonomic information. Most recently, Rempel et al.138 tested the provision of ergonomic training, a wide forearm support surface and a trackball input device in call-centre workers using computers extensively. Arm board support halved the incidence of neck–shoulder
disorders and reduced weekly pain scores. Whether these findings can be taken as evidence in support of work causation is, of course, a matter of interpretation. However, cohort studies of arm pain and work activity are being undertaken in increasing numbers across Europe and the United States, including studies that include planned elements of intervention, so the evidence base on work causation is set to grow significantly.

In the meantime, a variety of physiological, biomechanical and ergonomic investigations underpin the causal hypotheses, so WMSDs have come to be described as repetition strain injuries or cumulative trauma or overuse disorders. The mechanisms of injury are unclear (and perhaps different for different outcomes), but it is generally felt that undesirable permutations of force, repetition, duration and posture contribute to disease onset.

Unfortunately, work factors of this kind are only too common in industry. High productivity targets and machine pacing encourage highly repetitive actions of short cycle time with limited opportunity for respite. Persistent static loading arises in jobs that involve prolonged standing, holding objects at arms’ length and working above shoulder height for long periods. Work in confined spaces often requires awkward postures that load joints asymmetrically and require prolonged kneeling or squatting. Other common work circumstances include ill-considered workstation, tool and task design, and the manipulation of heavy loads, sometimes under adverse conditions (such as a slippery or uneven footing). Figure 57.3 illustrates some typical situations.

The different risk factors often coexist and in practice it is difficult to disentangle their effects. Thus, undesirable forces matter because of the load they impose on muscles and the torques they impose on joints, but the outcome probably depends upon the degree and direction of loading (posture), its duration and its frequency, muscle fatigue and recovery times. The effort of work can be minimized by ‘good’ postures that allow as many strong muscles to contribute as possible, or exaggerated by ‘bad’ ones, such as poor grip and ulnar or radial deviation of the wrist (which may reduce grip strength by up to 50 per cent) – hence force and posture are interrelated. In general, avoidance of prolonged static loading is desirable, as high intramuscular tensions interrupt the blood supply and enforce anaerobic metabolism, but the problem is heightened if high forces are required, the posture is awkward or effort needs to be maintained for any length of time. Work by Monod and Scherrer139 and Rohmert140 indicates that effort that exerts 50 per cent of the maximal force can last no more than a minute, while field studies suggest that loads of 15–20 per cent at maximum will induce painful fatigue if kept up for days or months.

There are reasons for considering some occupational groups such as typists to be at special risk from these factors. The static loading of the neck and trapezius muscles in VDU workers has been reported to be 20–30 per cent of the maximum voluntary contraction. Furthermore, the increasing use of a computer mouse encourages typists to spend more time with their wrist in ulnar deviation and with their shoulder externally rotated.

The concurrence of risk factors matters particularly as they may act synergistically. The study of carpal tunnel syndrome by Silverstein et al.74 described under Carpal tunnel syndrome, p. 694, provides an example of synergistic interaction between force and repetition: when either was present the risk increased about two- to three-fold, but when present together the risk of CTS was raised many times over.

Approaches to risk assessment and risk reduction take their cue from the putative risk factors, attempting to measure or control some combination of unwanted forces, repetitions and work positions. Many assessment methods have been attempted, though none has achieved primacy. Some techniques are time consuming, expensive and research focused. Others have been advocated for use in the workplace in the assessment and planning of control measures.

Most elaborate are the video recording methods. These often employ pairs or panels of cameras providing alternative views of the work, with markers on the body (such as reflective spots or small lights) to provide measurement points. The results can be digitally encoded and analysed by computer, providing detailed spatial and temporal information on work postures and movements. Alternatively, workers have worn electronic pendulum potentiometers and flexible lightweight tubes containing strain gauge strips that allow reconstruction of postures and movements (again computerized analysis is possible).

Static work activity has been assessed by mapping the various joint angles (for example, using photographs or goniometers), while static workloads and muscle fatigue have been investigated using electromyography (EMG). A high correlation has been shown between EMG activity and muscular force (for both static and dynamic activities), and muscle fatigue can be detected as an increase in the amplitude of the low frequency range of EMG activity. For research purposes, needle electrodes have been lodged in particular muscles, but in workplaces the technique has been adapted so that records can be obtained from surface electrodes.

These various analytical approaches enable biomechanical measurements of force, posture, frequency and duration to be compared with known human capability and the outcomes of health investigations. They further allow comparison across jobs, so that those expected to carry higher risk can be identified.

However, they require special expertise and skills. In occupational practice, simpler more rapid assessment techniques are required, and a number of systems have been proposed. In one of the earliest, the Ovako Working Posture Analysing System (OSWAS) method,141 postures were observed and recorded using a six-figure code during each stage of a representative task cycle. The first
Figure 57.3 Examples of some ergonomic risk factors in the workplace. (a, b) Some tasks requiring high force levels to be applied. (c–h) Some examples of static or awkward posture. three digits represented a fairly crude description of trunk and limb postures. The fourth figure indicated the load or force employed, and the remainder were task designated. The procedure, which requires observer training and standardization, is to glance, look away and record it. For frequent activities the proportion of time in which particular postures are adopted and loads incurred can be estimated.

Other analogous scoring procedures exist for the upper limbs and neck, such as the Rapid Upper Limb Assessment (RULA) technique,\textsuperscript{142} and these generally result in a risk score that is marked against advice on the urgency of corrective action. An alternative approach employs a risk factor checklist. Table 57.6 provides an example. In some cases, it has been suggested that the priority for remedial action should be determined by the number of risk factors identified: the situation is clearly more complicated than this, but in the absence of better information this provides a convenient means for assembling an action plan.

In some cases, these pragmatic tools have been tested empirically against levels of discomfort at work,\textsuperscript{142} but at present there is no hard evidence concerning their predictive value for occurrence of WMSDs, and hence for the adequacy of the risk assessment produced. Nonetheless, they have evident attractions: they can be readily understood and applied, and facilitate attempts to prioritize remedial actions in an area where knowledge is far from complete.

### IDENTIFYING WORK-RELATED MUSCULOSKELETAL DISORDERS

WMSDs arise in the context of a background incidence of musculoskeletal complaint, in workers who do not always seek medical advice. In some cases (as in hip and knee OA), they may present after retirement. Their multifactorial character and, for some disorders their transience, tend to impede detection. In clinical practice a high level of awareness is required if early recognition and intervention are to be achieved.

The starting point should be a knowledge of the occupations and tasks most likely to generate concern. Health professionals and safety managers should also be alert to the possibility of disease clustering. An ‘outbreak’ of apparently related symptoms in workers with a shared exposure suggests the need for wider investigation – for example, a health survey and a review of the work activity. The problem may be circumscribed, or bigger than first appreciated, and the process or materials may have changed, adding unrecognized risk to the job.

Many soft-tissue studies have used the Nordic questionnaire\textsuperscript{143} as the basis of health enquiry. This simple self-completed questionnaire has been developed to standardize the data collected by the researchers, and has been validated to some extent. It allows an estimate of the

Repeated movements and the musculoskeletal system

one-week and one-year period prevalences of limb and neck complaint (such as pain and interference with work), but further assessment would be required before making a clinical diagnosis. Other questionnaires of similar scope have been developed for use in surveys and screening, and some authors have given advice on analysing and interpreting the findings.144

PREVENTING AND MANAGING WORK-RELATED MUSCULOSKELETAL DISORDERS

Success in the prevention of work-related musculoskeletal disorders depends upon an informed assessment of risk, a sharing of information between medical personnel and employees, and a package of risk reduction measures, underpinned by suitable management systems for monitoring and enforcement.

A similar approach will help the affected worker to return to work, and to avoid a recurrent problem.

Preventive measures may include:

1. Advice and training, to ensure a higher risk awareness and better working practices.
2. An induction period, to allow new employees to start work at a slower pace than the established workforce.
3. Job rotation or job enlargement, to provide respite from work that requires repetitive monotonous use of the same muscles and tendons.
4. Rest breaks. These are often advocated as an alternative to job rotation, although little information exists on their value or the length that the break should be.
5. A rehabilitation programme, to ease affected workers back into productive work.
6. Redeployment, in recalcitrant and recurrent cases.
7. Task optimization. Better design of tools and equipment, and a better work layout make the task easier to perform. Often only a little thought is required to reduce work effort and to avoid undesirable working postures. Figure 57.4 illustrates, for example, how one tool and one task were redesigned to eliminate undesirable wrist and shoulder postures. The HSE website provides further useful further guidelines (www.hse.gov.uk/msd/hsemsd.htm).

Work with visual display units in Great Britain now falls under the Health and Safety (Display Screen Equipment) Regulations 1992,145 which are based on the premise that

Figure 57.4 Examples of some simple ergonomic solutions. (a) Redesigning the handles of a tool can lead to more comfortable hand positions and reduce the force required to do the job. (b) In this press operation repositioning of the control panel has eliminated the need for prolonged overhead work. Material taken from HS(G) 60 – Work related upper limb disorders – a guide to prevention, Health and Safety Executive, ISBN 0717619783.147 © Crown copyright material is reproduced with the permission of the Controller of HMSO and Queen’s Printer for Scotland.
use of VDUs is associated with musculoskeletal effects, visual fatigue and mental stress that can be controlled by simple ergonomic principles. Detailed guidance has been provided on the appropriate design of screens, chairs, desks, document holders and foot rests for work stations in users, as well as the need for frequent rest breaks.146

Finally, for non-specific low-back pain, randomized trial evidence has shown that patients tend to fare better if encouraged to remain active within the limits of pain, rather than strictly resting and this begs the presently unanswered research question – whether the same might be true of those with diffuse non-specific arm pain.

## Key points

- Work-related musculoskeletal disorders are common and may be disabling.
- They belong to one of two broad clinical categories: either to one of a number of specific diseases or to one of a number of non-specific pain syndromes. Among the specific disorders, osteoarthritis of the hip and the knee are most important in the lower limb, while shoulder capsulitis and tendinitis, elbow epicondylitis, wrist tenosynovitis and carpal tunnel syndrome are important disorders of the upper limb. However, the relative contribution of specific and non-specific disorders to the overall burden of disease is not well described at present.
- Two broad categories of risk factor are considered important in the causation of work-related musculoskeletal disorders: mechanical and psychosocial. In addition, personal vulnerability, health beliefs, mental health and pain perception may play an important part. The relative contribution of these factors is likewise poorly characterized and may perhaps differ between specific and non-specific disorders. Evidence exists for many health outcomes that adverse ergonomic factors pose a risk, but the role of psychosocial factors in the causation and presentation of disease is more problematic.
- When assessing a patient with musculoskeletal complaints, the physician should always consider whether or not work may have caused or aggravated his condition, whether a rehabilitation programme could ease the patient’s return to work, whether job modifications may be required, to mitigate against the risk of a recurrence and whether the risk posed by existing work circumstances has been adequately assessed and controlled.

Occupational back pain

JOS H VERBEEK AND FREDERIEKE SCHAAFSMA

INTRODUCTION

Back pain is commonly defined as a symptom that originates from a malfunction of a structure in the back. Even though pain is often not felt in the back, the definition also includes pain radiating from the back into the buttocks and the legs because its cause is located in the back. In the majority of cases, the back pain is called non-specific because the cause of the pain cannot be located with current diagnostic methods. Because the pain is mostly felt in the lower part of the back, it is also termed ‘low back pain’, but there is no specific additional value of this adjective because pain higher in the back does not seem to be different from low back pain. Low back pain is reported four times more frequently than mid-back pain.1

In the majority of cases, back pain is a minor affliction only, but the impact on individuals and society is considerable, because in a minority of cases pain becomes chronic and results in long-lasting disability.2 Back pain is limiting in activities where posture must be maintained for a long time (such as standing or sitting) and carrying out specific movements (such as lifting, bending or walking). In turn, the limitation of these activities leads to work disability and the restriction of participation in other important activities. In a small minority of patients, the pain and disability do not subside, leading to unemployment and loss of quality of life. The non-medical indirect costs of back pain that originate from work disability constitute a major proportion of all social security costs or general worker compensation. Chronic suffering and the economic consequences of lost productivity are the major drivers to improve the outcome of disability resulting from back pain.3

This chapter is based on our experience as occupational health physicians both in clinical practice and research. Our experiences are backed up by evidence from the scientific literature. Medline searches for systematic reviews of the specific aspects of back pain, such as aetiology, prognosis and treatment, have been carried out for the most up-to-date research.

HISTORICAL TREATMENT OF OCCUPATIONAL BACK PAIN

Research on back pain cannot be properly understood without some insight into its history. In 1996, Dempe gave an excellent overview of how social factors have influenced the concept of occupational back pain over the centuries.4

Throughout history, there have been descriptions of case reports involving back pain. There are no indications that the incidence of back pain has radically changed over time either in the distant or more recent past.

Views of back pain and theories as to its causes have changed according to prevailing medical opinion. Back pain has historically only occasionally been linked to occupational activities, such as sitting and other static postures. This was mentioned by Ramazzini in his classic work De Morbis Artificum in 1713. Throughout history, back pain has been attributed to rheumatism caused by the collection of rheumatic fluid and phlegm and aggravated by cold and draught.

Between 1850 and 1900, the concept of the ‘irritable spine’ was developed. The theory was formulated that pressure and constant movement could lead to all kinds of symptoms due to irritation of the spine. The irritable spine
was then attributed to the discomfort and injuries endured by travelling by train when railways became more common around 1830. Many injuries occurred while travelling by train due to low safety measures, with resulting legal liability of railroad companies for compensation of passengers injured during collisions. This increased the epidemic of railway spine injuries. However, after thorough discussion in the medical literature, the railway spine sank into oblivion around 1900.

Rheumatism was debated as the cause of back pain through new medical discoveries and measurement techniques. For example, the availability of x-rays around 1900 made anatomical changes in the spine, such as disc and joint degeneration, visible and the German anatomist Schmorl related these findings to autopsy findings. The first operations for herniated intervertebral discs were performed in the 1930s by Mixter and Barr in the United States and these were very influential in research on back pain.5 The first visibly ruptured disc led to an increasing belief that injury was the most important mechanism behind back pain.

Based on these medical developments, the injured back became the model for work-related back pain after the Second World War. The back injury was explained as an overload of the structures in the back. Measuring spinal load thus became an important aspect of research into occupational causes of back pain. Nachemson was one of the first to measure the pressure in the intervertebral disc directly. He showed that the pressure was highest when sitting on a chair without a backrest. This led to increased interest in seating with a proper back support as a means to prevent back pain among workers.

The more recent introduction of magnetic resonance imaging techniques made it possible to view different structures in the back, such as vertebral endplate signal changes and their relation to low back pain. Even though there might be an association with low back pain, it is unclear what their role is in its development.7

Attention being paid to work as the cause of back pain coincided with improved social security in the twentieth century. This led to an exponential increase in the number of people on sick leave due to back pain and later to an increase in the number of people on disability benefit. During the 1970s and 1980s, the main strategy to counterbalance these increases was to improve working conditions. At the same time, the emphasis of working life in industrialized countries changed, at least for men, from heavy physical work in manufacturing industry to administrative work in the service sector.

Medical opinions on the treatment of back pain have changed over time. Until about 1990, the prevailing opinion was that rest was needed to cure the injured structures. One of the landmark studies on the management of back pain was published by the Quebec Task Force in 1987. The group was one of the first to perform a systematic review of the literature and to critically appraise its quality. They proposed a standard nomenclature for back pain diagnosis, diagnosing subgroups with acute, subacute or chronic pain, restricted diagnostic procedures and a non-inference policy for most cases of acute low back pain.8 At about the same time, Waddell published an influential conceptual article in which he proposed to use a biopsychosocial model for the diagnosis and management of low back pain.9

Medical practice also changed as a result of the introduction of clinical practice guidelines based on research evidence from systematic reviews. The American Agency for Health Care Quality and Research produced one of its first guidelines on back pain in 1994. It contained many of the notions on back pain that we currently still use: such as diagnostic triage and continuing ordinary activities in spite of the back pain. To date, occupational medicine associations have made practice guidelines on the management of low back pain at work specifically for occupational health practitioners.10–12

The Cochrane Collaboration started its programme on reviewing the effects of healthcare interventions in 1992. Given the enormous amount of literature on back pain, systematic reviewing is needed to be able to transform this information into knowledge that can be used in practice. To date, the Cochrane Collaboration has produced 46 systematic reviews of prevention and treatment for back pain. The reviews are used as input for the development of practice guidelines.

The various drivers for change of management of low back pain have probably led to considerable changes in practice even though this is difficult to measure.13 Waddell is one of the strongest advocates of these changes and sees this as ‘the back pain revolution’.14

### Prevalence of Back Pain

Because back pain is a symptom, it is fairly easy to ask people about their back pain experience to shed light on the prevalence of back pain. However, different ways of phrasing questions about back pain experience lead to enormous differences in back pain prevalence. Both recall and the intermittent course of back pain lead to biased results. In addition, there is a gradual increase from no pain to severe and disabling pain. It has been agreed that asking about pain in the past four weeks, limitation of usual activities, radiation into the leg, the duration of the pain episode and a numerical pain rating scale probably give the best results for measuring back pain prevalence.15

Given the uncertainties surrounding back pain prevalence, the following figures give a rough indication of the situation.16,17 The lifetime prevalence, meaning a positive answer to the question did you ever have back pain in your life, is around 70 per cent with variations between studies from 11 to 84 per cent. The one-year prevalence (Did you have back pain in the past 12 months?) lies around 50 per cent and varies from 31 to 65 per cent. The point prevalence (Do you have back pain now?) ranges from 12 to 33 per cent. The incidence of new episodes of back pain is estimated to be considerably lower, with population studies reporting an incidence of new episodes of 4 per cent.18
The prevalence of back pain increases from early adult life to the late 40s or early 50s and remains relatively constant thereafter, at least to the mid-60s. In those who continue to have back pain, it is more likely to be more frequent or more constant with increasing age.22–26

Worldwide, 37 per cent of low back pain is estimated to be attributable to occupational risk factors. This fraction varies among different regions in the world and is higher in areas with lower health status in general, mostly due to the high proportion of farmers.20 Overall, the attributable risk fraction was higher for males than for females, largely because of men’s higher participation in the labour force and in occupations with heavy lifting and whole body vibration.

CAUSES OF BACK PAIN AT WORK

Research on occupational back pain, especially epidemiological research, is fraught with difficulties. Both measuring the outcome and the exposure are difficult and easily subject to bias.21 Over the past few years, many research groups have worked on obtaining consensus about which are the best measures to use and how to measure them.22–26 Despite these efforts, there are still a considerable number of measurement options which makes comparison between studies difficult.

The measurement problems also relate to how the development of back pain is conceptualized. We suggest that the clinician should look at back pain as a process starting with pain and finally leading to disability and unemployment. Some people experience only one clearly limited episode of back pain, but for most new episodes occur or the pain becomes a diffuse chronic problem. For others again, these chronic problems lead to disability and loss of employment over time. At different phases of this process, work and other factors have a varying influence on back pain outcome. In the first phase of incident back pain, back pain is thought to be related to work through biomechanical overloading that damages structures in the back. In general, genetic and biological determinants probably play a major role. Which structures cause the pain is unclear and also the relation between overload, damage and back pain is unclear. Personal factors, such as an individual’s beliefs about back pain, play a major role in reporting sick or becoming disabled.

There are a few older systematic reviews of epidemiological studies on work-related aetiology of back pain. The reviews differ considerably in the methodology used, but all come to more or less similar conclusions.

A NIOSH review of epidemiologic research on low back pain and occupational risk factors with 42 studies up to 1997 concluded that there was strong evidence for an association between lifting and forceful movements and back disorders. Thirteen of 18 studies found an association between these work factors and back pain. They also found evidence for an association between work-related awkward postures and back disorders, but not for an association between static work postures and back disorders.27

Burdorf and Sorock28 gathered evidence on a relation between individual characteristics or exposure at work and back disorders from the literature. They used a simple vote-counting method to combine the results of 35 cross-sectional and cohort studies and did not stratify according to study type. They concluded that there is evidence for a relationship between exposure due to manual material handling, frequent bending and twisting, heavy physical load and whole body vibration. They found contradictory evidence for psychosocial factors. For individual characteristics, there was evidence for a relation with back pain for age, smoking and education, and no evidence for a relation for gender, height, weight, exercise and marital status.

In a methodologically better systematic review, Hoogendoorn et al.29 used a rating system to assess the strength of the evidence for a relation between physical load at work and back pain. They based the rating on the methodological quality of 19 cohort and two case-referent studies which had looked into work-related factors. They found strong evidence for manual materials handling, bending and twisting, and whole body vibration as risk factors for back pain. The evidence was moderate for patient handling and heavy physical work, and no evidence was found for standing, walking or sitting.

Later, Lotters et al.30 carried out a systematic review and meta-analysis partly based on similar material as Burdorf and Sorock’s 1997 study.28 The review included 40 studies, 35 cross-sectional and five cohort studies. They adjusted the risk estimates for possible confounders and were able to statistically combine the study results. The pooled OR was 1.5 (95 per cent confidence interval (CI) 1.3–1.7) for manual materials handling, 1.7 (95 per cent CI 1.4–2.0) for frequent bending or twisting, 1.4 (95 per cent CI 1.2–1.6) for whole body vibration, 1.3 (95 per cent CI 1.2–1.5) for job dissatisfaction. Since the proportion of people with back pain in the studies is around 30 per cent, the reported odds-ratios are overestimations of the real risk. Transforming the odds-ratios to risk ratios would yield, respectively, 1.3, 1.4, 1.2 and 1.2 for the risk factors mentioned above. This means that the prevalence of back pain of 30 per cent in a non-exposed population would increase to 39 per cent due to exposure to manual materials handling.

Biomechanics provides another important part of the evidence underpinning the relation between spinal loading and back pain.31 Over the years, there has been considerable progress in measurement techniques that can predict the compression and shear forces on the lumbar intervertebral discs.32,33 Co-contraction of trunk muscles has been identified as an important factor in spinal loading. It has also been observed that due to inappropriate muscle contraction, patients with low back pain exhibit a greater than necessary spinal loading that might maintain their back pain. Waddell very strongly argues that mechanical overloading leads to dysfunction which he defined as any disturbance of normal strength, endurance, flexibility, coordination or balance, but he also admits that there is little evidence to support his theory.14
Biomechanical modelling using a so-called linked segment model can be used to better understand the forces that are elicited by various work tasks and it can be used for preventive purposes. However, it is difficult to translate biomechanical findings to effective interventional strategies. For example, most of our knowledge about lifting techniques is derived from biomechanical models. However, training workers in lifting techniques to prevent back pain has so far led to disappointing results.34

Various other approaches to measure spinal load have been tried in the past. Spinal shrinkage has been postulated as a biomarker for spinal load. It is a precision measurement of body length that enables a measurement of the shrinkage of the spine due to water loss of the intervertebral discs during loading. However, it is unclear what the benefits are over biomechanical modelling.

The advances in research on cartilage structure and metabolism have induced a search for biomarkers that could be used as either markers for spinal loading or as markers for early damage. Even though there have been promising studies, the contribution to unravelling the causes of occupational back pain is still unclear.35

The evidence for psychosocial occupational risk factors for low back pain is more difficult to interpret. There are no objective criteria for psychosocial load and the evidence on this topic has been somewhat contradictory. A systematic review by Hoogendoorn et al.36 published in 2000 found 13 studies, of which five were high quality studies that dealt with social support in the workplace. The authors concluded that there was strong evidence for a positive association between low social support and back pain based on four studies with risk estimates of 1.3 to 1.9. For job satisfaction, they also concluded that there was a positive association with back pain based on seven studies.

A systematic review published in 2001 of 21 studies concluded that there was evidence for a relation between the following six psychological risk factors and back pain: job satisfaction, monotonous work, work relations, work demands, stress and perceived ability to work. The strength of the relationships varied between the studies, but was consistent according to the authors.37

In a more recent systematic review of cohort studies, Hartvigsen et al.38 concluded, based on 40 cohort studies of which ten were considered high quality, that there was no evidence for an association between back pain and perception of work, organizational aspects of work or social support at work.

Person-related factors, such as smoking and obesity, have been studied to find a possible relation with the risk for low back pain.39,40 No clear evidence was found for a causal relation. A previous episode of low back pain is the most strong predictor for future sick listing because of low back pain.41–43

Pre-employment strength testing and ergonomic job design together were seen as the most promising intervention methods in review articles in the 1980s and 1990s.44,45 Snook46 concluded that it appears possible to control back pain by reducing the probability of the initial episode, reducing the length of the disability, and reducing the chance of recurrence. Realization of these goals was deemed possible with a combination of job design, job placement and education/training. However, recent evaluation studies have shown disappointing results from these preventive interventions.

**Exposure limits**

If spinal loading at work is a main risk factor for back pain, then it makes sense to try to reduce spinal load by setting maximum permissible limits. The American National Institute of Occupational Safety and Health (NIOSH) has greatly contributed to this idea by developing a relatively simple risk assessment tool that can be used to assess a ‘recommended weight limit’. The maximum recommended weight limit is 23 kg. The lifting conditions, such as distance of the load to the body and the degree of trunk rotation, have to be specified and entered into a formula which returns a recommended weight limit for these conditions.47 Even though the tool covers a wide range of situations, there remain difficulties in applying it to all workplaces.48,49 It is a serious drawback for its application that there are no studies that have evaluated the effectiveness of the NIOSH standard in reducing back pain due to lifting. Moreover, there are no exposure limits for bending and twisting.

Based on the risk for back disorders, exposure to whole body vibrations has been regulated in the EU. Exposure beyond an intensity of more than 0.25 m/s² is considered potentially dangerous and, beyond 0.50 m/s², it is required to take action to remediate the danger of exposure. The most frequently occurring whole body vibration in forklift trucks would be around 1.0 m/s². There are some studies that have evaluated the effectiveness of measures to reduce whole body vibration if the exposure were above the standard, but they could not show a decrease of exposure.50

**Workplace improvements, participatory ergonomics**

Ergonomics is commonly known as ‘the scientific study of human work’ or ‘the application of scientific information concerning human beings to the design of objects, systems and environments’. Recently, participatory ergonomics has stressed the importance of a participatory approach to prevention and solution finding to increase effectiveness.51

In a review of participatory ergonomic interventions, Cole et al.52 found five studies of which two were randomized controlled trials. In these studies, they found limited evidence that participatory interventions decreased musculoskeletal symptoms with four studies reporting a decrease and one no effect. Effect size could be estimated only in

**PREVENTION OF BACK PAIN AT WORK**

Researchers have proposed various interventions to prevent occupational back pain.
one study and it was small. In a recently published study on the effectiveness of kitchen ergonomics, the intervention did not reduce physical work load nor musculoskeletal disorders. In a partly overlapping review on workplace interventions for computer users, Van Eerd et al. found four studies that showed no effect of workstation adjustments on musculoskeletal symptoms. In another four studies, ergonomics training yielded contradictory results on musculoskeletal outcomes. Even though ergonomic improvements may improve comfort and efficiency, they apparently contribute little to the prevention of back pain.

Pre-employment examinations

In general, researchers are sceptical about the possibilities of reducing health problems through pre-employment selection. The problem is that, at the individual level, it is difficult to tell who is at risk for the disease and who is not. The positive predictive value of tests is low which means that there will be a high number of applicants who will be rejected, but that would never have been afflicted with the occupational disease. As part of an ongoing systematic review, we found three low-quality studies that evaluated pre-employment strength testing with contradictory results.

Worker education and training

A recent Cochrane systematic review found six randomized controlled trials and five cohort studies that evaluated worker training and advice on manual material handling. The included studies all had follow-up times of at least one year and had varying degrees of training intensity and hands-on training. None of the studies showed that the intervention decreased the occurrence of back pain. In their review on workplace interventions for computer users, Van Eerd et al. found four studies on ergonomics training that yielded contradictory results on musculoskeletal outcomes.

Exercise

Exercise is believed to be beneficial for many disorders, including back pain. The following three mechanisms are held responsible for the preventative effect of exercise: (1) strengthening of the back muscles and increasing trunk flexibility, (2) increasing the blood supply to the spine muscles, joints and intervertebral discs and (3) improving mood and thereby altering the perception of pain. A review found six randomized controlled trials that evaluated the effectiveness of an exercise programme for various types of workers in 2001. Four out of five studies that compared exercise with no intervention found a significant reduction in back pain experience and reduced work absenteeism. One study reported inconsistent findings. The conclusion of this review was that there is consistent evidence that exercise may be effective in preventing back pain. One other study reported that exercises are more effective than training in back care, but this result was contradicted in another study.

Reporting of occupational back pain to inform policy-making

Reporting of occupational diseases by physicians has been advocated as a useful instrument to inform policy-makers about preventive policy. Many countries maintain a system through which physicians can report cases of occupational diseases often including occupational back pain. The quality of these systems varies and many do not provide guidelines for diagnosis of the diseases to be reported but rely entirely on the professional expertise of the reporting physicians. Moreover, there is little evidence that reporting of occupational diseases to national registries leads to actual policy changes.

Occupational back pain can best be defined as back pain that for a major part is caused by exposure at work. As a clinical disorder, occupational back pain cannot be distinguished from back pain in general by specific symptoms or signs, nor are there specific tests that can elicit these symptoms or signs. Dutch researchers have constructed a model to calculate the probability of work-relatedness. This three-step method calculates this probability on the basis of data on exposure to established risk factors in the work situation. The calculated probability of work-relatedness provides information that can be used to support professional assessment of the work situation and proposals for improving it in the interests of workers with non-specific low-back pain.

The diagnosis of occupational back pain at the individual level can be at odds with the prevailing advice to continue ordinary activities as much as possible. If back pain is attributed to work, it will be difficult to return to the same job which caused the back pain in the first place. On the other hand, leaving a job because of back pain could easily lead to unemployment. A practical solution could be to discuss the pros and cons of continuing in the same job with the worker.

CLINICAL MANAGEMENT AND RETURN TO WORK

Many workers will experience back pain without occupational exposure, but there will still be a risk of long-term disability and unemployment. These risks are related to personal beliefs about the cause of back pain and the fear of reinjury. Proper management of back pain both within the work organization and by the attending physician probably decrease the risk of long-term disability.

The management of back pain is the topic of clinical guidelines that have been developed in many countries and languages. In principle, the clinical management of occupational back pain is no different from management of back pain in general and the authors refer readers to those clinical guidelines. We will summarize the general principles of clinical management of back pain in the following paragraphs.

For any health professional, it is important to differentiate at an early stage between non-specific low back pain, radicular syndrome and specific low back pain. Based on
the medical history and the physical examination, symptoms and signs for specific diseases can be detected. These signs and symptoms are called red flags because they potentially indicate serious disease. The absence of red flags excludes specific disease and thus leads to a diagnosis of non-specific back pain. The following red flags are mentioned in most clinical guidelines:

- back pain in workers less than 20 or more than 55 years old;
- constant progressive back pain;
- trauma;
- history of malignancy;
- prolonged use of corticosteroids;
- immunosuppression, drug use, HIV;
- general malaise or unexplained weight loss;
- neurological dysfunction (motor dysfunction, sensory abnormalities and/or miction disturbances);
- lumbar kyphosis and/or past history of lumbar lordosis;
- complaints that might relate to an infectious disease.

If one or more of these symptoms or signs are observed, further investigations should be carried out to exclude specific causes, such as a radicular syndrome due to a herniated disc, malignancy, osteoporotic vertebral fracture, vertebral canal stenosis, spondylitis ankylopoetica (Bechterew’s disease) and or forms of spondylolisthesis.

In the history, it is also important to identify psychosocial factors, potential obstacles to recovery and to identify workplace factors (physical and psychosocial) that may be related to the back pain problem and return to work.\(^6\)

People with non-specific back pain can generally be expected to recover, because most episodes settle unexpectedly with or without formal health care. Most patients recover at least enough to return to most normal activities, even if with some persistent or recurrent symptoms. Waddell and Burton\(^6\) state that only 1 per cent progress to long-term incapacity, but this is not backed up by evidence. The problem is not what makes these people develop long-term incapacity, but more so why do some people with a problem such as non-specific back pain not recover as expected.\(^6\) Biopsychosocial factors, separately and in combination, can aggravate and perpetuate disability. Workplace factors, such as the attitude of the employer towards low back pain, attitudes of co-workers, communication at the workplace, rules and regulations around sickness absence management, and occupational health provision are examples of obstacles for recovery.

The following psychosocial factors have been listed by a group of experts as yellow flags for risk of chronicity:\(^5\),\(^6\),\(^4\)

- dysfunctional attitudes, beliefs and expectations about pain and disability;
- inappropriate attitudes, beliefs and expectations about health care;
- uncertainty, anxiety, fear avoidance;
- depression, distress, low mood, negative emotions;
- passive or negative coping strategies (e.g. catastrophizing);
- lack of ‘motivation’ and readiness to change, failure to take personal responsibility for rehabilitation, awaiting a ‘fix’, lack of effort;
- illness behaviour.

The list should be interpreted with caution because not all of these factors are based on findings from rigorous research. Pincus et al. reported conflicting findings on the relation between fear-avoidance and both short- and long-term pain in a review of nine prospective cohort studies.\(^5\) In another review of six cohort studies, she found psychological distress, depressed mood and somatization to be prognostic for chronic pain and to some extent also catastrophizing as a coping strategy.\(^6\)

**Prognosis**

Assessment of prognosis is important because it is important information for workers and employers based on which they can adapt their personal circumstances or work. In addition, it will help the clinician to focus on those patients who need help most as they are at greatest risk of becoming a chronic patient. Most people will recover rapidly from an episode of acute low back pain and most of those absent from work with back pain also return to work within one month.\(^6\) Further but smaller improvements occur up to three months, after which pain and disability levels remain almost constant. Pengel et al.\(^5\) systematic review on prognosis of acute low back pain concluded that, although most people return to work within 12 months, low levels of pain and disability persist. From the studies included, it was not clear if these levels of low-term pain and disability reflect a small subgroup with high levels of pain and disability or a large subgroup with low levels of pain and disability. Nor is it clear whether chronic low levels of pain and disability are due to persistence of the original episode or to recurrences.

Steenstra et al. studied prognosis for duration of sick leave in patients absent from work because of low back pain. They found that the following factors were prognostic for longer sick leave: specific low back pain, higher disability levels, older age, female gender, more social dysfunction and more social isolation, heavier work and receiving higher compensation. A history of low back pain, job satisfaction, educational level, marital status, number of dependants, smoking, working more than eight-hour shifts, occupation, and size of industry or company did not influence duration of sick leave due to low back pain.\(^6\)

**Treatment interventions**

**EXERCISES**

Exercise is widely used as therapy for back pain. A Cochrane review summarized the evidence of the effectiveness of

---

\(^5\) Pincus et al.
\(^6\) Pengel et al.
\(^6\) Steenstra et al.
exercise therapy based on 61 randomized controlled with 6390 participants for chronic back pain patients relative to comparisons at various follow-up periods. The pooled mean improvement in pain score was 7.3 points (95 per cent CI, 3.7–10.9) out of a maximum score of 100, 2.5 points (95 per cent CI, 1.0–3.9) for function out of a maximum score of 100 at earliest follow-up. In studies that included only patients presenting to healthcare providers, mean improvement was slightly better with 13.3 points (95 per cent CI, 5.5–21.1) for pain and 6.9 score points (95 per cent CI, 2.2–11.7) for function.

In patients with subacute low back pain in occupational settings, there is some evidence of effectiveness of a graded-activity exercise programme, although the evidence for other types of exercise therapy in other populations is inconsistent.

In patients with acute back pain, exercise did not have an effect different from other interventions.69

EDUCATION IN BACK CARE

Knowledge of back pain and how to prevent it are assumed to decrease the risk of back pain. Therefore, educational programmes try to increase knowledge on the causes of back pain, often in combination with exercises to improve function or physical fitness. A Cochrane review on back care education included 19 randomized controlled trials with 3584 patients. The authors reported that there is moderate evidence that education in back care provides better short- and intermediate-term effects on pain and functional status than other treatments for patients with recurrent and chronic back pain. There is moderate evidence suggesting that back schools for chronic back pain in an occupational setting, are more effective than other treatments and placebo or waiting list controls on pain, functional status and return to work during short- and intermediate-term follow up.70

BEHAVIOURAL TREATMENT PROGRAMMES

Behavioural treatment emphasizes the modification of behavioural processes assuming that pain and disability are not only influenced by somatic factors, but also by psychological and social factors. A Cochrane review showed that both combined respondent-cognitive therapy and progressive relaxation alone relieve pain more effectively than waiting list control in chronic patients. No significant differences could be detected between various types of cognitive-behavioural treatments, between treatments with the addition of behavioural components and the usual treatment programmes, such as physiotherapy, nor between behavioural treatment and exercises. Whether clinicians should refer patients with chronic low-back pain to behavioural treatment programmes or to active conservative treatment cannot be concluded from this review.71

MULTIMODAL TREATMENT PROGRAMMES

Multimodal treatment programmes are based on the biopsychosocial model of pain which suggests that physical, psychological and social factors play a role in decreasing pain and disability. A Cochrane review on multidisciplinary biopsychosocial rehabilitation showed that only intensive multidisciplinary biopsychosocial rehabilitation programmes with a functional restoration approach improve pain and function.72 Functional restoration programmes refer to any intervention aimed at restoring a reasonable functional level for daily living.73 The idea behind these programmes is that after a certain time, limitation of activities because of low back pain leads to lack of physical fitness, also called ‘deconditioning syndrome’. This is associated with decreased lumbar spine mobility and back muscle strength and endurance, with psychosocial implications, such as increased anxiety and depression. A systematic review on functional restoration programmes showed different results in terms of return-to-work rates for controlled studies. Four studies conducted in the United States reported positive results with return-to-work rates of 80–90 per cent at 1 and 2 years’ follow up. Two studies from Denmark reported better results for functional restoration programmes compared to control groups at four months and one year, but the positive effects disappeared after two and five years. Results on return-to-work improved when programmes incorporated the provision of suitable modified duties.74

Communication, cooperation and common agreed goals between the worker with back pain, the occupational health team, supervisors, management and primary healthcare professionals appears to be important for improvement in clinical and occupational health management outcomes. There is general consensus, but limited evidence, that workplace organizational and/or management strategies can reduce absenteeism and duration of work loss. Examples of such cultures and strategies are an organizational culture committed to health and safety, high stakeholder commitment to improve safety, providing optimum case management and encouraging and supporting early return to work.11,19,75,76 A Cochrane review focusing on return to work outcomes and functional restoration programmes concluded that successful interventions incorporated:77

- a physical conditioning programme specifically designed to restore the individual’s systemic, neurological, musculoskeletal or cardiorespiratory function;
- significant cognitive-behavioural components (e.g. correcting dysfunctional beliefs);
- a close association with the workplace, with work-related goals and outcomes.

CONCLUSIONS

Occupational back pain is a result of spinal loading at work due to lifting, twisting and bending, whole body vibration
and psychosocial factors. The concept is not unequivocal due to a lack of evidence that exposure, physical damage and back pain are interrelated. Attribution of specific causes to back pain has changed considerably over time as a result of social and political factors. Back pain research is complicated due to the difficulty of measuring both exposure and outcome.

Preventative efforts to redesign workplaces, screen workers with limited physical capacities, train and educate workers in proper lifting techniques or the use of office ergonomics have not been shown to be effective in decreasing back pain outcomes.

Advising workers with back pain to continue ordinary activities has been shown to have beneficial effects on back pain-related disability. A simple clinical model of triage and advice will suffice for most workers with non-specific back pain. Workers with specific back pain should be referred to the appropriate medical specialist. Exercises are beneficial for workers with chronic back pain, but the effect size is only modest. The specific diagnosis and reporting of the work-relatedness of occupational back pain should be balanced against the potential increased risk of disability.

In spite of an immense body of scientific publications, the causes of occupational back pain are still not well understood. Improving the methodological quality of both primary research and systematic reviews will help. In addition, better collaboration between different disciplines will be beneficial. Better understanding of the causes of back pain and back pain-related disability are prerequisites for progress in the field.

Key points

- Back pain has a one-year prevalence of about 50 per cent and a yearly incidence of about 4 per cent.
- Factors at work, both physical and psychological, increase the risk of back pain by about 30 per cent. Occupational back pain is defined as back pain that is mainly caused by factors at work.
- Chronic pain and long-term disability occur probably only in a small percentage of back pain episodes and are the main drivers for better therapy and prevention.
- Clinical management of occupational back pain is similar to non-occupational back pain: triage and simple advice about maintaining normal activities suffice in the acute stage. In chronic pain patients, therapeutic exercises reduce pain levels by about 10 per cent and physical exercise is probably also helpful in preventing back pain.
- A work-directed approach involving patients and supervisors reduces the risk of disability and sick leave.

- Most preventive interventions, such as lifting advice and ergonomic improvements, do not lead to a reduction of back pain prevalence.
- Exercise after treatment might help in preventing recurrences of back pain.
- Better understanding of the mechanisms behind pain and disability is needed for progress in prevention and treatment.

Occupational infections

JULIA HEPTONSTALL AND ANNE COCKCROFT

INTRODUCTION

This chapter will consider in turn the main occupations at risk, and the infections associated with each occupation. The occupational groups considered here are:

- healthcare workers and people in related occupations;
- laboratory workers;
- people whose work involves frequent travel or living abroad;
- others.

Workers in almost any occupation may contract an infection as a result of their work, even if the occupation is not associated with a clearly recognized risk of infection, so the possibility that an infection may have been occupationally acquired should always be considered during the initial clinical assessment.

HEALTHCARE WORKERS AND RELATED OCCUPATIONS

Healthcare professionals, ancillary workers and staff in service laboratories have always been at risk of contracting infections from their patients. The spectrum of these infections has changed over time, as a result of changes in the pattern of infectious disease in the general population and advances in immunization and exposure prevention. However, with the exception of smallpox, none of the agents causing infections classically contracted by healthcare workers has been eradicated. A risk of infection, albeit small, remains, especially where lapses in exposure prevention occur. In developed countries, there are regulations covering the control of exposure to infectious agents at work; for example, in Europe there is the Biological Agents Directive, incorporated into the Control of Substances Hazardous to Health (COSHH) Regulations in the UK.¹

Blood-borne viruses

The hepatitis viruses (particularly hepatitis B (HBV) and hepatitis C (HCV)) and the human immunodeficiency virus (HIV) are important causes of occupational infectious disease, especially in healthcare workers. The occupational hazard is increased because of the frequently long carrier phase when patients with undiagnosed infection are relatively well, but nevertheless able to transmit infection. One estimate of the global burden of occupational blood-borne virus infections suggests that 16 000 HCV, 66 000 HBV and 200–5000 HIV infections due to percutaneous exposure may have occurred in healthcare workers worldwide in the year 2000, with the fraction of infections attributable to occupational percutaneous exposure being 39, 37 and 4.4 per cent for HCV, HBV and HIV, respectively. More than 90 per cent of these infections occur in low-income countries, where the prevalence of infection tends to be higher, and where there are fewer resources for occupational health services, or exposure prevention and management.²

EVIDENCE OF RISK OF INFECTION IN HEALTHCARE WORKERS

Hepatitis B virus

Viral hepatitis is a prescribed industrial disease in the United Kingdom in people whose work activities expose
them to frequent contact with blood and body fluids.\textsuperscript{3} It is well recognized that hepatitis B can be transmitted via infected blood and other body fluids, either from those with acute infection or from individuals who have become virus carriers. Hepatitis B virus is usually transmitted by unprotected sexual intercourse, by sharing of blood-contaminated needles or injecting equipment between drug users, and by transmission from an infected mother to her child at or during delivery. It may also be transmitted by transfusion of infected blood, particularly in countries where the prevalence of infection is high and resources for transfusion services are small, and by accidental exposure to blood and other body fluids. It is the transmission by blood-exposure incidents that is particularly relevant to occupational risk.

Surveys undertaken before the hepatitis B vaccine became widely available show an excess of serological markers of hepatitis B infection in workers exposed to blood and body fluids. West\textsuperscript{4} reviewed evidence from a number of seroprevalence studies in the United States and concluded that the overall risk to people employed in health-related fields was four times that of the general adult population; physicians and dentists were at five to ten times the risk of the general population; groups with over ten times the risk included surgeons, clinical workers in dialysis units and mental handicap units, and laboratory workers having frequent contact with blood samples. Later studies confirmed these findings.\textsuperscript{5–8} Among 5813 Italian healthcare workers tested prior to hepatitis B immunization, 23 per cent had markers of past or present hepatitis B infection, including 2 per cent who were HBsAg positive.\textsuperscript{9} A study from Stockholm of healthcare workers enrolling for hepatitis B immunization found a prevalence of hepatitis B markers of 4 per cent, not greater than in the general population, but related to age, duration of healthcare work and history of blood-exposure incidents.\textsuperscript{10} In the United States, a survey of hospital-based surgeons showed a significant rate of hepatitis B infection; 17 per cent of 770 surgeons tested had markers of infection and 0.4 per cent were HBsAg positive.\textsuperscript{11} Risk factors for infection were non-vaccination and surgical practice for ten years or more.

In the United Kingdom, in the 1970s and 1980s, there was an excess rate of acute hepatitis B among healthcare workers compared with the general population. In 1975–79, the average annual rate for men in the whole population was 4 per 100,000, while healthcare workers had rates of up to 36 per 100,000.\textsuperscript{12} In 1980–84, the average annual rate in men in the general population was 6 per 100,000 and again up to 37 per 100,000 among healthcare workers.\textsuperscript{13} However, cases of acute hepatitis B acquired occupationally in the United Kingdom are now rare.\textsuperscript{14} This is likely to reflect the results of the campaign to ensure hepatitis B immunization of healthcare workers and pre-entry medical students; the few cases that did occur in the period of review were in people who had not had hepatitis B vaccine. A similar effect has been seen in the United States, where the reported incidence of acute hepatitis B in healthcare workers is now lower than that in the general population, the result of improvements in transfusion and dialysis safety, the implementation of standard ("universal") infection control precautions, and the use of hepatitis B vaccine.\textsuperscript{15,16}

Even in countries where hepatitis B infection is endemic and the background seroprevalence is high, serosurveys provide evidence that there is an additional occupational risk among healthcare workers. Among 234 dentists in the Philippines, the prevalence of markers of hepatitis B infection was found to be 58 per cent, similar to the prevalence in the general population, but increasing with the number of years in dental practice.\textsuperscript{17} In Japan, a seroprevalence study found that over a third of hospital workers had evidence of previous hepatitis B infection, about the same as that in a group of healthy controls, but that the seroprevalence among nurses and surgeons was significantly higher than in other staff or the controls.\textsuperscript{18} A study in Cairo revealed a higher prevalence of hepatitis B infection markers among non-professional staff (60 per cent) than among doctors and nurses, presumably as a result of non-occupational infection in early life, but still found a relationship between infection markers and blood exposures and years of practice among the physicians.\textsuperscript{19} A serosurvey of healthcare workers in Belize found that 29 per cent had markers of past hepatitis B infection and 1 per cent had detectable HBsAg. Prevalence of hepatitis B markers reached 57 per cent in workers from one ethnic group.\textsuperscript{20} Similarly, a recent serosurvey of 167 surgeons working in hospitals in Lagos, Nigeria, found that 25 per cent were hepatitis B surface antigen positive, compared with 15 per cent of a control group of 193 administrative staff.\textsuperscript{21}

Occupations allied to health care may also carry a risk of hepatitis B infection. A serosurvey of 133 embalmers\textsuperscript{22} found that they had hepatitis B infection markers at about twice the rate of a blood donor comparison group and commonly gave a history of needlestick injuries at work. A Canadian study reported that 13 per cent of staff (and more than 20 per cent of specialized teachers) in a day school for mentally handicapped children had markers of hepatitis B infection.\textsuperscript{23} Emergency medical workers, such as emergency ambulance staff and paramedics, have been reported to have an increased risk of hepatitis B infection.\textsuperscript{24–26} However, other studies of groups of emergency workers and public-safety workers have not found an excess of hepatitis B infection markers. Morgan-Capner and Wallace\textsuperscript{27} found no excess of hepatitis B markers among Lancashire ambulance personnel compared with blood donors; their subjects undertook both routine and emergency work. Studies of police officers,\textsuperscript{28–30} prison officers\textsuperscript{31} and firemen\textsuperscript{32} have not documented an increased risk of hepatitis B infection.

Occupational hepatitis B infection has also been reported in professions unrelated to health care or the emergency services. Outbreaks of hepatitis B have been reported in butchers’ shops\textsuperscript{33,34} apparently spread from infected employees to colleagues as a result of frequent cuts sustained at work. Several studies have found an excess of hepatitis B infection among naval personnel and merchant
seamen; this can be partly explained by work in a healthcare setting for some personnel, but appears to be related mainly to para-occupational factors, such as injecting drug use, unprotected sexual contact and tattooing performed in areas of high endemicity.35–37

Hepatitis C virus (HCV)

Seroconversion after occupational percutaneous exposure to HCV infected blood is well documented,38 although most serosurveys of healthcare workers have indicated that the prevalence of hepatitis C antibodies is low. Abb found hepatitis C antibodies in eight of 738 healthcare workers (1 per cent), compared with much higher seroprevalences among certain patient groups.39 In another study, although only 0.58 per cent of 1033 hospital employees had antibodies to hepatitis C, this prevalence was significantly greater than the 0.24 per cent of 2113 blood donor controls.40 Klein et al.41 found antibodies to hepatitis C among 2 per cent of 456 dentists in New York compared with 0.1 per cent of 723 controls; among a small group of oral surgeons, the prevalence was 9 per cent. Dentists who had antibodies to hepatitis C reported more exposure incidents, and having treated more intravenous drug users in the previous month than did seronegative dentists. Among those dentists who had not been immunized against hepatitis B, 25 per cent had anti-HBs. Some 6 per cent of these had antibodies to hepatitis C, compared with only 2 per cent among those who were anti-HBs negative. This suggests a common mode of transmission for the two viruses, though with a lower risk for hepatitis C.

Later studies confirmed the low prevalence of hepatitis C antibodies among healthcare workers and investigated risk factors. In Argentina, a survey of 439 healthcare workers found antibodies to hepatitis C by enzyme immunoassay in 1.6 per cent.42 In the Johns Hopkins Hospital in the United States, antibodies to hepatitis C were found in 0.7 per cent of 943 healthcare workers and 0.4 per cent of local blood donors.43 Similarly, a study in a London teaching hospital among 1053 healthcare workers exposed to blood and body fluids found antibodies to hepatitis C in 0.28 per cent, no higher than reported in blood donors in the same area.44 Another UK study, from Nottingham, reported similar findings, with antibodies to hepatitis C in 0.2 per cent of 1949 healthcare workers enrolled in a hepatitis B immunization programme.45 Among 343 oral surgeons and 305 general dentists in the United States, 2 and 0.7 per cent, respectively, were found to have antibodies to hepatitis C.46 Hepatitis C infection was more prevalent in those who were older, had more years of practice and had serological markers of hepatitis B infection; but hepatitis C infection was much less common than markers of previous hepatitis B infection (8 per cent in general dentists and 21 per cent in oral surgeons). In serosurveys at 16 Italian hospitals, 2 per cent of 3073 healthcare workers had antibodies to hepatitis C.47 Infection was associated with previous acute hepatitis, blood transfusions, poor housekeeping and older age, but not with occupational risk factors.

The occupational risk of hepatitis C is lower than that of hepatitis B. In a study of hospital-based surgeons in the United States, 0.9 per cent of the 770 surgeons had antibodies to hepatitis C, compared with 17 per cent who had markers of hepatitis B infection and in a study of 3411 orthopaedic surgeons in the United States, 13 per cent without non-occupational risk factors had markers of HBV infection and 1 per cent had HCV antibodies.48 The prevalence of infection markers for both HBV and HCV was higher in older workers.

Human immunodeficiency virus (HIV)

In contrast to hepatitis B and C, the studies that have examined the seroprevalence of HIV among healthcare workers have found a low seroprevalence and no evidence of an excess related to occupation; most healthcare workers with HIV will have acquired it non-occupationally. For example, in a study of orthopaedic surgeons in the United States, none of the 3267 surgeons without non-occupational risk factors had antibodies to HIV.49 In six urban areas of the United States, only two of 8519 healthcare workers who had donated blood were HIV positive; information was not available on non-occupational risks.50

TYPES OF EXPOSURE AND RISK OF TRANSMISSION IN THE HEALTHCARE SETTING

The most important means of transmission of blood-borne viruses in the occupational setting is by percutaneous exposure to infected blood, either by skin-penetrating injuries with blood-contaminated needles (needlestick injuries) or by cuts with scalpels or other sharp instruments contaminated with blood (sharps injuries). There is a lower risk of transmission associated with mucocutaneous exposure: blood contamination of eyes, mouth and broken skin. In addition, cases of hepatitis B, hepatitis C and HIV transmission by skin-penetrating bite have been reported. Blood-borne viruses do not cross intact skin, and faeco-oral transmission does not occur.

Blood exposure is particularly common in surgery. Lowenfels et al.51 contacted surgeons in New York by letter or telephone and reported a median rate of puncture injuries of 4.2 per 1000 operating room hours, with 25 per cent of the surgeons having injury rates of nine or more per 1000 operating room hours. Hussain et al.52 asked 18 surgeons in Saudi Arabia to record all accidental injuries during surgery and reported that sharps injuries occurred in 5.6 per cent of operations. An observational study of 1307 surgical procedures at San Francisco General Hospital revealed accidental blood exposures in 6.4 per cent of procedures and percutaneous exposure to blood in 1.7 per cent.53 The risk of blood exposure was highest for procedures lasting more than three hours, when blood loss exceeded 300 mL, and for major vascular and gynaecological procedures. The lower rate of injuries in San Francisco was thought to reflect greater attention to safe practices because of the high rate of HIV infection among the patients.
However, in a later prospective observational study in four hospitals in the United States, sharps injuries were noted in 6.9 per cent of procedures\textsuperscript{54} and injuries were recorded by operating theatre staff in Glasgow at a rate of 1.6 per cent per surgeon per operation, calculated to give 4.6 per cent per operation overall.\textsuperscript{55} Williams\textsuperscript{56} studied blood exposures in theatre staff during 6096 operations over a six-month period. Sharps injuries occurred in 1.6 per cent of operations. The risk was increased with long procedures, high blood loss, major operations, wound closure with staples and the main surgeon wearing corrective spectacles. It was concluded that wearing spectacles could be a surrogate for increased age and reduced manual dexterity or that the spectacles themselves could be obscuring the operative field.

Blood exposures other than sharps injuries are also common in surgical practice. These include glove tears and perforations,\textsuperscript{57–59} and eye splashes with blood and other body fluids.\textsuperscript{60–62} It has been reported that even minor suturing procedures undertaken in the Accident and Emergency Department are associated with one or more glove perforations in 11 per cent of cases.\textsuperscript{63}

The risk of blood exposures is not confined to surgery. Albertoni \textit{et al.}\textsuperscript{64} found an overall rate of needlestick injuries over a one-year period of 29 per cent among 20 000 Italian healthcare workers interviewed in 1985; the rate was highest among surgeons (55 per cent) and nurses (35 per cent). Collins and Kennedy\textsuperscript{65} have reviewed a number of studies of sharps injuries among groups of healthcare workers and compared the results in terms of needlestick injuries per 100 employee-years for different occupational groups. Nurses appear to suffer the highest number of injuries, even allowing for the number of nurses employed. A group of workers at particular risk are phlebotomists, who spend most of their working day using needles to gain access to veins.\textsuperscript{66} Other groups at risk include domestic and portering staff, who get injured from improperly disposed needles and other sharp instruments, and laboratory staff.

Relatively few injuries in reported studies occur to doctors. Sharps injuries and other blood and body fluid exposures have also been found to be frequent among embalmers.\textsuperscript{57}

Surveys of routinely reported incidents must be interpreted with caution because of the high rate of under-reporting, particularly among doctors. Some authors have attempted to quantify this under-reporting. Astbury and Baxter\textsuperscript{66} using questionnaire responses to estimate the incidence of sharps injuries and bites and scratches over the preceding year, found that only 5 per cent of injuries had been reported by staff to the hospital occupational health service. The low (45 per cent) response rate to their questionnaire may have biased their results. McGeer \textit{et al.}\textsuperscript{69} reported a less than 5 per cent reporting rate for sharps injuries among medical students, interns and residents in Toronto, but they asked respondents to recall incidents occurring over several previous years, which may have led to inaccuracies. A questionnaire study of 158 operating department staff at the Royal Free Hospital in London on reporting of needlesticks recorded 26 sharps injuries and 240 other blood-exposure incidents during the preceding month; only 15 per cent of the sharps injuries and none of the other blood exposures were reported to the occupational health department (or indeed to anywhere else).\textsuperscript{70}

**TRANSMISSION RISKS**

The risk of transmission of HBV to a susceptible person following a single needlestick from a source who is HBeAg positive may be as high as 30 per cent. The risk of transmission when the source is HBsAg positive but HBeAg negative is much lower, with studies reporting rates of transmission of between 1 and 6 per cent (see Table 59.1 for a description of HBV serology).\textsuperscript{71–74} The risk of hepatitis C transmission is around 2 per cent,\textsuperscript{75–79} ranging from 0 to 10 per cent depending on the clinical status of the source patients and the tests used to identify infection in

the workers, markedly lower than for hepatitis B. The overall risk of transmission of HIV after percutaneous exposure to infected blood has been extensively studied and is around 0.3 per cent.\cite{80,81}

Some exposures may be of higher risk than others. A case–control study suggested that factors increasing the risk of HIV seroconversion after a percutaneous exposure to HIV-infected blood include: a ‘deep’ injury; the presence of visible blood on the instrument; procedures involving insertion of a device into an artery or vein; and exposure to a source patient who is terminally ill.\cite{82} These are probably proxy measures for increased risks associated with exposure to a greater volume of blood and exposure to higher titres of HIV. Similarly, a recent European case–control study found that the risk of HCV seroconversion after percutaneous exposure increased with deep injuries and procedures involving placement of a hollow-bore needle in the source patient’s vein or artery, and also suggested that the transmission risk increased with titre of virus in the source patient.\cite{83}

By 2002 (the latest date for which aggregate data from published reports worldwide are available), there were 106 reported cases of documented HIV seroconversion after occupational exposure and a further 238 reported cases of possible occupationally acquired infection.\cite{81} Most (87 per cent) of the documented seroconversions were reported from the United States or Europe; relatively few were reported from high-prevalence low-income countries, which have limited resources for occupational health and the enhanced surveillance needed to document seroconversion. Of the 57 documented seroconversions reported from the United States between 1991 and 2006, only three occurred after 1995, with the most recent in 1999.\cite{84} This decline in incidence probably reflects a combination of factors: improved exposure prevention; improved post-exposure management, and the widespread use of highly active antiretroviral therapy for HIV infection, which, by reducing the numbers of HIV-infected people needing inpatient treatment for advanced HIV-related disease, reduced the overall transmission risks for healthcare workers.\cite{85}

**CLINICAL FEATURES IN INFECTED HEALTHCARE WORKERS AND RISK OF TRANSMISSION TO PATIENTS**

The clinical features of infections with blood-borne viruses acquired occupationally by healthcare workers are essentially no different from the features of these infections acquired by any other means.

**Hepatitis B**

Acute icteric hepatitis, sometimes fulminant, can occur three to six months after occupational exposure to the virus in non-immune workers; though only around a third of adults who become infected will develop clinically significant symptoms. In clinically apparent hepatitis, a prodromal illness with fever, nausea, anorexia and abdominal discomfort precedes the development of jaundice and dark urine. In some cases of acute hepatitis B infection, the first symptom may be urticaria. Reports of acute infections acquired occupationally in the United Kingdom and other countries that have effective systems for ensuring that healthcare workers are vaccinated against hepatitis B are now rare.

Confirmation that a case of hepatitis is due to HBV infection requires serological testing. The serology of HBV infection is described in Table 59.1. This shows the pattern of hepatitis B markers found in different situations, including acute infection, natural immunity, the carrier state, and immunity as a result of vaccination.

During the acute infection, supportive treatment is usually all that is required. Severe cases should be managed in specialist units. Sexual partners and other family and close contacts should be investigated and offered vaccination if they are non-infected and non-immune.

Fewer than 10 per cent of adults with acute hepatitis B infection will fail to clear the virus and become carriers. The carrier state is indicated by either the presence of hepatitis B surface antigen (HBsAg) on two occasions at least six months apart or the finding of HBsAg in the absence of anti-core antibody of IgM type (anti-HBc IgM). Those carriers who remain positive for HBeAg have much greater infectivity than those who clear the HBeAg, but remain positive for HBsAg (see above). Treatment with antiviral drugs, such as alpha-interferon and other new agents, may sometimes be effective in helping to clear HBeAg or suppress viral replication. Long-term sequelae of chronic hepatitis B infection include chronic liver disease and hepatocellular carcinoma. Healthcare workers found to be infected with hepatitis B should be referred for specialist care.

Acutely or chronically infected healthcare workers who undertake exposure-prone procedures can transmit hepatitis B infection to their patients. An exposure-prone procedure is one where there is a risk that the patient’s open tissues may be exposed to the blood of a healthcare worker, as in surgery, dentistry and midwifery during complicated or instrumental deliveries. The risk of transmission depends on the types of procedure being performed, the role of the worker and the infectivity of the worker. In outbreaks associated with HBeAg-positive surgeons, overall transmission rates have been around 5 per cent, but transmission rates of 20 per cent have been recorded in groups of patients undergoing longer and more complex procedures.\cite{86} There is also evidence that some healthcare workers who are HBsAg positive but HBeAg negative can also transmit hepatitis B to patients during exposure-prone procedures, probably because of carriage of variants of hepatitis B virus, in which there is continuing viral replication, even though HBeAg is not detectable in the blood.\cite{87}

**Hepatitis C**

It is now known that HCV is the cause of a large proportion of cases of what was formerly called ‘non-A, non-B hepatitis’. Acute and even fulminant hepatitis can occur after occupational transmission of HCV but is rare. The majority of infections will be anicteric, and many will be asymptomatic, occupational transmission being indicated
by a rise in liver enzymes or by the detection of HCV RNA or of antibody to HCV on testing. Treatment with antiviral drugs, especially if instituted early, may help to prevent the carrier state being established. In chronic HCV carriers, there is sometimes a fluctuating hepatitis with ‘yo-yo’ transaminases. Sequelae can be serious, including cirrhosis, chronic liver disease and hepatocellular carcinoma.

Healthcare workers infected with hepatitis C virus can transmit the infection to patients during exposure-prone procedures. The transmission rate has not been quantified precisely, but, by analogy with the evidence on transmission to healthcare workers from needlestick exposures, it is likely to be substantially less than for hepatitis B (with HBeAg).

**Human immunodeficiency virus**

A seroconversion illness typically occurs about four to six weeks after the exposure. This is characterized by fever, generalized lymphadenopathy and a rash. Thereafter, the infection is asymptomatic until an HIV-related illness or full-blown AIDS occurs. The first AIDS illness in a young healthcare worker with undiagnosed HIV infection may be pneumonia due to *Pneumocystis jiroveci*. This may present with unexplained breathlessness on exertion or as failure of a chest infection to respond to the usual antibiotics. Immunocompromised people with AIDS can develop a variety of bacterial and fungal infections, sometimes with opportunistic organisms and parasitic infestations. Tuberculosis is a particular problem, especially in areas with a high prevalence in the population. There is a risk of infection with atypical mycobacteria or with multidrug-resistant *Mycobacterium tuberculosis*. Modern combination antiretroviral therapy for HIV infection and primary prophylaxis against opportunistic infections have greatly improved the prognosis of HIV infection in developed countries, prolonging survival and delaying the onset of AIDS in people infected with HIV. The prognosis remains very poor in countries where this effective but expensive treatment is not available. Anyone with HIV antibodies is considered to be infectious through sexual contact or contact with their blood, but infectivity is higher at times when the level of virus in the blood is higher, for example during seroconversion and in the late stages of AIDS.

The potential for HIV-infected healthcare workers to transmit to patients during exposure-prone procedures is a cause of great concern, given the very serious consequences of such an occurrence. There are three reports of transmission from a healthcare worker to patients: a dentist in Florida, an orthopaedic surgeon in France and a gynaecologist in Spain. The estimated risk of transmission to patients is much lower than for either hepatitis B or hepatitis C.

**MANAGEMENT OF INFECTED HEALTHCARE WORKERS**

A healthcare worker may be found to have an infection with a blood-borne virus, either as a result of routine testing (see below), or by testing in relation to an illness or reported occupational exposure, or by testing during investigation of the source of infection in one or more infected patients.

In the United Kingdom, all healthcare workers who undertake exposure-prone procedures are required to demonstrate by testing of an identified validated blood sample that they are immune to hepatitis B as a result of immunization or that they are not hepatitis B infected (HBsAg positive). Hepatitis B-infected healthcare workers who are HBeAg positive, or who are HBeAg negative but have a hepatitis B virus DNA level (HBV DNA) of more than $10^5$ genome equivalents per mL (geq/mL), may not perform exposure-prone procedures. Hepatitis B-infected healthcare workers who are HBeAg negative and have a baseline HBV DNA level of below $10^6$ geq/mL may practise unrestricted provided that their HBV DNA level is monitored annually, and remains below $10^6$geq/mL. HBeAg-negative healthcare workers whose baseline viral load is $10^3$–$10^5$geq/mL may, if on continuous oral antiviral treatment, and closely monitored by a consultant occupational health physician and a designated hepatologist, practise exposure-prone procedures, provided that their hepatitis B infection remains well controlled (i.e. HBV DNA level remains below $10^6$geq/mL).

Healthcare workers in the United Kingdom who have hepatitis C (HCV) infection and who are HCV RNA positive must not perform exposure-prone procedures; successful antiviral treatment may permit a return to practice. HIV-infected healthcare workers must not undertake exposure-prone procedures. Recent guidance on health clearance in the United Kingdom recommends that all new and returning healthcare workers should routinely be offered hepatitis B vaccine (with post-vaccination testing of response) and testing for HCV and HIV infection. If the worker is to undertake exposure-prone procedures, the worker should be shown, by testing of an identified validated blood sample, to be non-infectious for HBV, HIV and HCV before the offer of appointment is confirmed.

The guidance also requires that healthcare workers who believe they might have been exposed to HIV or HCV (whether sexually, through injecting drug use or occupationally) promptly seek advice on whether they should be tested to confirm their status. National authorities in other European countries and the United States have made similar, though usually less prescriptive, recommendations. In the United Kingdom, recommendations on testing medical and dental students for blood-borne virus infections have recently been revised and are closely aligned to new health clearance guidance. They require post-admission testing of medical students, and pre-entry clearance of dental students, and set out the roles and responsibilities of the college, the occupational health service and the student. They also make it clear that being infected with a blood-borne virus is not, of itself, a barrier to medical school entry or to medical registration.

It is recommended in the United Kingdom that, where there is evidence of HIV transmission from a healthcare
worker to a patient, all patients on whom the worker has undertaken exposure-prone procedures should be contact- ed and offered testing to confirm that they have not acquired HIV infection from the healthcare worker. In the absence of evidence of transmission, the decision on whether to undertake a 'look-back exercise' should be con- sidered on a case-by-case basis. 99 Recommendations on HCV are similar. 92

More general issues about fitness to work may arise in HIV-infected healthcare workers and other people in jobs of high responsibility. These include concerns about their risk of acquiring infection if they become immunocompromised and about the effects of the neurological complications of HIV infection. The infection in most people, including healthcare workers, will have been acquired non- occupationally. The issues about HIV infection and fitness to work are considered in detail elsewhere. 101

If a healthcare worker is found to be infected with a blood-borne virus, it is important to establish whether the infection is likely to be occupational, since they are eligible for certain benefits if this is the case. In the United Kingdom, since hepatitis B and hepatitis C are prescribed industrial diseases, all that is needed is to show that the person is infected and that their work involves (or has involved) exposure to potentially infected blood, whether in the clinical setting or the laboratory. HIV infection is not a prescribed industrial disease, but infected workers in the UK may be eligible for National Health Service Injuries Benefit if it can be shown that their infection is likely to be occupational in origin. For all blood-borne viruses, the most obvious way to demonstrate an occupational origin is to show seroconversion following an occupational exposure incident.

PREVENTION OF INFECTION WITH BLOOD-BORNE VIRUSES

Prevention rests mainly on reduction of the risk of exposure to blood or other infected body fluids. The most important risk is percutaneous exposure to blood, so reducing the use of sharp instruments, developing safer techniques and types of equipment, and making proper use of suitable containers and systems for disposal of used needles and sharp instruments are important. 102 Advances in the last decade include the widespread adoption of standard infection control precautions (formerly ‘universal precautions’), the introduction of safety-engineered intravenous cannulae and phlebotomy devices, which have been shown to reduce needlestick injury rates, 103–105 and, in the United States, legislation that makes provision of safety-engineered devices to healthcare workers mandatory. Together, these have resulted in a decline in hollow- bore needle injury rates, most marked for the injuries that present the greatest risk. 85 In the United Kingdom, the Health and Social Care Act 2008 requires that NHS trusts consider making provision of medical devices that incorporate sharps protection mechanisms where there are clear indications that they will provide safe systems of working for healthcare workers’ in order to demonstrate compliance, but it is not clear to what extent this requirement has been implemented. 106

In the laboratory setting, the use of sharp instruments or equipment can be virtually eliminated. Suitable personal protective equipment (PPE) and safe laboratory practice prevents exposure of broken skin and the mucosae of the eyes and mouth.

However, not all occupational blood-exposure incidents are preventable and some will occur even where preventive measures have been well implemented. Other preventive strategies are available. For hepatitis B, the most infectious of the agents, there is fortunately an effective and safe vaccine. Immunization of all healthcare workers who may have contact with blood and body fluids is recommended. Vaccines against hepatitis C and HIV have not yet been developed.

Around 90 per cent of young, fit healthcare workers produce an adequate anti-HBs response to hepatitis B vaccine. Response rates are lower in males, smokers, older people and those who are immunosuppressed. Response rates are also lower when vaccine is given intradermally (rather than intramuscularly), or given intramuscularly into the gluteal muscles rather than the deltoid. True vaccine failure is rare. 107 Apparent non-responders (no or low level anti-HBs response) should be tested for evidence of HBV infection. True non-responders, with no evidence of previous HBV infection, should be informed they are not protected and strongly advised to report any occupational exposures to blood. Non-response to vaccine should not be considered a bar to employment as a healthcare worker in any capacity. Although a quarter of a century has passed since hepatitis B vaccine first became available, there are still reports of under-vaccination of healthcare workers at risk: a study of transplant surgeons in the United States in 2003 found that a fifth (70/311) of respondents were inadequately vaccinated, and that surgeons under-estimated the risks of having a percutaneous exposure while operating, and of becoming infected if exposed; the authors suggest that the most expedient way to ensure protection is to require documented evidence of vaccination and testing for all staff at risk. 108

Once an exposure to infected blood has occurred, other measures can reduce the risk of infection in the worker. For hepatitis B, active immunization with the vaccine, using an accelerated course in those not previously immunized, is recommended. Passive protection may also be provided using hepatitis B immune globulin (HBIG). However, HBIG gives incomplete protection and should be given in conjunction with the first dose or booster dose of vaccine; in workers who have failed to respond to the vaccine, it is the only protection available. For hepatitis C, no effective post-exposure prophylaxis is available at present, but follow up to six months is recommended to check that transmission has not occurred. 92,109

For HIV, recommendations about post-exposure pro- phylaxis (PEP) have recently been revised in the United Kingdom 110 and in the United States. 111 A retrospective
case–control study suggests that the use of prophylactic zidovudine is associated with a reduced risk of HIV seroconversion after percutaneous (needlestick) exposure to HIV-infected blood. By extrapolation from the effectiveness of combined antiretroviral therapy in established infection, and in preventing mother-to-child HIV transmission, current guidelines on PEP now recommend routine use of three antiretroviral drugs in the United Kingdom (or two, sometimes three in the United States) for four weeks after a significant occupational exposure to HIV. The recommended three drugs for PEP in the UK and USA are zidovudine, lamivudine and indinavir, with modification of this regime if the source patient is believed to have infection resistant to any of these drugs. The prophylaxis should be started as soon as possible after the exposure and preferably within one hour. The effectiveness of this regime in reducing the rate of seroconversion (in any case small) is unknown, and seroconversion despite prompt prophylaxis has been reported. A significant proportion of those given PEP will experience side effects, which may be severe enough to require time off work. Although higher adverse event rates are reported among those given a three-drug regime, the discontinuation rates for three-drug regimes are similar to those for two-drug regimes.

Initiation of suitable post-exposure prophylaxis depends upon knowledge of the worker’s immunity (for hepatitis B) and the source patient’s infection status. Post-exposure testing of source patients for blood-borne virus infection is therefore important. Patients should be tested only with their consent and with appropriate pre-test discussion. If approached sensitively, few patients will refuse testing. If immediate testing is not feasible, or the patient refuses testing, but there is a strong suspicion of infection, for example with HIV, then PEP should be considered.

Healthcare workers who have been involved in blood-exposure incidents, especially when the source patient is known to be infected with a blood-borne virus, are understandably anxious and may become extremely anxious; post-traumatic stress syndrome has been reported. They should have access to timely, sympathetic and knowledgeable advice from an experienced designated physician (the occupational physician often takes on this responsibility). Giving accurate information and providing immediate and ongoing support is an important, though not always recognized, part of the management of blood exposures at work.

Other workers may have occasional contact with blood or contaminated sharp instruments, for example emergency care workers, refuse workers, police and prison officers. These workers should be trained to take appropriate precautions to reduce the risk of exposure to blood (especially sharps injuries) and should know how to obtain immediate post-exposure care. The need to offer them routine pre-exposure hepatitis B immunization is less clear-cut, although this may be appropriate for selected subgroups. Arrangements should be made for them to have access to expert advice, and treatment if necessary, if they are involved in a blood-exposure incident.

**Other viruses as occupational risks for healthcare workers**

**VIRAL HAEMORRHAGIC FEVERS**

Viral haemorrhagic fevers, caused by a range of viruses (from the arenavirus, flavivirus, filovirus and bunyavirus families), are severe and potentially life-threatening diseases. They are endemic in Africa, parts of South America, and in rural Eastern Europe and the Middle East. Cases in the United Kingdom are very rare and virtually always imported, but laboratory-acquired infection has been reported.

The infections are transmitted to humans by mosquito bite (yellow fever, dengue, Rift valley fever, Chikungunya); tick bite (Omsk haemorrhagic fever, Kyanasur Forest disease, Crimean Congo haemorrhagic fever (CCHF)); or through contact with virus excreted by infected rodents or other animal reservoir (the arenaviruses, including Lassa virus; Hantaan virus); the geographic distribution of the viruses matches that of any animal reservoir. However, only four of these infections are known to be readily capable of spreading from person to person and thus present a potential risk of transmission to healthcare workers: Lassa fever, CCHF, Marburg disease and Ebola haemorrhagic fever. A newly described arenavirus, presumptively termed Lujo virus, may also fit into this category: a safari booking agent, who had a possible history of a recent tick bite and contact with horses, was transferred by air from Zambia to South Africa with an undiagnosed, but clearly severe, illness in early October 2008 and died soon afterwards. Three fatal secondary cases occurred in healthcare workers (a paramedic who accompanied the transfer, an intensive care nurse and the worker responsible for terminal cleaning of the index case’s hospital room); a tertiary case (a nurse) survived; all had potential for exposure to the index case’s blood or body fluids.

CCHF was first recognized in the USSR in 1944, and the virus isolated from the patients was subsequently shown to be identical to that isolated in 1956 from a sick child in Zaire. The virus is now known to be widely spread in Africa, Central Asia, southern Europe and parts of the Middle East, though there appear to be geographical variations in virulence, the disease being more severe in Asia than in Africa. Lassa fever was first described in 1969 after three missionary nurses working in Lassa in north eastern Nigeria became seriously ill with an unknown infection, from which two died. The third nurse, who had cared for the other two, was flown to North America for treatment, and a new arenavirus was isolated from her serum, and subsequently from similar cases in Nigeria, and named Lassa virus.

Marburg virus takes its name from an outbreak of haemorrhagic fever among laboratory workers in Marburg, Germany in 1967. Workers in laboratories in Frankfurt and Belgrade also became infected. All 25 with primary infections had been in contact with organs, blood or cell cultures...
from a batch of wild-caught African green monkeys from Uganda; six secondary cases occurred amongst those who had contact with infected patients’ blood. Small numbers of cases have since occurred in South Africa, Zimbabwe, Kenya and Uganda; large outbreaks, amplified by nosocomial transmission, occurred in the Democratic Republic of the Congo (formerly Zaire) in 1998–2000, and in Uige province, Angola in 2004–2005. Ebola haemorrhagic fever was recognized in 1976, when outbreaks of a new haemorrhagic fever, with a high case fatality rate and considerable secondary spread through blood contact, occurred simultaneously in Zaire and in the Sudan. Five ebolavirus species have so far been recognized: Zaire ebolavirus, Sudan ebolavirus, Reston ebolavirus, Cote d’Ivoire ebolavirus and, most recently, in an outbreak in Uganda in 2007–2008, Bundibugyo ebolavirus.\(^{116,117}\)\(^{116,117}\)\(^{116,117}\) Outbreaks have occurred in Gabon, Sudan, the Democratic Republic of the Congo, and the Republic of the Congo. Cote d’Ivoire ebolavirus was isolated from a zoologist working in the country who became accidentally infected while doing a post-mortem on a chimpanzee found dead in the wild. Reston ebolavirus was first isolated from batches of cynomolgus macaques imported to the United States and Italy from the Philippines, and has since also been isolated from domestic pigs in the Philippines. An animal caretaker in the Reston primate facility became viraemic after a virus-contaminated scalpel injury, and he and three other asymptomatic workers had serological evidence of infection. Antibody has also been detected in workers in primate-supply facilities in the Philippines and, more recently, in pig farmers, but human illness associated with this ebolavirus species has not been reported.\(^{118}\)

The clinical illnesses are characterized by fever, haemorrhage and collapse, although serosurveys have suggested that subclinical and mild infections also occur. For Lassa fever, reported mortality rates range from 3 per cent (in a community outbreak) to 66 per cent (in hospitalized cases). Lassa fever tends to have a more insidious onset than Marburg or Ebola disease and can therefore be difficult to diagnose. The differential diagnosis of a fever in a patient who has been in rural West Africa within the previous three weeks includes Lassa fever, typhoid fever and malaria. In Lassa fever, there is usually fever and headache followed by pharyngitis, abdominal tenderness, sometimes with vomiting and diarrhoea, and evidence of pleural effusion. There may be little or no evidence of haemorrhage other than some bleeding of the gums. Severe haemorrhage is unusual in Lassa fever, but more common in Marburg or Ebola disease. Treatment is largely a question of providing intensive supportive care; antiviral drugs (specifically, ribavirin) reduce the mortality of Lassa fever, if started early, and may also be helpful in CCHF, but have not been shown to influence the course of either Marburg or Ebola disease.

The viral haemorrhagic fevers pose a significant risk of infection to healthcare workers caring for cases, laboratory workers handling specimens from them, and to research laboratory workers. The main risk in the healthcare setting is direct contact with infected blood (for example, by needlestick injury or contamination of broken skin or mucous membranes). In the ebolavirus epidemic in the Sudan in 1979, it was reported that staff providing direct clinical care for ill patients had a five times higher risk of contracting infection than staff with less physical contact with the patients, and there were no cases of infection in staff who entered the room but had no physical contact.\(^{119}\)\(^{119}\)\(^{119}\) UK guidelines on management and control of viral haemorrhagic fevers\(^{115}\) advise that patients returning from abroad with a fever should be categorized on the basis of a risk assessment that covers: area visited, clinical features and time of onset in relation to travel, household or occupational contact with known or suspected cases, or contact with potentially infected blood or body fluids. Any patient known or suspected to be suffering from a viral haemorrhagic fever, or in whom the diagnosis cannot immediately be excluded, should be urgently discussed with a senior infectious disease clinician working in a specially designated high security infectious disease unit. Nearly all suspected cases will in fact have malaria. The guidelines also cover the special precautions needed to obtain, transport and examine laboratory specimens from a patient with a suspected viral haemorrhagic fever and the management of patients’ contacts. The first investigation should always be to confirm or refute a diagnosis of malaria. If there is doubt, empirical treatment for malaria should be instituted.

SARS CORONAVIRUS

In 2002, a new infection, severe acute respiratory syndrome (SARS) emerged in Guandong province, China. Rapid person-to-person spread of virus caused outbreaks in Hong Kong SAR, Vietnam, Singapore and Canada in 2003, with more than 8000 cases in more than 30 countries.\(^{120}\)\(^{120}\)\(^{120}\) Transmission was amplified within hospitals, as early cases were cared for without effective routine infection control measures; 22 per cent of SARS cases in Hong Kong and nearly half (43 per cent) of SARS cases in Toronto and Singapore (41 per cent) occurred in healthcare workers. Further cases in Singapore, Taiwan and China in late 2003 and 2004 were associated with laboratory-acquired infections.\(^{121,122}\)\(^{121,122}\)\(^{121,122}\) Overall, 20 per cent of hospitalized patients required mechanical ventilation and 15 per cent of hospitalized cases died. Mortality was greater in the elderly and in those with co-morbidity. The usual incubation period is three to five days (range, two to ten days). Clinical features include fever, chills, rigor, malaise and myalgia, sometimes accompanied by diarrhoea, followed two to four days later by a non-productive cough, dyspnoea and pneumonia, with progression to respiratory failure in severe cases.\(^{123}\)\(^{123}\)\(^{123}\) However, there is a spectrum of disease, and many cases are mild and will not require hospital admission. Antiviral drugs (e.g. ribavirin) or other drugs, such as steroids, have not been shown to be effective; treatment is essentially supportive. Asymptomatic contacts are not infectious; cases are non-infectious from
ten days after resolution of fever. SARS coronavirus, although a newly emergent virus, is transmitted from person to person in the same way as more common respiratory infections, mainly by respiratory droplet spread and direct contact, and the SARS epidemic was controlled by the efficient application of long-recognized public health control measures: rapid identification and early isolation of cases, and stringent adherence to infection control precautions. In a study of almost 800 critical care workers who had cared for patients needing intubation during the outbreak in Toronto, factors identified as being predictive of the consistent use of recommended barrier precautions included caring for a patient identified as a definite SARS case and having had recent or interactive training in infection control. Of 17 healthcare workers from six centres in Toronto, who acquired SARS after infection control measures had been implemented, 15 were well enough to be interviewed in depth about their infection control practice; results suggested that risk factors for infection included the performance of high-risk patient care procedures (e.g. intubation, nebulizer therapy), inconsistent use of personal protective equipment, fatigue and lack of adequate infection control training.

One of the effects of SARS has been to provoke renewed interest in infection control and prevention of transmission of respiratory infections, which has led to development of the concepts of ‘cough etiquette’. Healthcare staff who will predictably undertake aerosol-generating procedures (intubation and related procedures including manual ventilation and suctioning, bronchoscopy, cardiopulmonary resuscitation) shown to be associated with an increased risk of respiratory pathogen transmission, for which the use of a respirator (e.g. FFP3 respirator) is required, and those (e.g. nebulization, non-invasive positive pressure ventilation) where evidence on transmission is less clear-cut, but where the use of a respirator may nevertheless be prudent, should be fit-tested by the occupational health service and trained in the use of the selected respirator, including fit-checking and safe removal and disposal. Such staff might include intensivists, emergency care clinicians, critical care response teams, chest physicians, respiratory therapists, surgeons and post-mortem room staff. Disposable respirators may not be suitable for all staff (e.g. those who have beards), but alternatives, including reusable powered respirators and helmets, are available.

SARS coronavirus may re-emerge: the virus is probably zoonotic (SARS-like coronaviruses have been identified in Chinese horseshoe bats, which may be the natural reservoir; masked palm civets were likely the intermediate host in the 2002–2003 epidemic). Occupational health clinicians have an important role to play in surveillance and should remain alert to cases of severe atypical respiratory illness in healthcare workers, particularly if there is more than one case within a short time span, and need also to be prepared to provide ongoing psychosocial support for workers involved, directly or indirectly in an outbreak, particularly if mortality is high or the outbreak prolonged.

VARICELLA ZOSTER

Varicella zoster virus (VZV) causes chickenpox (primary infection) and shingles (reactivation of previous infection). Healthcare workers who are susceptible to VZV are vulnerable to contracting the infection from patients. Chickenpox in adults tends to be more severe than in children, but the major concern is that healthcare workers who have chickenpox (who will have been particularly infectious in the 48 hours preceding the onset of the characteristic rash) may transmit the virus to susceptible patients. Any healthcare worker with chickenpox should remain off work until there are no new lesions and the existing lesions have crusted and dried; those with shingles are also infectious and should similarly remain off work. Recent UK guidance recommends that staff who will have direct patient contact (including ambulance staff, cleaners and receptionists) in hospitals or the community and who do not have a definite history of chickenpox should be tested to determine their immune status. More than half of UK healthcare workers give a history of chickenpox in childhood and have antibodies as a result, and antibodies are also detectable in most of those without a history of chickenpox: about 10 per cent of adults will be seronegative (i.e. have no detectable antibody to VZV). UK guidance also recommends that healthcare workers who were born and raised overseas should be serologically tested regardless of their clinical history. Non-immune workers should receive varicella zoster vaccine (two doses of live attenuated vaccine four to eight weeks apart); routine post-vaccination testing is not advised. Varicella vaccine is contraindicated in pregnancy and in the immunosuppressed. At the time of vaccination, healthcare workers should be told that they may develop a rash in the month after vaccination and that if this occurs they should be assessed by the occupational health service. Those who develop a generalized rash that is papular or vesicular should avoid all patient contact until the lesions have crusted or resolved. Non-immune healthcare workers who have a significant exposure to VZV should be offered vaccine if there are no contraindications; work exclusion (from day 8 to day 21 post-exposure) or occupational health surveillance for fever and rash is also necessary. Post-exposure management of susceptible healthcare workers who are immunosuppressed or pregnant requires consideration of the use of zoster immune globulin.

CYTOMEGALOVIRUS

Cytomegalovirus is found in many body tissues including blood, urine, breast milk, saliva and vaginal fluid. It is not vaccine-preventable. However, provided even the most basic infection control procedures are followed, any risk of transmission to healthcare workers from their patients is extremely small. Indeed, several studies have failed to show any excess of cytomegalovirus in healthcare workers with clinical contact compared with others with no clinical contact. The most important consequence of cytomegalovirus
in immunocompetent females is its potential to cause fetal damage if acquired in pregnancy.

MEASLES, MUMPS AND RUBELLA
Measles is a highly transmissible acute viral illness, characterized by a prodromal illness (fever, conjunctivitis, coryza or cough) followed by the development of an erythematous maculopapular rash which spreads over the body from the head downwards over three to four days. Koplik spots may be seen on the mucous membranes of the mouth 24–48 hours before the rash appears. Complications include diarrhoea, pneumonia, convulsions, encephalitis and subacute sclerosing panencephalitis. In the United Kingdom, it is estimated that 1 in 5000 cases is fatal. The case fatality-rate is age-related; disease tends to be more severe in infants and in teenagers and adults than young children, and is also more severe in the chronically ill, under-nourished or immunosuppressed.

Rubella infection in children (German measles) is usually a mild, self-limiting illness characterized by fever and a morbilliform rash. In adults, however, infection is more severe, with rash, fever, debility and prominent symptoms in small joints. Maternal infection in the first 16 weeks of pregnancy, particularly if in the first trimester, causes severe fetal damage. Healthcare workers are unlikely to be at increased risk of rubella, especially since many countries now vaccinate infants as well as adolescents against rubella. However, healthcare workers have been the source of rubella outbreaks.

Mumps is an acute viral infection caused by a paramyxovirus, with an incubation period of around 16 days (range, 12–25 days). It is characterized by a short prodromal illness (fever, headache, myalgia, anorexia) followed by bilateral or unilateral parotid swelling. Asymptomatic infection is common, particularly in children. Meningitis occurs in 15 per cent of cases; other complications include orchitis (25 per cent of post-pubertal men), oophoritis (5 per cent of post-pubertal women), pancreatitis (4 per cent) and sensorineural deafness. The virus is spread by droplet and airborne transmission. Non-immune healthcare workers who have an unprotected exposure to the virus must be excluded from work from the 12th to the 25th day after exposure.

Measles, mumps and rubella (MMR) vaccine prevents all three of these infections; vaccination of healthcare workers is particularly important because they may transmit infection to vulnerable groups. Self-reported immune status may be inaccurate. In the United Kingdom, satisfactory evidence of protection is documentation of receipt of two doses of MMR vaccine or serological evidence of immunity to measles and rubella.132

PARVOVIRUS
Parvovirus B19 infection (which is not vaccine preventable) produces a febrile illness with a transient macular rash which may be mistaken for rubella. In adults, particularly females, it can cause arthropathy which is usually self-limiting. It can cause complications in people with haemoglobinopathies and those who are immunosuppressed, and fetal damage. There is no specific treatment. Diagnosis is made serologically. Outbreaks in healthcare settings may necessitate ward closures to interrupt transmission.134

HERPETIC WHITLOW OR PARONYCHIA
These lesions on the fingers are due to direct contact with herpes simplex virus and used to be quite a common problem in healthcare workers. Diagnosis is by culture of virus from the lesions, electron microscopy or immunofluorescence. Contact with the mouth area, such as in mouth care or dentistry, with ungloved hands seems to be the major risk, and infection is therefore preventable by adherence to standard infection control precautions.135

Other infectious risks for healthcare workers

TUBERCULOSIS
The clinical features of pulmonary tuberculosis include fever, weight loss, cough, malaise, sweats and haemoptysis. The diagnosis should be considered in any healthcare worker who presents with such symptoms and no other apparent cause. Radiographs may be normal in early infection or show a rather diffuse bronchopneumonia, but in more advanced cases there may be the more typical upper lobe pneumonia with cavitation. Healthcare workers in the United Kingdom remain at increased risk of tuberculosis (TB), where although TB incidence rates have stabilized, they remain at higher levels than in the 1980s.136

Guidelines in the United Kingdom cover the health clearance of new and transferring National Health Service workers, protection of workers against infection (including the use of BCG (bacillus Calmette-Guérin)) and safe working practices (Figure 59.1).98,100,132,137 BCG is recommended for healthcare workers, whatever their age, who will have contact with patients or clinical material and who are not tuberculin skin test positive as a result of previous BCG immunization. BCG should not be used in HIV-infected workers; workers should be individually risk-assessed for HIV before BCG is given. Healthcare workers from high TB incidence countries, or who have worked in high TB prevalence settings who have a positive tuberculin test (or a positive interferon gamma test) should be referred to a chest clinic. Healthcare workers from low TB incidence countries, such as the United Kingdom, who are tuberculin test (or interferon gamma test) positive and have not previously had BCG should have a medical assessment and a chest x-ray, but should also be referred to a chest clinic for consideration of treatment of disease or latent infection. Healthcare workers who are found to be HIV positive during employment should have medical and occupational assessments of TB risk, and may need to be offered redeployment to reduce exposure. Guidance is also given on the management of
healthcare workers who have a significant occupational exposure to TB, and of those who are infected with TB, regardless of source. Tuberculosis acquired through an occupation involving contact with sources of tuberculous material is a prescribed disease in the United Kingdom.

In the last 20 years, multidrug-resistant tuberculosis (MDR-TB) has become a problem. It remains uncommon in the United Kingdom, accounting for around 1 per cent of new isolates, but worldwide, about 20 per cent of isolates are multidrug resistant. MDR-TB strains are not more transmissible, or more virulent, but are considerably more difficult, and more costly, to treat. The more recently described extensively drug-resistant strains of *Mycobacterium tuberculosis*, which first emerged in South Africa against a background of high HIV prevalence, may not be treatable. Occupational transmission of MDR-TB to workers has been described, and, coupled with implementation of a national TB control strategy, have resulted in a reduction in TB incidence. The guidelines, which were recently revised, include several levels of control: administrative controls to prevent exposing uninfected individuals to people who have infectious tuberculosis; then engineering controls to reduce spread of infectious droplet nuclei, such as local exhaust ventilation, air flow control and air filtration; and finally, the use of personal respiratory protective equipment in areas where there is still a risk of exposure to infection. The guidelines stress the need for early identification and treatment of patients with tuberculosis. Infection control guidelines for preventing the spread of tuberculosis in relation to HIV and multidrug-resistant tuberculosis have also been produced in the United Kingdom, designed to protect both patients and healthcare workers.

**SCABIES**

This skin disease is caused by the mite *Sarcoptes scabei* and transmitted by close personal contact. The itchy rash
characteristically presents on the finger webs, wrist and elbow flexures, and axillae but may sometimes present as a more widespread generalized dermatitis (Norwegian scabies). Linear burrows on the skin are present, but will not always be visible, particularly if hypersensitivity to mite antigen has developed. Nurses and other workers who provide physical care to patients are at risk. Cases are usually sporadic, but more extensive outbreaks have been described. The use of gloves and gowns when handling patients who may have scabies is advisable. Treatment of the case and family members is with malathion or permethrin, which should be applied to the whole body from the neck down and left for 24 hours. Benzyl benzoate can also be used, but often causes irritation and may need to be applied on up to three consecutive days.

Occasionally, strains of mites from infected pets can also cause a highly pruritic papular urticarial rash. In this case, it is pet owners (and possibly veterinary surgeons) who are at risk, rather than healthcare workers.

**STAPHYLOCOCCAL INFECTIONS**

Healthcare workers can become colonized with meticillin-resistant *Staphylococcus aureus* (MRSA), carried in the nose, throat, axillae, perineum and on damaged skin. Such colonized workers pose a risk of transmitting to patients an infection which can be extremely difficult to treat and may be fatal in immunocompromised patients, including those who have undergone recent surgery. Even non-colonized healthcare workers can spread the infection between patients. Scrupulous attention to hand washing and to changing any barrier garments (gloves, aprons) between each patient is vital. Where a colonized worker has been detected as a result of an outbreak investigation, eradication of the organism may be attempted, but sometimes proves difficult to achieve. In rare cases, for example a cardiovascular surgeon or a nurse on the intensive care unit, failure to eradicate MRSA may, if there is evidence of continuing transmission to patients, mean that they require long-term redeployment.

In the United Kingdom, where reporting MRSA bacteremia to the national surveillance system is a mandatory requirement, recent guidelines cover the prevention and management of MRSA in hospitals and other institutions.

**LABORATORY RESEARCH WORKERS AND ANIMAL HANDLERS**

The infection risk to laboratory research workers will depend on the precise nature of the work in which they are engaged and the techniques applied. Risk assessments of individual processes are necessary under the COSHH (control of substances hazardous to health) regulations, and should result in the development, implementation and monitoring of safe standard operating procedures.

Workers should carry a medical contact card which gives details of their work and provides the name of the doctor who should be contacted if the worker develops an unexplained fever or other signs of infection. Workers seeking medical advice should tell the doctor about their work, as well as doctors asking their patients about their occupations.

**Human immunodeficiency virus infection**

At least three research laboratory workers worldwide have acquired HIV infection after exposure while working with concentrated HIV. Workers should have the same access to post-exposure prophylaxis and care as described above for clinical healthcare workers.

**Work with primates**

Staff working with primates may be exposed to a number of infections, including herpes B virus, Marburg virus, Reston ebolavirus, monkeypox virus, rabies, tuberculosis, hepatitis A and enteric infections. Primates from reputable suppliers will, if wild caught, have been quarantined for six months and screened for these infections, although negative serological tests do not guarantee absence of infection. Primates for use in research which will involve human contact should, therefore, ideally have been bred in captivity and be herpes B virus seronegative. All primates should be regarded as potentially infective and handled with extreme care by trained staff. Suitable protective clothing should always be worn.

Infected animals shed herpes B virus from the oropharynx and genital tract; workers may acquire infection through bites or skin abrasions and subsequently develop a severe encephalomyelitis with a fatality rate of around 70 per cent. There is no evidence of asymptomatic infection in primate handlers. Guidelines have been published for the prevention and treatment of herpes B virus infections in exposed people. Wounds should be gently irrigated with soap and water or normal saline. Antibiotic prophylaxis against oropharyngeal bacteria (including anaerobes) should also be given for bites. Aciclovir may be given as prophylaxis after an exposure to a source known or potentially infected with herpes B virus, and should also be used to treat any worker with suspected infection.

**Work with vaccinia virus**

A number of occupationally acquired infections with vaccinia virus have recently been reported in research workers; any worker who will be handling cultures or animals contaminated or infected with non-highly attenuated vaccinia virus or other orthopox viruses that infect humans should have vaccinia vaccine before any exposure. If vaccine is contraindicated, redeployment may be necessary.
INFECTIONS ASSOCIATED WITH OCCUPATIONAL TRAVEL

The risk to travellers will depend on the countries visited, the proportion of time spent abroad, and working and living conditions while abroad. The most important hazard for occupational travellers is non-infectious: injury, particularly in road traffic accidents, is common and may often be fatal. There is good evidence that risk-taking behaviour abroad may differ from that at home; travellers should be counselled that unprotected sexual intercourse poses a clear risk of HIV and other infections and should be avoided.

Malaria

Malaria is a major infectious risk for travellers. Around 2000 cases are imported into the United Kingdom each year, of which rather more than half are due to \textit{Plasmodium falciparum}, which is the most serious of the four species of malaria parasite which cause disease in man, and is potentially fatal. \textit{P. vivax}, \textit{P. ovale} and \textit{P. malariae} are less likely to cause life-threatening illness. Most malaria infections will have been acquired through being bitten by an infected mosquito, but transfusion-acquired infection, transplacental transmission and acquisition through needlestick exposure to infected blood are also well recognized. Prevention requires risk recognition; travellers should be encouraged to take measures to avoid being bitten by mosquitoes (appropriate clothing, insect repellents (used directly on the skin or impregnated in wrist or ankle bands), insecticide-treated mosquito nets and insecticide sprays). They should comply with an appropriate chemoprophylactic regimen, and should understand that there is no chemoprophylactic regime which is 100 per cent effective. In choosing a regime, the risk of adverse reactions to any drug must be balanced against the risk of acquisition of disease.\textsuperscript{150} Guidelines for the prevention of malaria in travellers from the United Kingdom have recently been revised,\textsuperscript{151} and are regularly reviewed and updated. These contain up-to-date information about recommended chemoprophylaxis regimes by geographical area, and advice on the use of regimes for emergency self-treatment. The drugs most commonly used currently for prophylaxis include chloroquine, proguanil and mefloquine. Specialist advice should be sought on prophylaxis for people who will be sent on long-term postings, or who intend to live in a malaria-endemic area.

The incubation period for malaria varies depending on the species. Malaria due to \textit{P. falciparum} usually presents either in the endemic area or within two months of leaving and typically 9–14 days after a bite from an infected mosquito. Malaria due to other species, particularly \textit{P. vivax}, can take up to 12 months to present. Symptoms, especially in the early stages, are non-specific and include fever, headache, malaise and myalgia. The classically described fevers of specific periodicity associated with different species of malaria parasite are in practice rarely useful in diagnosis. It is important to have a high index of suspicion of malaria in anyone with an unexplained fever who has been in an endemic area. Particularly for falciparum malaria, sudden and catastrophic deterioration in clinical condition may occur; deaths can and do result. Complications of malaria include pulmonary oedema, coma, fits, hypoglycaemia, anaemia, renal failure and abortion.\textsuperscript{152} Widespread haemolysis can lead to haemoglobinuria, so called ‘black water fever’. Falciparum malaria should be treated as a medical emergency. The diagnosis of malaria is made by identification of the parasite in thick blood films; specialist help may be needed for interpretation. A single negative film does not exclude the diagnosis, particularly in a first episode of malaria when severe symptoms can occur with a low parasitaemia, and empirical treatment against \textit{P. falciparum} may be appropriate.

The treatment regime depends on the known or suspected species of parasite and its likely sensitivities (depending on area of origin) as well as the severity of the clinical illness.\textsuperscript{153} Expert advice should be sought about the appropriate treatment regime in each case. Chloroquine-resistant \textit{P. falciparum} is now so widespread that chloroquine should no longer be used for the treatment of falciparum malaria in the United Kingdom, although it remains the drug of choice for \textit{P. malariae} and \textit{P. ovale} and uncomplicated \textit{P. vivax} infections. Additional treatment with primaquine is needed for infection with \textit{P. vivax} and \textit{P. ovale} to eradicate the hypnozoite stage of the parasite in the liver and prevent relapse. If this is not done, there is a risk of late relapse, which may occur years after the primary infection. Oral treatment can be used unless the patient is severely ill, confused or unconscious. Supportive care is an integral part of management and may include fluid replacement, management of fits, control of blood glucose, ventilation and renal dialysis.

Traveller’s diarrhoea

In developed countries, \textit{Campylobacter} sp. and \textit{salmonellae} are the most common causes of infective diarrhoea. However, enterotoxin-producing strains of \textit{Escherichia coli} (ETEC) are the most common cause of diarrhoea in travellers to less developed countries, where other infections which have a human, rather than an animal, reservoir are also more likely to be acquired. Diarrhoea caused by ETEC, \textit{shigellae} and \textit{Giardia lamblia}, although unlikely to be life threatening, may cause considerable morbidity, misery and loss of efficiency.

PREVENTION

In theory, travellers’ diarrhoea is wholly preventable if simple precautions are followed faithfully. These include eating only thoroughly cooked food freshly prepared; washing and peeling all fruit; avoidance of salads, shellfish, unpasteurized milk or milk products, and tap water (including ice in drinks). In practice, it may be difficult to follow this advice
to the letter, especially for those who have little control over catering arrangements (e.g. delegates at an international conference). Some clinicians would advocate antibiotic chemoprophylaxis, which has also been shown to reduce the incidence of travellers’ diarrhoea. However, although this approach might perhaps be justifiable in people who are susceptible to infection or who suffer from inflammatory bowel disease, it cannot be generally endorsed, since it may increase susceptibility to infection with a resistant pathogen, will be ineffective against viral or parasitic causes of travellers’ diarrhoea, and may engender a false sense of security. Bismuth subsalicylate has also been shown to reduce the incidence of traveller’s diarrhoea and could be considered as an adjunct provided there are no contraindications.

**MANAGEMENT**

Most cases of travellers’ diarrhoea occur while the traveller is abroad, are self-limiting (90 per cent resolve within a week) and are never investigated. Travellers can treat themselves effectively. They should be instructed on how to replace lost fluids using a suitable oral rehydration solution (proprietary packs are available). It is, of course, essential to make up the solution using clean water. Short-term use of a simple anti-diarrhoeal agent (such as loperamide) may be helpful in limiting symptoms, but should not be used by patients with fever or bloody diarrhoea, and has been associated with adverse events, including toxic megacolon and severe sepsis. Where fever persists for more than 48 hours, or diarrhoea is severe, self-treatment with short course antibiotic therapy could be started. Appropriate agents would be ciprofloxacin or other fluoroquinolone (doxycycline or trimethoprim are no longer recommended because of the high level of drug resistance); bismuth subsalicylate can also be used in treatment.

Travellers who have bloody diarrhoea should seek medical advice. Causes include Entamoeba histolytica, which may cause liver abscess, and is usually treated with metronidazole.154

Diarrhoeal symptoms that persist despite simple measures require further investigation, including stool microscopy and culture. Blood cultures are appropriate in febrile patients. Symptoms beginning more than a week after travel or which persist for more than ten days suggest the possibility of Giardia lamblia infection. This infection may become chronic and cause malabsorption. Diagnosis is usually by stool microscopy, but this may be negative in chronic cases. Treatment is with metronidazole or tinidazole.

Food handlers who have suffered traveller’s diarrhoea following a trip abroad should consult their occupational health department before returning to work.

### Hepatitis A

Hepatitis A virus (HAV) is transmitted by the faeco-oral route, through close contact with an infected person or through contaminated food (particularly bivalve molluscs) or water. Travel to countries of high or intermediate endemicity is a well-recognized risk for infection. Other potential occupational risks include directly handling the virus in the laboratory, direct contact with untreated sewage and direct contact with faeces of infected patients. In the United Kingdom, where the numbers of cases reported annually have been declining for a decade, recent outbreaks have occurred amongst men who have sex with men, injecting drug users and the homeless.132 After an incubation period of two to six weeks, symptoms of fever, anorexia, nausea, abdominal pain, pale stools, dark urine and jaundice develop. Disease severity is age-related; 70–80 per cent of adults will develop jaundice, but young children are usually asymptomatic or have non-specific symptoms of viral illness. Viral excretion is at a maximum towards the end of the prodromal period, in the 48 hours before the onset of jaundice. Hepatitis A infection cannot be distinguished from other causes of viral hepatitis by clinical examination alone; diagnosis is made by testing for specific IgM antibody to HAV. The infection is usually self-limiting. There is no carrier state, but full recovery may take three to six months. Treatment is largely supportive. The mortality rate is below 0.1 per cent overall, but somewhat higher in those aged 45 years or over, and in those with pre-existing liver disease.

An inactivated hepatitis A vaccine is available, either as a monovalent vaccine or combined with either hepatitis B vaccine or typhoid vaccine. Passive prophylaxis, with human normal immunoglobulin (containing antibody to HAV) can provide immediate protection against infection for up to three months, but is no longer recommended for travellers, though it is still used, alone or in combination with vaccine, for post-exposure protection of contacts of a case and in outbreak control. Hepatitis A vaccine is recommended for those aged one year and over, travelling to countries of high or moderate endemicity for prolonged periods, and those who are posted to or will reside in, hepatitis A endemic countries. Vaccine may also be useful for those likely to make frequent short trips to endemic areas. Vaccine is also recommended for patients with chronic liver disease and for those with lifestyle risks for infection.

### OTHERS

#### Sex workers

Sex workers are clearly at risk of a variety of sexually transmitted infections and, if their transactions involve sex for drugs rather than money, may also be at risk of infective conditions associated with injecting drug use, including hepatitis C, abscesses, endocarditis and severe clostridial infection. The risks of sexually transmitted infection may be reduced by the use of condoms, although this may be difficult to negotiate with clients.
Sex workers in the United Kingdom with local symptoms of a sexually transmitted infection will usually present to a genitourinary medicine clinic for treatment, where investigations for the full range of infections, including HIV, syphilis, gonorrhoea and hepatitis B should be undertaken. Those who present to other services may be less likely to disclose their occupation.

**Sewage workers**

There is evidence that sewage workers are at increased risk of enteric infections, including hepatitis A. They are also at risk of leptospirosis (Weil’s disease) (see Chapter 60, Zoonoses). The risks are mainly confined to those who come into contact with raw sewage and can be reduced by the use of protective clothing. Hepatitis A immunization is recommended for higher risk subgroups, such as those with more frequent contact with raw sewage.

**Archaeologists**

Smallpox was officially declared to have been globally eradicated in 1980, but there is concern that viable virus could survive in corpses buried in permafrost or in cool dry crypts. Other viruses, including strains of influenza from previous pandemics, may also be able to survive in similar circumstances. Expert advice about the risks and about protective equipment should be taken before corpses are exhumed.

**Key points**

- Many infections can be transmitted by occupational exposure, but a relatively small number pose a significant risk.
- Healthcare workers are at particular risk, but occupational infections also occur in a wide range of other occupational groups.
- Knowledge of the worker’s occupation may provide a key clue to the diagnosis of an infection.
- Many occupational infections are preventable if measures to prevent or reduce exposure are implemented.
- Where a safe and effective vaccine is available, it should be offered to at-risk workers.

Zoonoses

ALASTAIR MILLER AND JULIA HEPTONSTALL

INTRODUCTION

The World Health Organization (WHO) defines zoonoses as diseases or infections that are transmitted naturally between vertebrate animals and man. Other authorities extend the definition to encompass infections that are transmitted only between human hosts by arthropod vectors, but this is a less common use of the term. In some circumstances, man is a dead-end host and in others he may transmit onwards to other animals or humans. A 2001 review concluded that 75 per cent of emerging pathogens and 61 per cent of all infectious organisms are zoonotic.1

Important recent examples include the emergence of novel influenza virus H1N1 in Mexico and the United States in 2009, with rapid evolution into a global pandemic, the severe acute respiratory syndrome (SARS) epidemic in 2002–2003, and the introduction of monkeypox into the United States from Africa in 2003.2–4

Zoonotic infections encompass the whole range of infective agents, including bacteria, rickettsia, viruses, fungi, protozoa and helminths. In addition to occupational exposure to zoonoses, humans can be infected by recreational exposure, keeping of pets, overseas travel, and ingestion of animal products. Many routes of infection are possible, including respiratory spread, gastrointestinal acquisition, percutaneous exposure by animal bite and spread by insect vector. Some zoonotic infections having initially been acquired from an animal source are then capable of human-to-human transmission and in these situations human health workers can be at risk through occupational exposure.

A large variety of occupational settings may expose man to the risks of infections transmitted from animals. Key areas are detailed in Table 60.1. Zoonotic infection may produce no disease, may produce organ damage with no initial symptoms or may present with any of the characteristic syndromes of clinical infection. There are usually no clinical features that specifically draw attention to the chance of its being an infection derived from animals and so clearly the history of animal exposure is critical and should be sought whenever an infection is diagnosed and its source is not immediately obvious. In this context, a detailed occupational history is vital. Characteristic clinical syndromes are illustrated in Table 60.2.

It is difficult to obtain accurate figures about the proportion of infections that are attributable to occupational exposure, but many countries have surveillance and notification systems that provide data on zoonotic infection in general. In Europe, data on zoonotic infections provided by member states to the European Centre for Disease Control are included in the centre’s annual report.5 In the United Kingdom, the Department of Environment, Food and Rural Affairs (DEFRA), in conjunction with the Health Protection Agency (HPA) and other agencies produces an annual report on the incidence of zoonotic infection.6 A summary of the UK data for 2006 is shown in Table 60.3.

The risk to a worker of acquiring a zoonotic infection depends on the prevalence of the infection among the animals involved (which may be modified by specific control mechanisms), the infectivity and route of infection of the organism, and the steps taken to limit exposure. Measures to prevent or minimize exposure may include: provision of appropriate protective clothing, including masks and respirators (collectively known as personal protective clothing).
equipment (PPE)) accompanied by training to use it effectively; safe disposal of animal carcasses and waste products; environmental engineering (e.g. ventilation and/or filtration to reduce dust exposure, caging systems); standard good hygiene (e.g. hand washing), and pre-exposure vaccination (e.g. against rabies or anthrax) in some occupational groups.

### OCCUPATIONAL ZOONOSES PRESENTING AS CHEST DISEASE

**Anthrax**

Anthrax is a bacterial infection caused by a Gram-positive spore-forming organism, *Bacillus anthracis*. The term 'anthrax' is derived from the Greek word for coal and refers to the black eschar that is characteristic of cutaneous anthrax. It is the vegetative bacilli that cause diseases in animals and man and when they are excreted in body fluids or when the host dies, then the bacilli will sporulate and spores may survive in the soil and remain viable for many years. They may even replicate in the soil. After the Scottish island of Gruinard (Figure 60.1) was used for anthrax experiments during the Second World War, it remained quarantined for 48 years. Soil is contaminated in many areas of the world especially in Africa, the Middle East and Asia, but the concentration of spores is higher when infection in animal herds (principally herbivores, such as cattle, sheep and goats) is highest so annual vaccination of at-risk herds, coupled with case-finding and safe disposal of animal carcasses remains the mainstay of disease control.

Man becomes infected either by inoculation of spores through the skin to produce cutaneous anthrax, by inhalation of spores to give inhalational anthrax (historically, 'wool sorter’s disease', caused by exposure to spore-contaminated fleeces) or by ingestion of contaminated meat containing viable vegetative bacilli to give gastrointestinal

Anthrax. Thus, anyone in close contact with animals and animal products may be at risk of infection.

Occupational exposure to anthrax can be divided into non-industrial exposure affecting farmers, butchers, slaughtermen and abattoir workers, and vets; and industrial exposure affecting those involved in processing animal hides, carcasses, or animal byproducts, e.g. bone meal, gelatin, bristles or hair (Figure 60.2). Recently, cases of inhalational anthrax have been reported in the United States when anthrax spores were sent through the US mail.\(^9\) There were 11 cutaneous cases and 11 inhalational cases, of which five were fatal (see Chapter 61, Bioterrorism). These were the first cases of inhalational anthrax in the United States since 1976.

Anthrax is essentially a disease caused by exotoxins. Three principal protein toxins are involved: protective factor, oedema factor and lethal factor. These toxins are elaborated by the vegetative bacilli and may disseminate around the host to cause cell and organ damage.

Cutaneous anthrax is the most common form of occupationally acquired anthrax. Spores are inoculated into the skin (minor cuts or abrasions are probably required for entry) by direct contact with infected animals or animal products. The usual incubation period is five to seven days, but a range of 1–19 days has been reported. The skin lesion (historically, known as ‘malignant pustule’) usually occurs on an exposed area of skin, and consists initially of a painless, often itchy, papule that rapidly evolves into the classical black eschar, and is associated with considerable surrounding oedema. There are frequently systemic manifestations as the toxins are released into the bloodstream, but the case–fatality rate is said to be very low if appropriate antibacterial agents are administered.

Inhalational anthrax is uncommon, and our understanding of the clinical presentation, disease process and outcome is derived from a relatively small number of cases: a recent systematic review of case reports published over the last century (1900–2005) identified 82 cases that were described in sufficient detail for inclusion in the analysis.\(^13\) These included the cases from the 2001 US outbreak, but 74 cases from an outbreak in Sverdlovsk, Ukraine in 1979 that followed the inadvertent dissemination of anthrax spores from a military research facility were among the 178 cases excluded.\(^14\) Inhalational anthrax occurs when spores are inhaled and are of an appropriate size (less than 5\(\mu\)m) to enter the terminal bronchioles, from where they are carried by macrophages to the regional lymph nodes and germinate into vegetative bacilli. The release of toxin into the mediastinum leads to a haemorrhagic mediastinitis, rather than a pneumonia. The characteristic radiological appearances are of a widened mediastinum, but pleural effusions and consolidation can also be seen. Bacilli and toxins may disseminate via the bloodstream to produce features of general sepsis and anthrax meningitis is also frequent, and, being an indicator of late-stage, fulminant disease, is a poor prognostic sign.\(^13\)

Gastrointestinal anthrax is rare in a western setting, but may occur more frequently in the developing world when contaminated meat is eaten and therefore is often reported as a point source outbreak. This is not usually an occupational issue. It may be either oropharyngeal or intestinal.
The former presents as oral ulceration, with oedema and membrane formation, so may be difficult to distinguish from diphtheria. The intestinal form may present as a generalized abdominal catastrophe and has a high mortality, particularly if presentation is late. Ascites may be a prominent feature.10,15

The differential diagnosis of anthrax is wide and depends on the clinical form. For cutaneous disease, this includes rickettsial infections, tularaemia, pseudomonal bacteraemia (ecthyma gangrenosum), orf, herpes virus infection, spider bites and other bacterial skin infections. In gastrointestinal anthrax, any severe abdominal pathology may be included in the differential diagnosis; inhalational anthrax can be confused with any severe chest infection. The diagnosis is established by culture of B. anthracis from appropriate clinical specimens. A polymerase chain reaction (PCR)-based test is also available. A high index of suspicion is required and diagnosis may be delayed unless other recent cases have been reported.

Treatment is with appropriate antibiotics. B. anthracis is sensitive to benzyl penicillin and this was traditionally the treatment of choice. Naturally occurring penicillin-resistant B. anthracis is extremely rare. However, because of concern about genetically manipulated resistance in organisms destined for deliberate release, and because beta-lactams do not penetrate so well into cells and tissues, the treatment of choice these days is usually ciprofloxacin, supplemented, in inhalational anthrax, with at least two of rifampicin, clindamycin and vancomycin. B. anthracis is not sensitive to cephalosporins. Prior to the 2001 cases in the United States, the mortality of inhalational anthrax was reported as being greater than 80 per cent, but with early combination antibiotic therapy, pleural fluid drainage, and modern intensive care the mortality in 2001 was less than 50 per cent. Presentation with fulminant late-stage disease and a requirement for intubation or tracheostomy were poor prognostic features.13

Prevention of occupationally acquired anthrax requires careful management and handling of animal products to minimize exposure to the infective spores. Hair, wool, hide and bone meal should be sterilized or disinfected before processing; in industrialized countries, importation of these products is tightly regulated. An inactivated vaccine is available, and recommended in the UK for selected workers at risk of exposure in higher-risk occupations, including veterinary medicine, research laboratory work, wool or hide-processing plants, and certain military settings.16 Following a known exposure, post-exposure antibiotic prophylaxis may be offered. Ciprofloxacin and doxycycline are the two agents that are favoured. Antibiotics will be inactive against the spores and because of the long incubation period from acquisition of the spores to germination, post-exposure treatment is prolonged (up to 60 days was recommended in the 2001 outbreak in the United States). An alternative is to start a vaccination course and give antibiotics for 30 days until it is felt that the vaccine will be effective.

**Chlamydia*** infection (chlamydiosis, ornithosis, psittacosis)

The two most important zoonotic chlamydial infections are caused by *Chlamydophila psittaci* and *Chlamydia abortus*. Both are found worldwide.

*Chlamydophila psittaci* infects a wide range of wild and caged birds, but human infection is usually the result of exposure to pet psittacine birds (e.g. parrots, parakeets, macaws, budgerigars) or to poultry. Infected birds may be asymptomatic, but nevertheless shed the organism in nasal discharges and faeces; infection in imported, quarantined birds may pass undetected. Chlamydiophila can survive in the environment for months. Human infection follows inhalation of the organism, usually during activities like cage cleaning, pet handling, or carcass evisceration or dressing.17 Outbreaks have been described in poultry processors, pet shop workers, vets and veterinary medicine students, bird-fanciers, zoo and wildlife workers, and others (for example, customs officials exposed to birds at work may also be at risk).18–23 Human infection is probably underdiagnosed. The incubation period ranges from one to four weeks; infection typically presents as an influenza-like illness with features of a community-acquired pneumonia, although milder and asymptomatic infections also occur. Diagnosis is made by serology on paired sera; PCR-based assays can be used to determine the infecting serovar, which may give a clue to the source. Clinical algorithms for the management of severe community-acquired pneumonia usually now include treatment with a macrolide (clarithromycin, azithromycin, erythromycin), which will treat the infection; doxycycline is an alternative.

*Chlamydia abortus* is the most common cause of abortion and fetal loss in sheep (ovine enzootic abortion, enzootic abortion of ewes), and also causes abortion in goats and cattle. The organism is found in quantity in birthing fluids and placentae from infected animals; human infection is thought to occur by inhalation, and there may be a greater risk of transmission when birthing takes place in barns or lambing sheds rather than outdoors. However, infection after handling footwear and clothing contaminated during contact with infected animals has also been reported. Infection is a particular risk for pregnant women, as it may cause a severe febrile systemic illness, with multiorgan involvement, disseminated intravascular coagulation, and fetal death or premature delivery. Treatment (with a macrolide or, provided that the effects of tetracycline use in pregnancy have been considered, a tetracycline) of severe disease should not await confirmation of diagnosis, which is made serologically, or, if the test is available, by direct detection by PCR. Pregnant women should therefore avoid risk exposure (e.g. lambing, kidding, bottle-feeding young, milking, handling boots, clothing or other possibly contaminated objects), and should also avoid exposure to the live vaccine used to prevent infection in animals.24–25
Q fever

Q fever is a febrile illness caused by a Gram-negative coccobacillus, Coxiella burnetii. The disease was originally described following an outbreak of a febrile respiratory illness among workers in an abattoir in Queensland in 1935 and it has long been controversial whether the ‘Q’ stands for ‘Query’ or for Queensland. Q fever is a widespread zoonotic infection that can affect many mammals and birds. Domestic herbivores (cattle, sheep and goats) are the principal source of human infection; the main occupational groups at risk are agricultural workers, meat-processing workers, vets and research laboratory workers. Arthropods, such as ticks, can also be infected and may be responsible for maintaining the animal reservoir. Pet dogs, cats and rodents may also be infected. Animal infection is usually asymptomatic and chronic, but may cause abortion in sheep, goats and cattle. High concentrations of the organism are found in amniotic fluid, fetal membranes and the placenta, which may contain as much as 10^9 organisms/g. Birthing fluids may contaminate the surrounding environment, and, because the organism is relatively resistant to heat and to drying, it can survive in litter, bedding and dust for weeks. It can also be found in the milk, urine and faeces of infected animals, but inhalation of aerosolized organisms seems to be the major method of spread to humans. The infective dose is low: fewer than ten organisms may be sufficient to produce clinical disease. In a well-known outbreak in Switzerland, more than 400 people living along a road on which sheep descended from their mountain pastures became infected.27,28 In Briançon, France, investigation of a community outbreak suggested airborne infection from exposure to a sheep slaughterhouse, where aerosols of contaminated dust were created by helicopters flying over from a nearby heliport.29 More recently, extensive community outbreaks, associated with large-scale goat farming, have been reported from the Netherlands.30 Other reported outbreaks have involved workers in a cosmetics supply factory that handled ovine products,31 staff and patients of a psychiatric institution who worked on a goat farm,32 veterinary high school students on a training course on a sheep farm,33 workers in a cardboard manufacturing plant where a recent refurbishment might have exposed them to straw board dust,34 and military or peace-keeping personnel deployed to Bosnia, Kosovo and Iraq.35–37

In man, many infections are asymptomatic (54 per cent in the Swiss outbreak). The main features of clinically apparent infection are an acute pneumonic syndrome (one of the causes of the so-called ‘atypical pneumonias’), a non-specific febrile illness or acute hepatitis. The incubation period following exposure is about two weeks (mean, 15 days; range, 2–41 days). The non-specific symptoms are usually self-limiting within one to three weeks as is the pneumonia, although this will often have been treated empirically with antibiotics before the diagnosis becomes apparent. Headache and myalgia are prominent features in the pneumonic and non-pneumonic forms of illness. The hepatitis can mimic acute viral hepatitis or become more chronic with the development of granulomata.

In addition to hepatitis, the major manifestation of chronic Q fever is endocarditis. This tends to occur in those who have previous heart valve damage, are pregnant, or are immune compromised.38,39 Q fever endocarditis is often a delayed diagnosis and it is common for patients to have the more chronic features of endocarditis, such as finger clubbing and splenomegaly, together with features of immune complex activation.

There are no specific clinical features to aid in diagnosis and therefore there must be a high index of suspicion and requests for specific diagnostic testing. It is important to take a careful history about occupational or other exposure. Routine blood cultures are negative. There may be elevated inflammatory markers, white blood cell count is typically normal, but there may be thrombocytopenia and elevated liver transaminases.

The diagnosis is usually made by serological testing using immunofluorescence or complement fixation to detect antibodies to phase-1 and -2 antigens. Somewhat confusingly, antibodies to phase-2 antigens suggest acute Q fever (especially if there is an IgM response), whereas high titre antibody to phase-1 antigens suggests chronic infection.

Treatment of acute Q fever is usually with doxycycline. In Australia, a Q fever vaccine has been licensed and used in a national programme targeted at abattoir workers and farmers, and an online register of workers’ immune status has been developed. The number of cases of Q fever notified in Australia decreased by 50 per cent between 2002 and 2005.40,41 Vaccine is contraindicated in those previously exposed to C. burnetii because severe local reactions may occur at the vaccination site, so pre-vaccination serology and skin testing are required. The vaccine is not commercially available elsewhere, but in other countries, vaccine for researchers working with live C. burnetii may be available under investigational new drug protocols. Guidelines on safety in laboratories and sheep research facilities cover risk reduction for workers and visitors; guidance has also been produced for farmers.42–44

OCCUPATIONAL ZOONOSES PRESENTING AS FEVER

Brucellosis

Brucellae are facultative intracellular Gram-negative coccobacilli that produce the clinical condition known as ‘brucellosis’. There are at least eight named species, each closely associated with specific animal hosts, but Brucella abortus, B. melitensis and B. suis cause most human disease. B. melitensis, first isolated by Bruce in 1886, and soon after shown to be the cause of Malta fever, acquired by drinking unpasteurized milk from infected goats, is found also in
sheep and camels, and has recently emerged as a problem in cattle in southern Europe. B. abortus was shown by Bang to cause abortion in cattle, and also occurs in buffalo, bison and elk. B. suis was first isolated from aborted pigs, and is also found in wild boars and hogs, and cattle; one serovar is host adapted to reindeer and caribou. The other species – B. ovis (found in sheep), B. neotomae (found only in desert wood rats), B. canis (dogs), B. maris (possibly three separate species, found in marine mammals) and B. microti (voles and red foxes) are either rarely (B. canis, B. maris) or never (B. neotomae) associated with human disease.\textsuperscript{45–48} Nearly all human cases of brucellosis are acquired directly or indirectly from animals, and disease incidence in humans reflects the prevalence of infection in local domestic animal herds. Infection is found worldwide, but is especially prevalent in the Mediterranean countries, the Middle East, South Asia, Africa and parts of Latin America. Humans acquire infection by direct contact with infected animals, or their birthing or abortion products (when the organism gains entry through cut or abraded skin, or conjunctivae or mucous membranes) or by inhalation of aerosolized animal material. Infection can also follow ingestion of raw milk or unpasteurized dairy products. Human-to-human spread by sexual contact has been described, but is uncommon.\textsuperscript{49} Test and slaughter policies combined with vaccination programmes have led to the near eradication of B. abortus in cattle in the United States, United Kingdom and other industrialized countries, and this has been paralleled by a decline in the incidence of cases in humans. Programmes to control B. melitensis have been less effective. Many countries in Northern Europe are animal brucellosis free, although infections may occur in returning migrants occupationally exposed abroad, in travellers who have eaten unpasteurized dairy products, and in older or retired workers infected when animal disease was still prevalent.

Brucellosis is an occupational hazard for agricultural workers, veterinary workers, abattoir workers and meat packers, hunters and laboratory personnel. Although laboratory work on brucelae has long been recognized as hazardous, and work with the organisms requires biosafety level 3 containment, laboratory-acquired infection still occurs.\textsuperscript{50} Cases are often attributable to open-bench exposure to cultures derived from patients in whom the diagnosis had not been suspected.

The clinical syndrome of brucellosis usually develops between two and four weeks after exposure. The onset may be acute or more insidious and the features can be divided into general systemic features and those features related to more specific sites of infection. The initial features are usually those of non-specific pyrexia of unknown origin – fever, malaise, sweats, headache, back pain and anorexia. Chronic brucellosis has been described as causing a depressive illness and cases of suicide in farmers have been attributed to this, but the evidence is not convincing.

Objective physical findings are not usually prominent. Rash is rarely apparent and apart from the fever, unimpressive lymphadenopathy has been described together with an enlarged liver and/or spleen.\textsuperscript{18,51} There is not thought to be any major distinction between the clinical syndromes produced by the different species. In a review of 530 cases of disease caused by B. melitensis approximately one-third developed a localized complication.\textsuperscript{57} These may include bone and joint infection (especially sacroiliitis and/or spondylitis), aseptic meningitis, endocarditis (which is uncommon, but may account for much of the mortality from brucellosis), hepatic abscess (granulomatous hepatitis on liver biopsy when investigating pyrexia of unknown origin (PUO) is a common finding, but very non-specific) and epididymo-orchitis. Rarer complications include pneumonitis, uveitis, other abscesses (e.g. paraspinal, spleen, brain) and occasionally infection of prosthetic material.

Initial laboratory findings are non-specific and include evidence of an acute-phase response often accompanied by pancytopenia. Liver function tests may show a low-grade hepatitis. Various imaging modalities may be used to demonstrate abscess or other localized infection in areas that may then be accessible for biopsy or fine needle aspiration.

Diagnosis is achieved either by isolation of brucellae from blood cultures or by demonstrating a definitive serological response to brucella infection. It is important to consider the diagnosis on the basis of the clinical picture together with a detailed travel, occupational, recreational and dietary history. Cultures may be positive in up to 90 per cent of cases and the yield may be greater if bone marrow and liver biopsy (or other clinical material, e.g. from an abscess) samples are cultured in addition to blood.\textsuperscript{52} It is essential that clinicians inform laboratory colleagues that a diagnosis of brucellosis is suspected: this not only ensures that the samples will be processed safely, but also ensures that they will be processed in a way that will provide the optimum diagnostic yield, by prolonging the period for which samples are incubated.

Serological testing usually uses the tube agglutination test or an ELISA technique. A single titre of antibody at a dilution greater than 1:160 in the context of a compatible clinical picture is regarded as diagnostic. Demonstration of a greater than four-fold change in titre over 4–12 weeks provides even stronger evidence of infection. The ELISA test is generally felt to have higher sensitivity and specificity than tube agglutination. Tests for antigen detection are in development.

Treatment of brucellosis with antibiotics improves symptoms, shortens the duration of illness and reduces risk of complications and relapse. Single-drug therapy has produced an unacceptably high level of relapse, so combination therapy with doxycycline and an aminoglycoside and/or rifampicin is recommended.\textsuperscript{53} Most of the early aminoglycoside studies used streptomycin, whereas these days most clinicians would probably be more familiar and comfortable with gentamicin. Doxycycline should be given in a dose of 100 mg twice daily together with rifampicin.
Hantavirus infection

Hantaviruses, RNA viruses that form a genus in the bunyavirus family, generally each have a single species of rodent (e.g. cotton rat, striped field mouse, deer mouse, bank vole) as their primary reservoir. The viruses do not cause overt illness in the rodent hosts, but an infected animal excretes virus in urine, saliva and faeces. Hantaviruses cause two clinical syndromes: haemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). Infection is thought to be usually acquired by inhalation of dust containing virus-contaminated saliva or excreta; infection has also followed the bite of an infected rodent.

Four hantaviruses (Hantaan, Seoul, Puumala and Dobrava viruses) found largely in Europe and Asia, cause HFRS of varying severity. Hantaan virus infection (first described in the English language literature as Korean haemorrhagic fever, but occurring more widely in eastern Asia, in China and Russia) is the most severe, with a mortality rate of up to 15 per cent. By contrast, Puumula virus, which occurs throughout northwestern Europe, and is the cause of ‘nephropathia epidemica’, has a mortality rate of less than 1 per cent. Seoul virus occurs worldwide; infection after exposure to infected laboratory rats has been described.

HPS occurs in North and South America. Hantaviruses were identified as the cause in 1993, when Sin Nombre virus was discovered during the investigation of an outbreak of adult respiratory distress syndrome with a high case fatality rate in the southwestern United States. HPS is relatively uncommon in the United States, where fewer than 100 cases are reported annually; most are caused by Sin Nombre virus, although other hantaviruses (New York, Bayou, Monongahela and Black Creek Canal) are also known to cause disease. HPS is more common in South America, where it has been caused by Andes, Oran, Lechiguana and Juquitiba viruses; Andes virus is unusual in that it is the only hantavirus known to have been transmitted from person to person, and nosocomially.

Hantavirus infection is diagnosed serologically; reference laboratory testing is usually required. Intravenous ribavirin is effective in the treatment of HFRS, but not useful in HPS, for which treatment is essentially supportive.

Guidelines on risk reduction highlight precautions that may limit the occupational risk (likely to be greatest for those whose work involves frequent handling of wild rodents, e.g. field biologists, mammologists, rodent operators), including the use of personal protective respiratory equipment.

Hepatitis E

Hepatitis E virus is a non-enveloped single-stranded RNA virus, which is usually transmitted by the faeco–oral route, causing fever and acute hepatitis, with anorexia, jaundice.
and hepatomegaly. Infection late in pregnancy may be especially severe, with fulminant hepatitis and a high (>20 per cent) mortality rate. In industrialized countries, infection is usually sporadic, but large epidemics, associated with contamination of water supplies, have occurred in developing countries. Swine and wild boar may act as an animal reservoir; viruses found in sporadic human cases in non-endemic areas have been found to be closely related to hepatitis E viruses detected in pigs. There are case reports of infection in butchers and slaughterhouse workers without a history of travel to an endemic area, and there is some evidence also from seroprevalence surveys of a possible occupational risk from work that involves exposure to swine. Diagnosis is made serologically; infection is clinically indistinguishable from other causes of viral hepatitis. There is no carrier state, nor is there a specific treatment. A vaccine is not available; prevention of sporadic infection involves adoption of standard infection prevention measures, including good hand hygiene.

Leptospirosis

Leptospirosis is a zoonotic infection that can cause a variety of different clinical pictures in man ranging from asymptomatic infection to severe multiorgan disease with hepatorenal failure (Weil’s disease). It has a worldwide distribution (except for the polar regions), but is particularly prevalent in the tropics. The taxonomy of leptospires (spirochaetes with hooked ends) is complex and still evolving. Historically, two phenotype-based species – Leptospira interrogans (containing pathogenic strains) and L. bireflecta (containing non-pathogenic strains) – were further subdivided on the basis of serological tests into more than 250 serovars, with antigenically related serovars grouped into a smaller number of serogroups. Each serovar has a defined host range, and the number of serovars present in any given geographical area tends to be restricted, particularly in temperate zones. Advances in molecular biology have led to a genotype-based classification, which recognizes at least 17 different species. For the moment, the two systems exist in parallel.

Rodents and other small mammals are the most important animal reservoir. They become infected in infancy, develop a chronic renal infection and excrete leptospires in their urine throughout their life. Excreted organisms may remain viable in soil or water for weeks. Larger mammals, such as dogs, cattle and pigs, develop a symptomatic infection that may be fatal, or become chronically infected and shed leptospires into the environment. People who have direct contact with animals, water or soil are at greatest risk of occupationally acquired leptospirosis, which was first described in miners in the early twentieth century, although jaundice in rice-paddy workers has been recognized since ancient times in China. Infection is seasonal, with a peak in incidence in the rainy season in the tropics, and in the summer or autumn in countries with temperate climates. Infection rates may rise after heavy rainfall or flooding.

Occupational risk groups include dairy and pig farmers, vets, abattoir workers, hunters and trappers, rodent control workers, sewage and canal workers, fish workers and fish farmers, sugar cane cutters and banana farmers, and the military. In a western setting, infection is also acquired by recreational exposure to water, and has been reported in canoeists, wild-swimmers, cavers, white-water rafters and triathletes, and in the UK, an increasing proportion of infections are reported in travellers exposed on adventure holidays abroad.

Leptospires invade through mucous membranes, conjunctiva or microabraded or water-sodden skin; it is not known whether they can penetrate intact skin. They are disseminated via the bloodstream and are therefore widely distributed throughout the body where they produce a vasculitis, the exact mechanism of which remains obscure.

The clinical features are very variable. Many of those infected will have an asymptomatic seroconversion. Others may have a mild non-specific febrile illness and others may have one of the more easily appreciated syndromes. The average incubation period seems to be about ten days, although it is often difficult to establish exactly when exposure occurred and a range of incubation periods from two to 26 days has been reported. The majority of symptomatic cases present with sudden onset of fever, rigors, myalgia and headache. Nausea, vomiting, diarrhoea and cough are also common features. On examination, the most characteristic finding is conjunctival suffusion and muscle tenderness, but these probably only occur in a minority of cases. Less common physical findings include lymphadenopathy, hepatosplenomegaly, chest signs and a rash. Clinical features of meningitis may also be present. Although the illness is often described classically as ‘biphasic’, in practice such a pattern is rarely recognized. However, as the immune response appears the patient may deteriorate and develop one or more of the more specific syndromes associated with leptospiral infection. These include aseptic meningitis, Weil’s disease (with the classic triad presentation of jaundice), thrombocytopenia and renal failure (where, despite the jaundice, liver function is usually relatively well preserved), cardiac syndrome (with myocarditis leading to cardiac failure), and pulmonary syndrome. The pulmonary syndrome has been described particularly in South America, and may vary from mild respiratory symptoms and signs to severe pulmonary haemorrhage and adult respiratory distress syndrome. A recent review in Peru suggested that nearly 4 per cent of patients with serologically confirmed leptospirosis had severe pulmonary manifestations, but would not have been otherwise diagnosed if they had not been part of the study.

The differential diagnosis during the non-specific febrile phase is wide and includes malaria, typhoid, influenza, rickettsial infection (especially scrub typhus) and arbovirus infection (including dengue fever). Routine
laboratory investigations are similarly non-specific – the white cell count may be elevated or lowered (usual range 3000–25 000/mm³) often with a left shift. About half the patients have elevations of liver transaminases (fairly mild) and creatinine kinase. The urine is often abnormal with proteinuria, white cells, casts and occasional microscopic haematuria. In Weil’s disease, renal function deteriorates and the bilirubin may be very high. The chest x-ray may show non-specific shadowing. The platelet count may sometimes be reduced. The cerebrospinal fluid may show an elevated white cell count with neutrophils or lymphocytes, minimal to moderately elevated protein concentrations and normal glucose.

Because of the non-specific nature of the clinical picture and the laboratory findings, a high index of suspicion must be maintained if the diagnosis is not to be missed.

Leptospira can be seen by dark ground microscopy of blood or urine, but sensitivity and specificity are low and the technique is rarely used in practice. The organism can be cultured from blood (taken in the first ten days of the illness and before antibiotics have been administered) and from urine from the end of the first week and for some time afterwards, but culture requires special media, prolonged incubation, and is also relatively insensitive. Most patients have their infection identified serologically. The traditional gold standard test has been the microscopic agglutination test (MAT), which uses live organisms and can be technically demanding to perform. Therefore, most laboratories use a screening test first, such as an ELISA for IgM antibodies – these are usually detectable on day 5 of illness. PCR-based methods are in development, but are not yet in widespread use.

Leptospira are susceptible to many antibiotics in vitro, including penicillins, third-generation cephalosporins, macrolides and tetracyclines; intravenous penicillin has been used in the treatment of severe infection for decades. There is debate about the effectiveness of antibiotics if given any later than early in infection, doubt about whether mild disease needs to be treated, and few trials on which to base recommendations. Nevertheless, in endemic areas, where it is common for leptospirosis to be misdiagnosed as a rickettsial infection or vice versa, oral doxycycline 100 mg bid is a sensible option, as it will treat both conditions empirically while serological diagnosis is awaited. If the patient is very unwell, then intravenous penicillin 1.2 g six-hourly or ceftriaxone 1 g once daily should be used. There are no trials on duration of therapy, but ten days is usually recommended.

Infection risks can be reduced by effective rodent control, avoidance of high risk exposure, and use of personal protective equipment (e.g. boots, goggles, rubber gloves, waterproof overalls, depending on the type of exposure expected) and standard veterinary infection control precautions when dealing with potentially infected animals. A study on chemoprophylaxis from 1984 showed significant benefit of weekly doxycycline 200 mg among American troops in the jungles of Panama.

**Streptococcus suis infection**

*Streptococcus suis* is a porcine pathogen with a worldwide distribution, found wherever pigs are farmed. It causes septicaemia, meningitis, arthritis and meningitis in pigs; illness is more common when pigs are intensively farmed in suboptimal conditions. Human infection is associated with direct contact with sick or carrier pigs, and with eating undercooked pork products (particularly traditional foods, e.g. pig’s blood), so there is an occupational risk for pig farmers (including ‘backyard farmers’), abattoir workers, slaughterers, butchers and veterinarians. Wild boar workers may also be at risk.

Although more than 30 serotypes of *S. suis* have been recognized, human infection is usually caused by *S. suis* serotype 2. Infection is uncommon and sporadic in the United Kingdom and the United States, but the organism has recently been recognized as an important zoonotic pathogen in China and Southeast Asia. In 2005, it caused an outbreak of streptococcal toxic shock syndrome (STSS) and meningitis that affected 204 people (with 38 deaths), mostly men who had slaughtered or eaten sick pigs; recent surveys suggest that *S. suis* is a common cause of acute bacterial meningitis in adults in Thailand, Vietnam and Hong Kong SAR. The infection has a short incubation period (from a few hours to three days); cases present with clinical features of meningitis (fever, headache, neck stiffness, photophobia, nausea or vomiting) or septicaemia, and may in addition have signs of STSS, including purpura or a haemorrhagic rash. Septic arthritis and endocarditis may also occur. Diagnosis is made by culture of blood and cerebrospinal fluid (CSF); a PCR-based test is also available. The organism is sensitive to penicillins (although resistant strains have been reported), cephalosporins and vancomycin. Mortality rates (particularly in STSS) may be high; deafness is a common sequel of meningitis.

Prevention involves standard good hygiene (e.g. using appropriate PPE during slaughtering, hand hygiene) and ensuring that all pork products are thoroughly cooked before being eaten.

**Toxoplasmosis**

This is the clinical condition caused by infection with the intracellular protozoon parasite *Toxoplasma gondii*. Cats are the definitive host; humans, other mammals and birds serve as intermediate hosts. In sheep and goats, infection may cause abortion or fetal loss, with considerable economic costs. Humans become infected either by exposure to oocysts excreted from cats (e.g. by handling cat litter or through gardening), by handling raw meat, or eating
undercooked meat derived from an infected intermediate host. Seroprevalence of infection increases with age (because of cumulative exposure), but is generally falling with increased standards of living. Overall, between 20 and 70 per cent of adults in the United States have serological evidence of previous exposure (and therefore have long-term subclinical infection).84

There may be an occupational risk for workers exposed to animals with clinical toxoplasmosis or to aborted lambs, kids, piglets and their placentas (e.g. farmers, shepherds, vets, animal shelter employees), and those who may be exposed to infected animal carcasses or raw meat (e.g. hunters, abattoir workers, meat packers, butchers, chefs and zoo workers). Infection might be acquired orally (by transfer of organisms on unwashed hands to the mouth), or through inoculation via damaged skin. Laboratory-acquired infections have been reported (including infection caused by needlestick injury while performing the Sabin Feldman dye test, which requires the use of live organisms), but a study of workers in a toxoplasma reference laboratory concluded that the risks to workers were low.85 The live attenuated vaccine used to control infection in sheep may cause human infection if accidentally inoculated, and should not be administered by women of childbearing age. In practice, most infections are probably acquired non-occupationally. However, an information sheet on preventing exposure in pregnant women during the lambing season is available.86

Most acute infections result in an asymptomatic seroconversion. A small proportion of immunocompetent adults develop a ‘glandular fever-like syndrome’ of malaise, fever, headache and lymphadenopathy. Atypical lymphocytes may be found in the peripheral blood and there may be a pharyngitis, although this is probably less prominent than with the infectious mononucleosis produced by Epstein–Barr virus (EBV) infection. Monospot or Paul Bunell testing is negative, as is IgM serology for EBV. The differential diagnosis includes cytomegalovirus (CMV), human herpes virus 6, lymphoma, HIV seroconversion illness and cat scratch disease. Toxoplasmosis is sometimes diagnosed histologically when lymph nodes are excised, but is more often diagnosed by tests for specific antibody. Acute toxoplasmosis is usually a benign self-limiting condition with no sequelae; no active treatment is needed. If a woman acquires toxoplasmosis infection during pregnancy, there is a significant risk of transmission to the unborn child, which can result in congenital toxoplasmosis and disability in the infant. Infection early in pregnancy is less likely to transmit to the fetus, but more likely to cause severe damage, whereas infection later in pregnancy is more likely to transmit to the fetus, but less likely to result in organ damage, although infants who have subclinical infection at birth may develop signs of disease much later. As most acute infections are asymptomatic, some countries (e.g. France) have serological screening programmes. Elsewhere, prevention is dependent on exposure reduction through education.87

The greatest concern about *T. gondii* infection is in patients who are immune compromised as a result of malignancy (especially myelo- or lymphoproliferative disease), iatrogenic immune suppression or by HIV. In these individuals, latent toxoplasma infection can reactivate, causing encephalitis, pneumonitis and chorioretinitis. Diagnosis of cerebral toxoplasma in an HIV-positive patient is made by diagnostic imaging (magnetic resonance imaging (MRI), plus possibly positron emission tomography (PET)). The majority of patients have positive serology for toxoplasma. Primary prophylaxis reduces the incidence of reactivation-associated disease; treatment of established disease is with pyrimethamine and sulphadiazine.

### West Nile virus

West Nile virus is a flavivirus that is a pathogen for birds (the natural hosts), equines and humans. The virus was first identified in Uganda, and recognized as a cause of acute meningoencephalitis in Israel 20 years later. It is endemic in Africa and the Middle East, and since 1999 has emerged as a cause of meningoencephalitis throughout the United States, with spread to adjacent countries.88–90 The majority of clinically apparent infections are mild, with fever, headache and occasionally a rash on the trunk. Neuroinvasive disease occurs in less than 1 per cent of infections, but mortality in hospitalized cases is significant; the risk of severe disease increases with age. Treatment is essentially supportive. Human infection is usually mosquito borne, but infection in laboratory workers after exposure via needlestick or aerosol while working with infected animal tissues or cell cultures has been reported.91 A cluster of cases among turkey breeder farm workers in Wisconsin led to recommendations to include the use of insect repellents, alongside standard infection prevention measures that include good hand hygiene and use of personal protective equipment.92 Infection in an alligator farm worker who had cared for sick alligators has also been reported.93,94 Recommendations to prevent West Nile virus exposure in outdoor and field workers (likely to be primarily mosquito-borne) also emphasize the importance of insect repellents and protective clothing.94,95 A vaccine has been developed for prevention of equine infection, but a vaccine for humans is not yet available.

### OCCUPATIONAL ZOONOSES PRESENTING AS GASTROINTESTINAL INFECTION

#### Salmonellosis

The nomenclature of the salmonellae has recently been revised to accommodate advances in taxonomy. DNA hybridization studies showed that the ‘one serotype, one species’ concept – which, as the number of organisms distinguishable by serotyping increased, had led to an
accumulation of over 2000 pathogenic species – was no longer tenable because the organisms had such closely related DNA. All clinically important salmonellae are now classified as a single species – *Salmonella enterica* – with serotypes (now grouped within one of six subspecies) referred to with a capital letter and in plain, rather than italic, type. For example, *Salmonella typhimurium* becomes *S. enterica* subsp. *enterica* ser Typhimurium, or is short-ened to *S. Typhimurium*.96,97

Despite their microbiological similarities, there are major clinical and epidemiological distinctions between the so-called ‘typhoidal’ and ‘non-typhoidal’ salmonellae. The former group, which includes *S. Typhi* and *S. Paratyphi*, are exclusively human infections that are spread from person to person. Infection is acquired by the faeco–oral route, but the major manifestations (at least in the early stages) of infection are due to bacteraemia rather than luminal infection within the gastrointestinal tract. By contrast, the non-typhoidal salmonellae are mainly zoonoses and having been acquired via the faeco–oral route, their initial pathogenesis is within the gut to produce ‘gastroenteritis’, although they may go on to produce invasive disease, with bacteraemia and subsequent localized infection. Most infections are caused by ingestion of contaminated food or water, and are not occupationally acquired. Many cases are associated with overseas travel and several serotypes of salmonella can also be acquired from pet animals, including amphibians, and reptiles and the small rodents used to feed them.98,99 The main occupational groups at risk are veterinary and agricultural workers, and laboratory workers. Infection of workers in a vaccine production plant has also been reported.100 Food handlers may transmit infection; food safety and hygiene regulations cover employment and exclusion practices.101,102

Salmonellosis as a cause of gastrointestinal infection has been declining in the west since a peak in the mid-1990s.5,6 *S. Enteritidis* and *S. Typhimurium* are the most frequently isolated serotypes. The former organism is a particular problem in the poultry and egg production industries, though rates of infection in breeder flocks have fallen in the last decade; the latter organism is found in dairy products, pork, turkey, beef and lamb. Monitoring farm premises for control purposes often reveals widespread environmental contamination, with reports of isolation of salmonellae from farm offices, tractor cabins, boots and animal pens post-disinfection.6 Workers who are occupationally exposed to salmonellae may inadvertently contaminate their home environment. In New Zealand, where *S. Brandenburg* has emerged as a pathogen only in the last decade, a case–control study found that infection was significantly associated with occupational contact with sheep, or having a household member who had occupational contact with sheep.103 In the United States, *S. enterica* was isolated from the contents of vacuum cleaner bags in 27 per cent (15/55) of households where one or more occupants had workplace exposure (in veterinary practice, a salmonella reference laboratory or on livestock farms), but not from households without such exposure.104

The gastrointestinal illness produced by infection with non-typhoidal salmonella is clinically indistinguishable from that caused by many other gastrointestinal pathogens. Diarrhoea is the main feature and this may be initially, or may become, bloody. It may often be associated with vomiting, abdominal pain and cramps, and sometimes with fever. The usual incubation period following ingestion of contaminated food or water is 12–72 hours (in contrast to typhoid where the incubation period is 10–14 days and the initial presentation is with fever, often accompanied by constipation). Approximately 5 per cent of patients with salmonella gastroenteritis will develop a salmonella bacteraemia; this is more likely with *S. Typhimurium* infection, especially if the organism is quinolone resistant.105 Localized infection (e.g. of bones or joints) may then follow; more rarely endocarditis may occur.

Salmonellae have also been reported as a cause of pustular dermatitis (usually of the forearm), without gastrointestinal symptoms, in veterinarians who had delivered calves without adequate personal protective equipment.106 A recent Cochrane review found no clinical evidence of benefit in treating otherwise healthy adults (or children) with antibiotics for non-severe salmonella gastroenteritis, confirming previous reports that giving antibiotics increases the risk of adverse events and of prolonged stool carriage of salmonellae.107 Antibiotics are recommended in those who are ill enough to require hospitalization, especially if they have high fever suggestive of invasive infection. Quinolones remain the first choice of treatment, although reports of resistance in typhoidal and non-typhoidal salmonellae mean that sensitivity should not be assumed. Third-generation cephalosporins (cefotaxime or ceftriax-one) or azithromycin are potential alternatives.

### Campylobacteriosis

Campylobacters are colonizing organisms found in the gut of many vertebrates and were first shown to be human pathogens in the early 1970s. By the mid-1980s, they had become the most commonly identified bacterial cause of acute infectious intestinal disease in the United Kingdom.6,108 Two species, *Campylobacter jejuni* (found in poultry and a broad range of farm animals) and *C. coli* (found in swine) are responsible for most human infections. Studies suggest that a high proportion of fresh chicken may be contaminated with campylobacter.

Campylobacter gastroenteritis is clinically indistinguishable from any other cause of gastroenteritis and presents with diarrhoea that is often bloody, associated with abdominal pain and nausea. Vomiting seems to be less common than with salmonella infection, and bacteraemia is less frequently identified, although it may be underestimated. The abdominal pain may be severe, may precede the diarrhoea and may mimic an acute abdomen. The role
of antibiotics in the treatment of campylobacter is not clear. A meta-analysis suggested that antibiotic treatment shortened the duration of diarrhoea by 1.32 days. Quinolones and erythromycin are effective treatments, but there is concern because of increasing resistance to quinolones (perhaps worsened by their use in veterinary medicine). In practice, most illness is self-limiting, and infection is often not diagnosed sufficiently early for antibiotic therapy to be beneficial. Guillain–Barré syndrome is a well-recognized complication. The greatest risk for campylobacter infection is eating undercooked poultry or food cross-contaminated by contact with poultry; infection is also associated with foreign travel. However, agricultural workers and those employed by the meat and poultry industries are at risk of campylobacter infections, as are veterinary staff. Outbreaks among workers on poultry (including turkey and pheasant) farms have been reported. The risk of infection may be greater early in the course of employment: an explosive outbreak among workers in a poultry abattoir occurred when temporary student workers were employed to provide cover during the holiday season. In the United States, a case–control study of sporadic C. jejuni infection estimated that 18 per cent of infections in rural areas were attributable to poultry husbandry, although poultry husbandry was not necessarily the primary occupation. These infections are largely preventable, by good hand hygiene.

**Enterohaemorrhagic Escherichia coli infection**

In the United Kingdom, these organisms are called Vero cytotoxin-producing E. coli (VTEC), whereas in the United States they are called Shiga toxin-producing E. coli (STEC). These organisms are also known as enterohaemorrhagic E. coli (EHEC), and cause a characteristic, toxin-mediated, bloody diarrhoea, first recognized in 1982, when two outbreaks of haemorrhagic colitis were associated with eating hamburgers from a national restaurant chain. There are a number of serotypes in the group: E. coli 0157: H7 is the most frequently identified in Europe and the United States; in Australia E. coli 0111: H- is more common. Their main ‘natural’ habitat is the gut of healthy cattle and other ruminants; carcasses become contaminated at slaughter. Outbreaks have been associated with inadequately cooked contaminated beef and exposure to other foodstuffs (including raw milk, cured sausages and cheese) or contaminated water. Infection may also follow direct contact with live animals; risks extend to visitors to open farms and petting zoos. VTEC present occupational risks similar to those of campylobacter and salmonella, although the lower infective dose may make infection after direct exposure and transmission from person to person more likely.

The incubation period after ingestion of organisms is about three or four days, although a range from one to nine days has been reported. The spectrum of disease ranges from mild diarrhoea to severe haemorrhagic colitis, haemolytic uraemic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP) and death. The disease is more severe and mortality is higher in children and the elderly. There is usually the onset of abdominal cramps followed by diarrhoea that initially may be watery, but in the majority of cases becomes bloody at some stage in the illness. Fever is often absent, which may, in the absence of a known outbreak, lead attending clinicians to entertain diagnoses of non-infectious diarrhoea, such as ischaemic colitis or inflammatory bowel disease. A detailed occupational and food history is important; cases should be promptly reported to relevant public health authorities to enable rapid outbreak detection and control.

HUS is a syndrome of acute renal failure, microangiopathic haemolytic anaemia and thrombocytopenia. It can occur in between 5 and 10 per cent of those infected with E. coli 0157; young children are especially vulnerable. At least half of those diagnosed with HUS will need acute renal support and the long-term sequelae are not insubstantial – there is a 12 per cent risk of death or end-stage renal disease and a 25 per cent risk of other sequelae, such as hypertension, persistent proteinuria or some degree of chronic kidney disease. HUS does not develop then there are generally no renal sequelae from E. coli 0157 diarrhoea. TTP has similar underlying mechanisms, but is more likely to occur in the elderly, and to affect the central nervous system to produce stroke syndromes or the colon to produce ischaemic colitis.

Treatment is essentially supportive; prompt, effective volume repletion may prevent the development of HUS. The effect of antibiotic therapy on the subsequent risk of developing HUS, TTP or other complications remains controversial, but most authorities advise against it on the grounds that no benefit of antibiotic treatment has been demonstrated and some studies have suggested that antibiotics induce the expression and release of toxin and may precipitate HUS.

Prevention of EHEC infection requires scrupulous attention to hygiene in handling of animal carcasses in abattoirs and butchers’ premises, and to standard good practice in the catering industry, including adequately cooking meat. Patients admitted to hospital with bloody diarrhoea should be isolated and strict enteric precautions must be taken by all staff to minimize the risk of person-to-person transmission. There is specific guidance about avoiding risks of zoonotic infection at farms and petting zoos that have been opened to the public.

**Cryptosporidiosis**

Cryptosporidia are coccidian protozoa that were first described in the stomach of mice in 1907. By the early 1970s, they were recognized as a cause of diarrhoea in cattle, but were not really thought of as a human pathogen until the 1980s, when it was recognized that they were the...
cause of a severe, intractable, diarrhoeal syndrome in patients with AIDS or other severe immune suppression. It is now realized that cryptosporidia can cause an unpleasant diarrhoeal illness even in the immune-competent. Although 16 species of cryptosporidia are now recognized, *C. hominis* (usually not zoonotic) and *C. parvum* (usually zoonotic) cause most human infections. Cattle farmers are at particular risk of cryptosporidia infection119 and it is a risk to others on farm visits and open days.

Cryptosporidian oocysts are excreted by infected animals (especially calves and lambs) and may survive in the environment for some time. They are resistant to chlorination and have a low infective dose, so waterborne spread – either from drinking water or recreational or occupational use of water – is possible. The oocysts are infective at the time they are released, so person-to-person spread can occur. Cryptosporidia are found worldwide, although infection is probably underdiagnosed in developing countries.

The diarrhoea is usually watery and free of blood. It may be accompanied by nausea, anorexia and abdominal discomfort. Fever is uncommon. Infection is generally self-limiting and resolves within about two weeks. In AIDS patients, the diarrhoea generally improves as immune restoration takes place in response to antiretroviral drugs; nitazoxanide may be an effective specific therapy. Treatment is not indicated in the immune-competent.

In the developed world, prevention has focused on reducing the risk of cryptosporidial contamination of drinking water supplies, by fencing off reservoirs from animals and improvement of water treatment processes.

**OCCUPATIONAL ZOONOSES PRESENTING WITH SKIN PROBLEMS**

**Lyme disease**

Lyme disease is the most common tick-borne infection in the northern hemisphere. It was first formally described in 1977, after an outbreak of arthritis associated with a characteristic skin rash affected residents of the towns of Lyme and Old Lyme in southeast Connecticut over a five-year period.120 Transmission by an arthropod vector was postulated, but it was not until 1982 that the causative organism was isolated both from humans and ticks.121 The condition is caused by infection with organisms of the genus *Borrelia*. The main species responsible for Lyme disease is *Borrelia burgdorferi* sensu strictu, although in Europe the condition may be caused by two closely related organisms, *B. afzelii* and *B. garinii*. The bacterium is transmitted by hard ticks of the genus *Ixodes* (Figure 60.3). Forest rodents and small mammals, such as deer, are the usual animal hosts. Man is infected by the bite of an infected tick (usually the nymph stage). Lyme disease can theoretically occur wherever there is the pool of infected mammals and the appropriate hard ticks to maintain transmission. In practice, it is mainly reported from the United States and Europe. In the United States, more than 90 per cent of cases are reported from the northeastern states with just a few reports from the southwest. It occurs in the United Kingdom, but is more often reported from other European countries, particularly Austria, Germany, Slovenia and Sweden, usually from rural areas that have the requisite mammal and tick populations. The distribution of Lyme disease outside North America and Europe remains unclear: there is controversy about whether infection occurs in Australia, and few data for Africa, Asia or Latin America.

Occupational exposure may occur in forestry workers, agricultural workers, veterinarians and those employed in the leisure industry in endemic areas.

The clinical manifestations are conventionally divided into three stages: (1) early localized cutaneous involvement, (2) disseminated infection to heart, nervous system and joints and (3) persistent or late Lyme disease.122 In most patients with Lyme disease (80 per cent), the initial indication of infection (stage I) is the characteristic skin rash known as erythema (chronicum) migrans (Figure 60.4).

---

**Figure 60.3** A hard tick. Vector for a number of zoonotic infections including Lyme disease. See website (www.hodderplus.com/hunters) for colour plate.

**Figure 60.4** The classical rash of Lyme disease. See website (www.hodderplus.com/hunters) for colour plate.
This is a red lesion centred on the site of the tick bite. There is often some fading of the rash in the middle zone of the lesion so that the rash is said to resemble a ‘bull’s eye’. This usually appears any time between three and 30 days after the tick bite and may be accompanied by systemic features of general malaise, fever, arthralgia and headache. The rash fades slowly over a few weeks with or without treatment and may be the only manifestation of infection.

The early disseminated stage (stage II) is initially characterized by disseminated erythema migrans lesions and then later by neurological or cardiac involvement. The main neurological symptoms are isolated cranial nerve palsies (especially Bell’s palsy), a lymphocytic meningitis, a radiculopathy and more controversially a form of encephalitis. These are described in about 15 per cent of patients with initial Lyme disease. Cardiac involvement is more rare and includes conduction disturbances or a myocarditis that can be severe and lead to long-term cardiac damage. Cardiac involvement occurs in about 5 per cent of untreated initial infections.

Late Lyme disease may develop months or years after initial infection especially if the initial episode was unrecognized or inadequately treated. It can affect up to 60 per cent of those initially infected. The most common manifestation is a chronic or intermittent arthritis that affects large joints, especially the knee. The arthritis may become established and chronic and may fail to improve even after long-term high-dose antibiotic therapy.

Neurological late Lyme disease (sometimes known as chronic neuroborreliosis) can afflict up to 5 per cent of those initially infected. This may present as sensory disturbances, radicular pain, and sometimes as muscular weakness. The pathology seems to be an axonal neuropathy with characteristic features on electromyography (EMG). A picture of encephalitis with cranial nerve involvement or cognitive impairment has also been described. Cerebrospinal fluid serology for B. burgdorferi antibody is commonly positive in those with late neuroborreliosis, but PCR testing is usually negative.

The diagnosis should be suspected on the basis of the clinical features and the history of potential exposure in an endemic area. If Lyme disease is suspected, serological tests for antibody to B. burgdorferi should be carried out; positive serology in the appropriate geographical and clinical setting is diagnostic. During the first few weeks of infection (even when erythema migrans is present) only 20–30 per cent of those infected have positive serology (usually IgM antibodies), but in the convalescent phase, several weeks later, up to 80 per cent have positive serology, even after antibiotic therapy. However, a significant proportion of those who are treated rapidly and appropriately never develop a serological response. Antibody titres may fall slowly after antibiotic treatment and may persist for several years.

Evidence-based guidelines for the treatment of Lyme disease were published by the Infectious Diseases Society of America (IDSA) in 2006. They recommend doxycycline 100 mg twice daily, amoxicillin 500 mg three times daily or oral cefuroxime axetil 500 mg twice daily for treatment of early disease, whether localized or disseminated (stages I and II), unless there is a suggestion of cardiac or neurological involvement. Macrolides are not recommended unless the three first-line drugs are inappropriate or unavailable for some other reason. For early Lyme disease with a suggestion of neurological or cardiac involvement, intravenous ceftriaxone 2 g once daily for two weeks is recommended (although oral treatment with first-line drugs is a possible strategy for cardiac problems). Late Lyme arthritis can be treated with first-line oral therapy, whereas late Lyme neurological involvement is an indication for four weeks of intravenous ceftriaxone (or cefotaxime).

A controversial area in the management of Lyme disease is whether the condition of ‘chronic Lyme disease’ really exists. Campaign groups in the United States and to a lesser extent in Europe believe that a variety of medically explained symptoms, such as those that make up the chronic fatigue syndrome, are caused by Lyme disease, even if there is no serological evidence of exposure to infection. The main medical and scientific view is that this condition does not exist and that long-term antibiotic therapy (longer than 30 days) should not be offered. However, this view is vigorously disputed by campaign groups, and the area remains contentious.

### Erysipeloïd

Erysipeloïd (‘pork finger’, ‘whale finger’, ‘fish-handler’s disease’) is caused by the Gram-positive bacterium Erysipelothrix rhusiopathiae, which is widely distributed in nature and found in a wide range of vertebrates and invertebrates, including domestic swine (causing swine erysipelas), sheep, poultry, shellfish and fish (where it survives in mucoid exterior slime). Most human infections are occupationally acquired, by direct contact with infected animals, fish or their products; minor trauma (e.g. puncture wounds from crab claws, fish hooks or bone spicules; cuts during autopsy or butchery) facilitates transmission. Infection usually presents five days to two weeks after exposure as an extremely painful, well demarcated, slightly raised cellulitis on the finger or hand, centred on the site of inoculation, which is characteristically violaceous at the spreading edge with central clearing. Fever is unusual. Less commonly, disseminated cutaneous infection, with bulla formation, occurs. E. rhusiopathiae is a rare cause of endocarditis (usually of a native aortic valve); around 40 per cent of cases have a recent history of an erysipeloïd-like skin lesion, or a concurrent one.

Diagnosis requires culture (blood, needle aspirate or biopsy from the leading edge of the cellulitis); the organism is sometimes misidentified as a ‘diphtheroid’ or a lactobacillus. E. rhusiopathiae is sensitive to penicillins, cephalosporins and macrolides, but intrinsically resistant.
to vancomycin—important because the empirical treatment of severe sepsis in penicillin-allergic patients often relies on vancomycin to cover Gram-positive organisms. Although the localized skin infection will heal naturally within three to four weeks, healing is faster with antibiotic therapy.

**Listeriosis**

Although *Listeria monocytogenes*, the usual cause of listeriosis (septicaemia, meningitis, or, in pregnant women, abortion or congenital infection of the fetus) in humans, is a frequent cause of similar disease in animals, infection is usually sapronotic rather than zoonotic, and normally not associated with occupational exposure. However, cutaneous infection, presenting as pustular dermatitis, may occur in farmers and veterinarians one to four days after exposure to an infected animal (e.g. during delivery of an infected calf), usually affecting the forearm or hand. Diagnosis is made by culture of the organism, which is usually sensitive to penicillins and macrolides.

**Monkeypox**

Monkeypox, an uncommon zoonotic orthopox viral infection that can mimic smallpox, occurs mainly in tropical central and west Africa. In 2003, a cluster of 47 confirmed and probable human cases occurred in the midwestern United States among people who had direct or close contact with sick pet prairie dogs, which had become infected when they were co-housed with wild-caught rodents imported as exotic pets from Ghana. Common clinical features included fever, headache, chills, lymphadenopathy (unusual in smallpox) and a vesiculopustular rash. Occupational exposure was identified as a risk: cases included veterinarians and clinic staff, pet shop employees and animal distributors, as well as prairie dog owners. Investigators noted that standard veterinary infection control precautions had not been universally implemented: although their use would not have prevented the outbreak, it might have limited transmission. Control measures included expansion of existing restrictions on the importation and sale of animal species likely to carry monkeypox virus.

**Mycobacterium marinum**

*Mycobacterium marinum*, the cause of ‘fish tank finger’ is a non-tuberculous mycobacterium that is widely distributed in aquatic environments and is also recognized as a pathogen of fish, including farmed food species and farmed tropical species (e.g. Siamese fighting fish). Cutaneous infection in humans follows exposure of cut or damaged skin while cleaning fish tanks or inoculation via a scratch or puncture wound (e.g. in fish filleters, boat builders). After an incubation period of several weeks, a reddish tender papule develops (usually on the hand or forearm, or other cooler, exposed area of the body) which may ulcerate, but eventually heals with scarring. Less often, multiple papules develop in a sporotrichoid distribution, or infection may involve deeper tissues, e.g. tendon or bone. Disseminated infection may occur in the immunosuppressed. Diagnosis is by histology and culture of the organism from a tissue biopsy. It is important to inform the laboratory of the suspected diagnosis, as the organism grows at a lower temperature than that routinely used for incubation. Treatment is usually with doxycycline, minocycline, clarithromycin or rifampicin with ethambutol; surgical debridement may also be required. Strong, water-impermeable gloves, and covering cuts and lacerations with waterproof dressings will prevent exposure, but there may be a lack of awareness of the hazard amongst those at risk.

**Orf**

Orf is a classic occupationally acquired zoonotic infection. It is caused by a DNA parapox virus that usually infects sheep and goats, and is sometimes called ‘contagious pustular dermatitis’. It can also occur in cattle and reindeer. In ewes, pustular and scabby lesions develop on the teats and udder. Lambs then become infected when suckling, and develop lesions on the lips and nostrils, and inside the mouth. The occupationally at-risk population includes farm workers and shepherds (particularly after bottle-feeding lambs or after shearing), abattoir workers and slaughterers, veterinarians and others with frequent exposure to sheep and goats.

Orf infections in flocks are controlled by vaccination with a live, non-attenuated vaccine. Vaccinated sheep develop a mild form of orf, and recently vaccinated animals therefore also present a transmission risk to their handlers. Infection may also follow needlestick exposure.

Three to five days after exposure, an erythematous, itchy, macule develops, usually on the finger, hand or forearm. This becomes papular, and then develops into a vesicle surrounded by erythema. The lesion may grow to about 2–3 cm in diameter and may progress to ulceration within two to three weeks (Figure 60.5). Complete healing generally takes place by four to six weeks. The lesions may be solitary or there may be several at the point of inoculation; infections in the immune-suppressed may be much more severe. The differential diagnosis includes erysipeloid, tularemia and cutaneous anthrax. If there is diagnostic doubt, then a skin biopsy will show characteristic histological features; a PCR-based test (of vesicle fluid, scab debris or tissue sections) is also available. There is no specific treatment. Secondary bacterial infection can be treated with standard antibiotics. There is anecdotal support for the use of cidofovir cream.
Echinococcosis is a parasitic infection caused by the larval stages of cestodes (tapeworms) of Echinococcus granulosus (which causes cystic echinococcosis (CE)) and E. multilocularis (which causes alveolar echinococcosis (AE)). The adult E. granulosus tapeworm lives in the small intestine of dogs or other canids (e.g. dingoes); gravid tapeworm segments and eggs are excreted in the faeces. Sheep, cattle or other intermediate hosts ingest the eggs when grazing on contaminated pasture; the oncospheres released in the gastrointestinal tract then migrate to the liver, lungs or less often, other organs, where they slowly mature into a metacestode (hydatid cyst). The cycle is perpetuated when dogs eat, or are fed, infected meat or viscera. The parasite is found worldwide, particularly in Asia, Africa, Central and South America, and throughout the Mediterranean. In the United Kingdom, animal infection is most common in sheep-farming areas in Wales, Herefordshire and the Western Isles. Control measures include voluntary, incentivized or mandatory dog worming, abattoir inspection, the prompt and correct disposal of animal carcasses, and education. Humans become infected through close contact with infected dogs, either by hand-to-mouth transfer of eggs after handling the animal or its faeces, or, less often, by exposure to contaminated food. Infection is often acquired in childhood, but adults, including shepherds and farmers who keep sheep (or other intermediate host, e.g. cattle, camels) and dogs are also at risk of infection. E. multilocularis is found only in the northern hemisphere, with red foxes (including urban foxes), arctic foxes and dogs as definitive hosts, and small rodents as intermediate hosts. Again, man is an accidental intermediate host; possible routes for occupational infection include exposure to infected sled or hunting dogs, or foxes, or their faeces. Risk groups therefore include animal hunters and trappers, fur traders, and field and wildlife biologists.

Human infection is always asymptomatic initially, and may remain so. CE may be discovered by the incidental finding of a calcified cyst wall on radiographic or ultrasound examination, or may present with clinical features caused by the pressure effects of a mass lesion, or by the effect of spontaneous or traumatic cyst rupture. Most patients have a single cyst in a solitary organ, most often of the liver (60 per cent) or lungs (20 per cent); less often in brain, kidney, spleen, heart or bone. Pulmonary disease tends to present earlier than hepatic disease. Alveolar echinococcosis primarily affects the liver, and – since the metacestode has no capsule, but is multiloculate – more invasive than CE, though like CE, infections are initially asymptomatic and cyst growth may be very slow. Diagnosis of CE and AE is by serology (though false negatives are not uncommon) combined with imaging. Management requires specialist assessment: treatment options include surgical resection or PAIR (puncture, aspiration, injection of a scolicide, re-aspiration) combined with pre- and post-procedure anti-helminthic therapy (usually with albendazole), or long-term anti-helminthics alone.

Special safety precautions are recommended for laboratory workers and for field workers at high risk of exposure to infective Echinococcus eggs, which are highly adapted for environmental survival and disinfectant resistant. Serological testing after a single, identified, one-off exposure may be appropriate, and regular testing of workers potentially exposed over longer periods is recommended.

Rabies and related lyssavirus infections

Rabies is an acute viral encephalitis caused by rabies virus genotype 1 (classical rabies), or, less often, by the related bat lyssaviruses (European bat lyssaviruses (EBLVs), the African bat lyssaviruses (Duvenhage and Mokola), and Australian bat lyssavirus) which cause a clinically indistinguishable disease. Infection usually follows exposure to saliva via a bite or scratch from an infected animal (most often a dog), but has also followed mucous membrane exposure. The viruses do not cross intact skin. The incubation period is usually 3–12 weeks, but may be as short as four days, or, rarely, longer than a year. Disease onset is insidious, with non-specific prodromal symptoms including fever, headache, sore throat and malaise, sometimes accompanied by itching, tingling or fasciculation at the site of the wound. These are followed by the development of signs of encephalitis, with hyperanxiety, aerophobia or hydrophobia, bizarre

**Other important zoonotic infections**

**Echinococcosis (hydatid disease, hydatidosis)**

Echinococcosis is a parasitic infection caused by the larval stages of cestodes (tapeworms) of Echinococcus granulosus (which causes cystic echinococcosis (CE)) and E. multilocularis (which causes alveolar echinococcosis (AE)). The adult E. granulosus tapeworm lives in the small intestine of dogs or other canids (e.g. dingoes); gravid tapeworm segments and eggs are excreted in the faeces. Sheep, cattle or other intermediate hosts ingest the eggs when grazing on contaminated pasture; the oncospheres released in the gastrointestinal tract then migrate to the liver, lungs or less often, other organs, where they slowly mature into a metacestode (hydatid cyst). The cycle is perpetuated when dogs eat, or are fed, infected meat or viscera. The parasite is found worldwide, particularly in Asia, Africa, Central and South America, and throughout the Mediterranean. In the United Kingdom, animal infection is most common in sheep-farming areas in Wales, Herefordshire and the Western Isles. Control measures include voluntary, incentivized or mandatory dog worming, abattoir inspection, the prompt and correct disposal of animal carcasses, and education. Humans become infected through close contact with infected dogs, either by hand-to-mouth transfer of eggs after handling the animal or its faeces, or, less often, by exposure to contaminated food. Infection is often acquired in childhood, but adults, including shepherds and farmers who keep sheep (or other intermediate host, e.g. cattle, camels) and dogs are also at risk of infection.

**Rabies and related lyssavirus infections**

Rabies is an acute viral encephalitis caused by rabies virus genotype 1 (classical rabies), or, less often, by the related bat lyssaviruses (European bat lyssaviruses (EBLVs), the African bat lyssaviruses (Duvenhage and Mokola), and Australian bat lyssavirus) which cause a clinically indistinguishable disease. Infection usually follows exposure to saliva via a bite or scratch from an infected animal (most often a dog), but has also followed mucous membrane exposure. The viruses do not cross intact skin. The incubation period is usually 3–12 weeks, but may be as short as four days, or, rarely, longer than a year. Disease onset is insidious, with non-specific prodromal symptoms including fever, headache, sore throat and malaise, sometimes accompanied by itching, tingling or fasciculation at the site of the wound. These are followed by the development of signs of encephalitis, with hyperanxiety, aerophobia or hydrophobia, bizarre...
behaviour, seizures and signs of autonomic disturbance, or an ascending flaccid paralysis. Rabies is almost invariably fatal.

The World Health Organization estimates that between 40,000 and 70,000 human cases of classical rabies occur annually, mostly in developing countries, especially in South and South East Asia. Human infections caused by the other lyssaviruses are far less common: fewer than a dozen cases have been reported worldwide. These include a fatal case in an unvaccinated bat conservationist in Scotland in 2002.143

In the United Kingdom, pre-exposure prophylaxis with rabies vaccine is recommended for laboratory workers handling lyssaviruses (including those working in vaccine production), workers who will regularly be exposed to animals imported from rabies-enzootic areas, e.g. in primate holding facilities, quarantine centres, ports; state veterinary and technical staff, licensed and voluntary bat handlers; animal inspectors; veterinarians and zoologists who will be exposed to animals in enzootic areas, and healthcare workers who are about to provide care for a rabies case. Pre-exposure vaccine is also recommended for longer-term travellers to enzootic areas, and for short-term travellers whose activities may place them at risk, if access to post-exposure care is likely to be limited. In the UK, the Department of Health recommends that those who are working with live virus and others at high risk should be serologically tested at regular intervals, and reinforcing doses of vaccine given to maintain an antibody level above the recommended acceptable minimum.16 Recommendations elsewhere are similar. Post-exposure vaccine, with or without rabies-specific immunoglobulin is given after a significant risk exposure; expert advice is available from national public health authorities.

Key points

- Seventy-five per cent of emerging pathogens and 61 per cent of all infectious organisms are zoonotic.
- No specific clinical features will suggest zoonotic origin for any particular infection. A detailed occupational history is essential to exclude zoonotic exposure in an occupational setting.
- Agricultural workers and veterinarians are at particular risk, but many other occupations may potentially expose workers to zoonotic infection.
- Most zoonotic infections will present with fever with or without skin lesions, chest symptoms or diarrhoea.
- The risk to a worker of acquiring a zoonotic infection depends on the prevalence of that infection among the animals involved, the infectivity and route of infection of the organism, and the steps taken to limit exposure.

INTRODUCTION

The use of microorganisms with intent to cause harm or fear has a long history. Ancient Persian, Greek and Roman manuscripts describe the use of decaying bodies to contaminate water sources; the Tartars, laying siege to Caffa in 1346, catapulted the corpses of plague victims over the city walls, and during the French and Indian War (1754–67) the British forces attempted to spread smallpox amongst American Indians by distributing blankets from a smallpox hospital.1,2 In the early twentieth century, interest in the hostile uses of pathogens developed in parallel with increasing understanding of the effects of specific pathogens and other technological advances, which included industrial-scale production of microorganisms. Although the Geneva Protocol of 1925 proscribed the use of biological weapons by signatory states, it does not prevent their possession or development, and many nations, including Canada, France, Great Britain, the United States and the former Soviet Union invested in bioweapons research.3 These programmes, which were not without occupational risk (456 cases of laboratory-acquired infection occurred between 1942 and 1969 in workers at Fort Detrick, United States, including two fatal cases of anthrax and one fatal case of viral encephalitis4) had largely been terminated by the 1970s. The 1972 Biological Weapons Convention – which has over 140 nation-state signatories – prohibits the development, production or stockpiling of biological agents (or their toxins) in ‘quantities that have no justification for prophylactic, protective or other peaceful purposes’.3 However, in some states, notably the Russian Federation and Iraq, offensive bioweapons research continued until at least the early 1990s.5 In 1979, the accidental release and airborne spread of anthrax spores from a research facility in Sverdlovsk caused more than 60 deaths from inhalational anthrax in the surrounding community, and in 1990, immediately before the Gulf War, concern about a possible threat resulted in the vaccination of more than 150 000 coalition military personnel against anthrax.6,7 The revelation that Iraq had developed bioweapons, the deliberate release of sarin gas on the Tokyo subway by the Aum Shinrikyo sect in 1995, and fears that a sharp decline in financial support might have compromised biosecurity in laboratories in Russia and the former Soviet Union provided the impetus for a detailed review series that examined the potential use of specific pathogens as bioweapons and encouraged policy-makers and planners to ensure that health and other civilian services were adequately prepared to deal with the potential threat of bioterrorism.8–11

In the last 50 years, there have been only five reported incidents involving the intentional release of pathogens. Four involved gastrointestinal or foodborne pathogens (Salmonella typhi, Salmonella enteritidis, Shigella dysenteriae and Ascaris suum). In the largest of these incidents, over 700 people developed symptoms after eating from salad bars in two restaurants in Dalles, OR, in 1984, though the source of the outbreak was not recognized until late in 1985, when it was discovered that followers of Baghwan Shree Rajneesh had deliberately contaminated salads with cultures of S. enteritidis.12–15 In 2001, however, the attacks on the World Trade Center and the Pentagon were followed, a month later, by an outbreak of anthrax caused by deliberate dissemination of anthrax spores via the US Postal Service.16 These events stimulated a period of intense public health activity at international and national levels, focused initially on improving biosecurity and emergency preparedness for bioterrorism, but which now seek to ensure that preparedness planning for bioterrorist threats is integrated in a more rational, generic ‘all-hazards’
approach, with planning for infectious disease emergencies (including pandemic influenza), natural disasters and other public health emergencies.

The Centers for Disease Control (CDC) in the United States has combined the risk assessment concepts used to develop laboratory biosafety guidance (which assign pathogens to a risk category by considering the severity of human infection, transmission potential and the availability of effective treatment or prophylaxis) with assessments of ease of dissemination and estimates of the overall impact that any accidental or deliberate dissemination of the pathogen would have, and used the results to identify the pathogens for which preparedness is most essential. These ‘category A agents’ are: variola virus (smallpox), Bacillus anthracis (anthrax), Yersinia pestis (plague), Clostridium botulinum toxin (botulism), Francisella tularensis (tularemia), filoviruses (Ebola and Marburg haemorrhagic fevers) and arenaviruses (Lassa fever). ‘Category B agents’ include Burkholderia pseudomallei (melioidosis), Burkholderia mallei (glanders), Coxiella burnetii (Q fever), and Brucella abortus, B. suis and B. melitensis (brucellosis), staphylococcal enterotoxin B, and Venezuelan equine encephalitis virus. The global eradication of smallpox was certified in 1980, and infections caused by the other agents listed above are rare in industrialized countries, where few clinicians will have direct clinical experience of them. It is nevertheless essential that all clinicians maintain a working knowledge of their epidemiology, clinical features, differential diagnosis and initial investigation and management (Table 61.1). Extensive web-based and other training materials, including pathogen-specific guidelines, fact sheets, slide sets and decision-based algorithms for clinical management, have been developed since 2001, can be readily accessed through national authorities’ websites and are particularly useful for self-directed learning when formal face-to-face training is not readily available.

SMALLPOX

The last community-acquired case of smallpox – a severe infection with a case-fatality rate of around 30 per cent in susceptible people – occurred in Somalia in 1977. The last case of laboratory-acquired infection occurred in Birmingham, UK, in 1978. Smallpox (variola) virus is now held only in two secure repositories, in Russia and the United States, and research work on the virus is strictly regulated. Routine smallpox vaccination programmes ceased around 30 years ago, although vaccination is still recommended for those who directly handle vaccinia (smallpox vaccine) virus cultures, infected dressings or other potentially infectious materials, recombinant vaccinia virus or other orthopox viruses (e.g. monkeypox), or handle animals infected or contaminated with any of these viruses. In the pre-outbreak setting, vaccination is contraindicated in those who have atopic dermatitis, eczema or any other active or chronic skin condition involving the epidermis, are pregnant or immunosuppressed, or have a close contact who has any of these conditions. Adverse events after smallpox vaccination include inadvertent inoculation, generalized vaccinia, eczema vaccinatum, fetal vaccinia, progressive vaccinia and post-vaccinal encephalomyelitis. In 2001, concerns about the possible bioterrorist use of smallpox led many industrialized countries to develop national smallpox preparedness plans, to stockpile vaccine supplies and to vaccinate selected military personnel and healthcare workers in ‘smallpox response teams’ – infectious disease clinicians, public health workers and first responders – who would be involved in the diagnosis and immediate management of any initial cases. In the most extensive programme, in the United States, 39 566 civilian volunteers had been vaccinated by June 2004; vaccination of military personnel is ongoing, but more than 1.4 million defence staff and contract workers had been vaccinated by June 2007. Since so few clinicians were expected to have experience of smallpox vaccination, intense preparation and training were required: around 1.7 million people accessed the smallpox training materials provided on the CDC website, and the 318 people who attended central ‘train the trainers’ courses subsequently trained a further 15 349 people in disease recognition, differential diagnosis of fever rash-illness syndromes, pre-vaccination screening, vaccination technique (which requires multiple punctures with a bifurcated needle) and vaccination site care and follow up. Adverse events mostly occurred at, or below, the frequency expected, perhaps because the civilian programme (though not the military programme) preferentially selected workers with a history of previous smallpox vaccination and because of the intensive education on deferring those at risk and on vaccine site care. Safety monitoring also confirmed an association between vaccination and myo/pericarditis, but did not confirm an association between vaccination and ischaemic cardiac events, though amended selection criteria for pre-event vaccination exclude people with a history of ischaemic heart disease, or three or more cardiac risk factors (including hypercholesterolaemia, smoking, diabetes and hypertension), or an immediate family member with onset of cardiac disease before the age of 50 years.

ANTHRAX

Anthrax is a zoonosis, caused by Bacillus anthracis, which primarily affects sheep, cattle and goats. The organism has a spore form that is extremely well adapted for environmental survival and can persist in soil for decades: Gruinard Island, off the northwest coast of Scotland, was contaminated during experiments in the 1940s; spores remained detectable until the island was decontaminated in 1987. Naturally acquired human infection follows contact with an infected animal, carcass or animal product (e.g. hide, wool, bone). The clinical features of infection depend on the route of exposure to the spores: contact with abraded skin (e.g. while butchering an animal or handling a hide) causes cutaneous anthrax; breathing the spores

viruses and
others, e.g.
dengue virus)

Disease-specific
(range 1–21 days)

Fever, malaise, headache, plus tender local
lymphadenopathy  painful ulcer/exudate at
site of infection

Local disease: orf, anthrax, syphilis, herpes
simplex infection, chancroid,
staphylococcal/streptococcal infection, cat
scratch disease, mycobacterial infection,
rickettisial infection, sporotrichosis

Pneumonia: fever, dry cough, pleuritic pain

Pneumonia: community-acquired pneumonia
(bacterial or viral), Q fever, tuberculosis,
lung abscess/empyema, anthrax, plague

Febrile prodrome (fever, malaise, nausea,
vomiting, myalgia, prostration) of up to
seven days, followed by signs of vascular
involvement
In second week of illness, cases either recover
or deteriorate rapidly
High mortality in outbreaks, particularly for
filoviruses

Malaria

Typhoid, shigellosis
Meningitis

Leptospirosis
Tularaemia, plague
Other causes of DIC (including Gram-negative
sepsis, leukaemia, lymphoma, liver failure
CNS, central nervous system; DIC, disseminated intravascular coagulation.

Naturally acquired human disease follows
exposure by: bite of infected vector (tick,
mosquito, deerfly); handling infected animal
or carcass; breathing infected aerosol (from
infected animal or carcass, contaminated
hay, lawn mowing); eating contaminated
food or water
Occupational risks: laboratory work; hunting,
trapping, or farming
Deliberate release most likely to be via
aerosol, causing pneumonic tularaemia
Very low risk of person-to-person spread: use
standard precautions
Mortality low given appropriate antibiotic
therapy (aminoglycoside or quinolone)
All are zoonoses; distribution of natural
disease is governed by the geographic
distribution and ecology of the animal
reservoir
Imported cases are rare in industrialized
countries
High risk of person-to-person spread via
percutaneous or mucocutaneous exposure
to blood or infected body fluids; nosocomial
amplification of outbreaks
Occupational risk for: healthcare workers,
laboratory workers
Asymptomatic afebrile contacts are not
infectious
Ribavirin effective against Lassa virus and
Congo Crimean haemorrhagic fever virus


causes pulmonary anthrax; eating undercooked spore-contaminated meat causes gastrointestinal anthrax. There are an estimated 2000–20 000 cases of human anthrax each year, largely in countries where animal infection is still endemic; human anthrax in industrialized countries is rare. Cutaneous infection accounts for 95 per cent of reported cases.31

The intentional dissemination of anthrax via the US Postal Service (USPS) in 2001, in envelopes containing \( \text{B. anthracis} \)-positive powder and addressed to prominent media or government figures, led to 22 cases of anthrax (11 pulmonary, 11 cutaneous) among residents in seven states in the eastern United States. These were the first cases of pulmonary anthrax in the USA since 1976; five (45 per cent) were fatal.36,32–37 Cases occurred in two clusters, associated with at least two separate mailings of spore-containing envelopes. Most occurred in people who worked either at the USPS sites through which the contaminated mail passed (mail processor, three cases; mail worker, four cases; mail machine mechanic, one case) or at sites where the contaminated mail was received (government office or media company mail room worker, three cases; media company employee, six cases). Widespread contamination with anthrax spores was detected at these sites by environmental testing. Cases also included a seven-month-old infant, who was probably exposed while visiting one of the media companies, and four other people (a mail carrier, a book-keeper, a hospital storeroom worker and a retired elderly female) who were thought to have become infected after exposure to mail that had been cross-contaminated as it passed through the postal system.38 It was not initially realized that anthrax spores could leak through sealed, intact envelopes, and lack of familiarity with the clinical signs of cutaneous anthrax (which should be included in the differential diagnosis of an unusual skin lesion, particularly if the lesion is relatively painless, but is accompanied by intense, extensive oedema) may have led to delays in diagnosis of the cases in the first cluster, many of which had already occurred before the index case of pulmonary anthrax was diagnosed in Florida by an alert clinician who had recently undergone bioterrorism preparedness training. Post-exposure antimicrobial prophylaxis (a 60-day course of ciprofloxacin, doxycycline or amoxicillin) was recommended for approximately 10 000 people assessed as being at risk of pulmonary anthrax; no cases of anthrax occurred in this group. In a follow-up study, over half of those (3032/5343; 57 per cent) who reported taking at least one dose of prophylaxis reported adverse events during treatment. Fewer than half (2712, 44 per cent) reported completing the 60-day course; reasons for stopping treatment reported by the 2631 who did not complete the course included: adverse events (43 per cent); low perceived risk of anthrax (25 per cent) and concerns about the effects of long-term antimicrobial use (7 per cent).39,40

Health and safety guidance for workers at sites where mail is handled or processed is designed to reduce the potential for inhalational or cutaneous exposure to anthrax spores, and emphasizes the importance of risk assessment-based selection of control measures. These include engineering controls (e.g. avoiding the use of compressed air to clean machinery and advice to use industrial vacuum cleaners fitted with HEPA filters to clean high-speed mail sorting machinery); administrative controls (developing strategies to limit the numbers of personnel and visitors exposed); housekeeping (e.g. using ‘wet’ dusting techniques in preference to ‘dry’ dusting) and the selection and use of appropriate personal protective equipment, which may include protective clothing, gloves and masks or respirators. All workers who process, handle or receive mail should be trained to recognize and manage a ‘suspect package’, and every worksite should have an emergency plan that describes the actions that should be taken if a suspect package incident or a potential exposure to \( \text{B. anthracis} \) occurs.41,42 Pre-exposure vaccination is recommended for laboratory workers who will work directly with the organism or with high-risk specimens, and for occupational groups at risk of exposure to infected animals or their byproducts.43

**EMERGENCY PREPAREDNESS**

It is important that all clinicians remain open to the possibility that a deliberate release may occur – and that they may be the first to recognize it. Clinicians must be prepared to consult urgently with their local infectious disease specialist, clinical microbiologist or public health department on the basis of suspicion alone, and should keep a regularly updated list of relevant emergency contacts. Although the initial cases in any deliberate release are most likely to present to primary care or emergency medicine clinicians, occupational health clinicians are well placed to identify unusual or unexpected sickness absence, and should remain alert for changes in expected patterns and for the case that ‘just doesn’t fit’. Examples include an unusual number of cases of the same illness presenting in a short time-frame; an illness unusual for the time of year (influenza in summer); an illness unusual for the patient’s age group (chicken pox in a middle-aged adult) or with an unusual clinical presentation (chicken pox rash concentrated on the extremities), or an illness, or report of a diagnosis of an illness acquired in an unusual place (e.g. tularemia in a worker who has not travelled outside the United Kingdom).

As a result of the resurgence in biodefence-related research, and the recent expansion in the numbers of BSL3 and BSL4 (high and maximum containment) laboratories, more laboratory workers are working with category A and other high-risk pathogens than at any time in the last 50 years, increasing the risks of occupational exposure and occupationally acquired infection. Since 2000, there have been reports of occupationally acquired glanders (in a worker in a military research laboratory; the first case of glanders in the United States since 1945);44,45 tularemia
(three cases, in research scientists working on vaccine development using an attenuated strain of Fr. tularensis that was subsequently found to have become contaminated with a virulent strain); 46 staphylococcal enterotoxin B-related illness (three cases, in workers in a military research laboratory between 1989 and 2002) 47 and Ebola haemorrhagic fever (a research scientist in a Russian laboratory who developed infection and died after a needlestick injury sustained while working with Ebola virus-infected guinea pigs in 2004, 48 in the same year a virologist in a military laboratory in the United States was isolated, but did not become infected, after scratch from a needle potentially contaminated with Ebola virus; 49 a similar incident occurred in Germany in 2009). 50 Laboratory workers in clinical laboratories may be exposed while working on diagnostic or surveillance-related samples (a case of cutaneous anthrax was reported in a laboratory worker in Texas who processed environmental samples associated with the 2001 anthrax outbreak), 51 or during laboratory proficiency testing. In 2007, a US laboratory participating in an exercise designed to test laboratory preparedness inadvertently processed a test sample containing B. abortus RB51 on the open bench, potentially exposing 24 laboratory workers to the organism, which, although attenuated, has been associated with human infection. Written information about safe processing had been provided with the test samples, but further investigation identified 916 potentially exposed workers in 254 of the 1316 laboratories involved in the exercise. Post-exposure prophylaxis was recommended for workers assessed as having had a high-risk exposure; no infections were identified. 52

Guidelines on laboratory biosafety advise that laboratory workers should have access to expert occupational health advice, including, where appropriate, pre-exposure prophylaxis. An occupational history is an integral part of the initial management of any sick patient, and, if a laboratory or animal house worker presents with an unexplained febrile illness, further information should be sought urgently from the laboratory director about the agents to which the patient may have been exposed, regardless of whether the patient can recall a specific exposure. Workers in BSL3 or BSL4 laboratories require a pre-employment medical examination and should carry and use ‘medical contact’ cards. 53 Provision of occupational health care for workers in BSL-4 laboratories is highly specialized and presents special challenges and effective care provision requires close collaboration between the laboratory and the occupational health clinician. 54, 55 Occupational infection may result from trivial or inapparent exposure, and since the initial signs and symptoms of laboratory-acquired infection may be non-specific, systems for monitoring and follow up of unexplained worker absence should be in place. Facilities working with, or storing, risk group 3 or risk group 4 pathogens should have a written contingency plan for dealing with accidents and other emergencies, based on a thorough biorisk assessment, and containing operational procedures for immediate incident management, decontamination, surveillance and emergency and clinical management of exposed people, with relevant contact details so that access to specialist medical advice can be rapidly obtained. Guidelines on the evaluation and management of exposures to potential bioterror agents have been published. 54 It is recommended that all procedures and protocols should be tested and practised through a programme of regular drills or exercises, thus improving emergency preparedness.

Preparedness for a bioterrorist incident – a ‘low likelihood, high impact’ event – should be integrated with major incident and business continuity planning; occupational health clinicians have key roles to play in such planning. All major events – whether accidents, natural disasters or outbreaks caused by newly emergent infections – and the fear and uncertainty associated with them – have profound psychosocial effects on individuals and communities. Provision of, and access to, psychosocial support for those involved, either directly, or indirectly, is essential.

Key points

- The risk of a bioterror event is small, but real.
- Integrated preparedness planning of emergency responses is essential.
- Occupational health clinicians have key roles to play in planning, surveillance, response and recovery.
- Know the main clinical features of illnesses caused by potential bioterror agents.
- Remain alert to the unusual and the unexpected – and be prepared to consult urgently with local public health clinicians on suspicion.

Genetic modification and biotechnology

DAVID ROOMES

INTRODUCTION

Biotechnology brings together the fields of biology and technology in order to harness the power of living organisms. Fermentation, one of the fundamental biotechnological processes has been known to man for millennia, although it was Carl Wehmer in 1893 who first patented the manufacture of citric acid using microorganisms, thus ushering in the modern era of commercialization of biological processes. The term ‘biotechnology’ has had many different meanings since its first use in 1919, ranging from a branch of technology concerned with the development and exploitation of machines in relation to the various needs of human beings to today’s meaning, which is principally based on genetic modification. The definition is broad, but may be described as the use of biological processes for the production of goods and services, and for environmental management. The United Nations Convention on Biological Diversity has defined it as ‘any technological application that uses biological systems, living organisms or derivatives thereof to make or modify products or processes for specific use’. As the uses and applications of biotechnologies have grown, it is becoming more common for the term to be used in the context of a specific industry, for example food biotechnology, pharmaceutical biotechnology and marine biotechnology. It is essentially a technology which integrates biology, microbiology, chemistry and biochemistry, as well as chemical and process engineering. A legally accepted definition of genetic modification is ‘the alteration of genetic material in a way that does not occur naturally by mating or natural recombination or both’. This includes recombinant DNA techniques using viral or bacterial vectors, the direct introduction of DNA into any organism, e.g. by microinjection, and cell fusion or hybridization.

Biotechnology is widely employed in industry. It is estimated by the Department for Trade and Industry that over 23,000 people in the United Kingdom are directly employed in the industry in roles ranging from molecular biologists and biophysicists to technical and non-technical staff. In the United States, there were 1415 biotechnology companies at the end of 2005 with a market capitalization of US$410 billion, a ten-fold growth since 1994. It is still growing rapidly and as it expands so does the range of biological, chemical and physical hazards to which employees may potentially be exposed. The rate of change and development within the industry is also rapid, necessitating frequent revision of health, safety and environmental management of the potential risks surrounding rapidly changing processes.

In general, the view that ‘biotechnology poses no risks that are fundamentally different from those faced by workers in other processing industries’ is still valid today, although the rapid development of new technologies, such as nanotechnology, may pose as yet undefined risks. Product hazards are deemed ‘not likely to differ qualitatively from those encountered in other sectors of the pharmaceutical and chemical industries; the fact that the molecules … are the products of organisms rather than of synthetic catalysts will not alter their reactivity or toxicity’. Risks from handling recombinant organisms may be considered to be no greater than those arising from handling unmodified pathogens. Reports of illness or health effects...
attributable specifically to work with genetically modified microorganisms and recombinant DNA (rDNA) cells are rare. Although exposure to these genetically modified microorganisms, biologically active products and processing chemicals constitutes a potentially serious risk to the health of employees, it is concluded that biotechnology processes are safe if practised with appropriate risk control measures in place.

DEVELOPMENT OF BIOTECHNOLOGY

Traditionally, biotechnology has been based on the purification and enhancement of the products of naturally occurring organisms through selection and mutation, in processes such as brewing and baking. Alcohol remains one of the main products of the biotechnology industry, not only ethanol, but also alcohol for industrial use.

In the last four decades, the introduction of genetic modification has improved the yield and purity of products, and allowed the development of new ones. In the 1950s, antibiotics and vaccines were produced using biotechnology methods, and in the 1960s, single cell protein as a source of food for animals and humans was developed. The early 1970s saw the development of recombinant DNA techniques. This had a major effect on biomedical research and diagnostics, on agriculture, and on food, chemicals and pharmaceutical manufacture.

The first pharmaceutical products made were human insulin, somatostatin and growth hormone. Development since then has been in the area of pharmaceutically active mammalian peptides, such as hormones, enzymes and antibodies. Biological response modifiers, such as the interferons, and growth factors, such as epidermal growth factor, fibroblast growth factor and platelet-derived growth factor, have also been manufactured using biotechnology techniques. Tissue plasminogen activator was a successful product of the late 1980s which has been used extensively as thrombolytic therapy for coronary artery disease. Erythropoietin was developed for use in the treatment of anaemia secondary to renal disease and various clotting factors have also been produced. Since the turn of the century, there has been a rapid growth in approvals for new pharmaceutical products made possible by new biotechnological techniques, most notably in the fields of vaccines and cancer treatments. A multitude of healthcare applications is currently in development utilizing techniques such as monoclonal antibody technology, stem cell technology, cell culture, cloning, nanobiotechnology, microarrays and protein engineering. Table 62.1 shows a list of peptides, their host systems and clinical indications.

The increasing use of genetically modified organisms in laboratory research and large-scale industrial processes resulted in concern about the potential health and environmental hazards of the organisms and their products. These concerns led to the introduction of legislative measures to ensure adequate control of any risks.

The traditional applications of biotechnology have usually been within the scope of general health and safety law. However, the European Union has legislation to cover work in this area; specifically European Directives 98/81/EC for Contained Use and 1990/220/EEC and 2001/18/EC for Deliberate Release of GM organisms. In the UK, these directives on GMOs and also the requirements of the Environmental Protection Act 1990, have been implemented by specific regulations made under the Health and Safety at Work Act 1974, namely the Genetically Modified Organisms (Contained Use) Regulations 2000 and the Genetically Modified Organisms (Contained Use) (Amendment) Regulations 2005 (for work involving contained use of GMOs) and also the Genetically Modified Organisms (Deliberate Release) Regulations 2002 (for work involving deliberate release of GMOs).

The EU also has a directive (EU86/609/EEC) (currently under active revision) covering the protection of laboratory.
animals, together with the European Convention for Protection of Vertebrate Animals (ETS No. 123), as amended in 1993 (ETS No. 170). These are implemented in the UK under the Animals (Scientific Procedures) Act 1986 and the Animals (Scientific Procedures) (Amendment) Order 1993, and are applicable to any work with laboratory animals, including any transgenic animals.

The UK regulations specify the following requirements:

1. To assess the risk to human health and the environment, and to keep records.
2. To establish a local genetic modification safety committee to advise on risk assessments.
3. To classify organisms and operations.
4. To notify the Health and Safety Executive (HSE) of the intention to use premises for genetic modification work for the first time and of subsequent individual activities above the lowest risk class and, in some cases of higher risk, to seek consent from the HSE.
5. To adopt controls, including suitable containment measures.
6. To inform the HSE of accidents involving genetically modified organisms.

Guidelines have been produced by the HSE and the Department for Environment, Food and Rural Affairs (DEFRA), which give further information on procedures for risk assessment and control. Independent expert committees have been established to advise government in this complex area (the Scientific Advisory Committee for Genetic Modification (SACGM) and the Advisory Committee for Releases to the Environment (ACRE), for contained use and deliberate release, respectively). In the UK, some techniques are exempt from the regulations, including mutagenesis, the construction and use of somatic hybridoma cells (for the production of monoclonal antibodies), plant cell fusion where the resultant organisms can be produced by traditional breeding methods and self-cloning.

In the United States, the Federal Government has developed a coordinated, risk-based system to ensure new biotechnology products are safe for the environment and human and animal health. Established as a formal policy in 1986, the Coordinated Framework for Regulation of Biotechnology describes the federal system for evaluating biotechnology products developed using modern biotechnology. The Coordinated Framework is based upon health and safety laws developed to address specific product classes and a number of different agencies are involved including the Food and Drug Administration (FDA), the Environmental Protection Agency (EPA) and the Department of Agriculture. The US Government has written new regulations, policies and guidance to implement these laws for biotechnology as products have developed. Additional guidance includes guidelines for research involving recombinant DNA molecules and guidelines for biosafety in microbiological and biomedical laboratories. The former constitutes regulatory guidelines for laboratory research which must be followed by organizations receiving federal funding, and the latter assigns biosafety levels to organisms and specifies the equipment and procedures to be used within each biosafety containment level.

NANOTECHNOLOGY

Nanotechnology (which includes the field of nanobiotechnology) is a rapidly developing area of science with a worldwide market for commercial application estimated to reach US$1 trillion by 2015. Man-made nanoparticles have existed for many years, mainly in the form of inhaled air pollutants as a byproduct of the burning of fossil fuels or occupations such as welding and tyre manufacture. The health effects following inhalation of such particles have been widely studied and the detrimental effects thereof on the cardiorespiratory system are well understood. The term ‘nanotechnology’ was first used in 1974 to refer to the ability to engineer materials precisely at the nanometer level, although a more complete definition is ‘the purposeful engineering of matter at scales of less than 100 nm to achieve size-dependent properties and functions’. It is believed that some of the health effects of inhaled nanoparticles may be predicted from the epidemiological study of available occupational and environmental aerosol exposure information and that an initial assessment of risk can be made using these data. What is less well understood is the ability of manufactured nanoparticles to penetrate the system via the intestinal tract and skin and once taken up, the pharmacokinetics and end organ effects that may occur.

As the science advances, it is expected that nanobiotechnology will be a major area of development in biology and medicine with applications in current development including biological labelling, drug and gene delivery, tissue engineering and the biodetection of pathogens. For the occupational health professional, it will be necessary to work closely with toxicologists and other experts in allied fields to understand the possible health effects and to implement appropriate controls and risk management strategies.

GENETIC MODIFICATION

Genetic modification has proved an immensely powerful tool for the biotechnology industry enabling discovery of novel drugs, as well as directly being the driving force for production of biopharmaceuticals, such as human growth hormone and interferon. The development of organisms for use in biotechnology commonly involves the improvement of desirable properties, such as the level of production of a metabolite, as well as eliminating properties that are less useful. Such modification, either incidentally or deliberately as a control measure, may also reduce the ability of the organism to survive outside the bioreactor. Traditional methods for altering such characteristics included mutation...
by either chemical or physical means followed by selection of organisms with the desired properties.29 Because mutagenesis is a random process, laborious and careful screening is necessary to isolate organisms with the required properties and thus it is rarely used today within the biotechnology industry. An alternative method for improving the process characteristics of organisms is hybridization; for example, by conjugation between closely related species or strains of bacteria, or by recombination between different mating types of yeast. Protoplast fusion offers an additional method of strain improvement, particularly between organisms of different species.

A specific example of hybridization is the formation of ‘hybridomas’ for the production of monoclonal antibodies. In this technique, antibody-producing cells from the spleen of an immunized animal (normally a rat or mouse) are fused with homologous myeloma cells and the resulting mixture of cell types grown in selective media. The fusion products are then screened to obtain clones of ‘hybridoma’ cells that produce useful amounts of antibody against the antigen used for the immunization. These clones are genetically identical and the resulting antibody will be a pure species, or ‘monoclonal antibody’.

A more recent development for obtaining essentially similar antibodies has been ‘phage display’, where genes for an antibody with extensive variation of the ‘variable regions’ have been fused to a surface protein on a bacteriophage, to create a library of recombinant bacteriophages displaying the antibodies on their surfaces.30,31 This library can be panned by trapping the phage on to the desired target, immobilized on a suitable support, and washing away the unbound bacteriophage before releasing the bound ones. These can then be grown up further, to produce a population enriched for those binding to the target protein, since the gene for the antibody is now linked to its presence on the surface of the bacteriophage, and the panning repeated until a population with high and specific affinity is obtained. Individual bacteriophage can then be cloned from this population, to give clones containing the wanted gene sequences, which can then be recloned into appropriate expression vectors for the production of the antibody.

Much of the current interest in biotechnology is over the use of techniques to develop microorganisms that produce products coded for by genes from a wide variety of sources. Potential donor organisms include viruses and eukaryotic microorganisms (i.e. microorganisms in which DNA is contained in a distinct nucleus), such as bacteria, plant and animal cells. The choice of organism is dependent on a number of factors including the ability to express functional products, the cost of manufacture and ultimate use of the product. Hormones and antibodies tend to be produced from animal cells, whereas biotechnology enzyme manufacturers, making components for polymerase chain reaction kits, might use a thermophilic microorganism, e.g. *Thermophilus aquaticus*, to produce the Taq enzyme. Virus donors include hepatitis B virus, whose DNA is used to make vaccines by expression in a heterologous organism.

The underlying technology for modern biotechnology is the ability to manipulate DNA. A typical manipulation is outlined in Figure 62.1. Initially, the target gene of interest is identified and isolated and the selected gene is cleaved using restriction endonuclease enzymes and inserted into a vector capable of being inserted or incorporated into the recipient cell (either a circular piece of DNA termed a plasmid, or a virus). The ‘new’ gene is joined to that of the vector’s nucleic acid using ligase enzymes. The vector can then be used to introduce the gene into the recipient or host cell, to which it is able to pass on the characteristics coded in the gene from the donor organism. Host species have included *Saccharomyces cerevisiae*, *Bacillus* spp. and *Streptomyces* spp., but the most frequently used is *Escherichia coli* through which nearly all genetic manipulations are made before using the vector DNA and introducing into the final destination host.

**ORGANISMS USED IN BIOTECHNOLOGY**

These come from a wide range of taxonomic groups, including bacteria, fungi and viruses, as well as animal and plant cells. The most common organisms used for biotechnology medicines are animal cells and bacteria; however, fungi are still widely used in other industrial (i.e. non-pharmaceutical) processes. Viruses can carry and donate DNA and are most commonly used during vaccine production. Viruses are also
used extensively as vectors in molecular biological research and in therapeutic delivery systems. Routinely used organisms such as *Escherichia coli*, have been genetically modified, selected and improved to enable a number of factors. Examples include the inability to undergo homologous recombination, modification of biochemical pathways to enable growth on only certain types of media, removal of genes that might enable the bacteria to transfer genetic material to other cells by conjugation and removal of resistance genes from the chromosome. The resultant organism is optimized for genetic manipulation, but severely impeded in its ability to grow outside the laboratory environment, such that the safety profile for the worker and the environment is enhanced. The modification of host microorganisms in this way plays a major role in assessment of biosafety hazards.

**PRODUCTS AND APPLICATIONS OF BIOTECHNOLOGY**

The various applications of biotechnology can be divided into five main categories: biomass production, metabolite production, recombinant DNA pharmaceutical production, transformation processes and enzyme production.

**Biomass production**

Biomass production involves the use of the organism itself as the product, usually for animal feed, but in some cases as a human food product. Apart from the use of yeast cells in the baking industry, biomass production is often referred to in the UK as single-cell protein production. Examples include the use of *Fusarium graminearum* to produce Quorn* for human consumption and *Methylophilus methylotrophus* for the production of Pruteen* for animal feed.

**Metabolite production**

Metabolite production exploits the biosynthetic capabilities of organisms and has resulted in the establishment of many industrial processes. A metabolite is something that is produced during growth, stationary or even death phases of culture. Growth of an organism results in a range of metabolites, and specific activities of some peptides can be modified by adding various ingredients to the culture broth. Occasionally, the rRNA product differs slightly from the natural product, but retains therapeutic activity, as with gamma interferon produced from *E. coli*. In other cases, molecules or transformation steps can be added by the recombinant cell. Mammalian cells are frequently used and genes coding for reproductive hormones, such as human chorionic gonadotrophin and luteinizing hormone have been cloned and expressed in such cells. Recent advances in generating active proteins through refolding of bacterial inclusion body proteins has seen great improvements in the yield and purity of products, such as human TPA (tissue plasminogen activator) using bacterial cells. The qualities and specific activities of some peptides can be modified by producing various ingredients to the culture broth. The peptides themselves can be changed by recombinant technology, e.g. by recombination of hybrid genes to produce proteins (analogue) with different but more desirable properties.

**Recombinant pharmaceutical products**

Following the discovery of recombinant DNA in the early 1970s, within four years, genetically modified bacteria were being used to make human insulin, somatostatin and growth hormone. Since then, the major thrust of recombinant DNA technology has been the production of rare mammalian peptides, which are pharmaceutically active hormones, enzymes, antibodies and biological response modifiers. Previously, these peptides were harvested from animal tissue. Large numbers of animals and a significant amount of processing activity were required to produce tiny amounts of the desired substance. Now they can be made on demand, in bacterial or yeast culture and quality is easier to control. The problems associated with contamination of the product with infectious agents present in the host animal can be eliminated (e.g. the risk of transmission of the Creutzfeldt–Jakob disease agent from growth hormone derived from human pituitary glands). The proteins yielded are purer and the process is more economical.

Examples of recombinant pharmaceutical products are human insulin, growth hormone, tissue plasminogen activator, erythropoietin, interferons and interleukins. Commonly used organisms are *E. coli*, Bacillus subtilis, *Saccharomyces cerevisiae* and *Aspergillus niger*. Occasionally, the rDNA product differs slightly from the natural product, but retains therapeutic activity, as with gamma interferon produced from *E. coli*. In other cases, molecules or transformation steps can be added by the recombinant cell. Mammalian cells are frequently used and genes coding for reproductive hormones, such as human chorionic gonadotrophin and luteinizing hormone have been cloned and expressed in such cells. Recent advances in generating active proteins through refolding of bacterial inclusion body proteins has seen great improvements in the yield and purity of products, such as human TPA (tissue plasminogen activator) using bacterial cells. The qualities and specific activities of some peptides can be modified by producing various ingredients to the culture broth. The peptides themselves can be changed by recombinant technology, e.g. by recombination of hybrid genes to produce proteins (analogue) with different but more desirable properties.
The pharmaceutical industry is also using this technology to research the amino acid sequence of naturally occurring bioregulatory proteins. This will allow the development of analogues which act as inhibitors or promoters of activity. Many vaccines are now produced using biotechnology. Genes can be cloned and expressed, which code for specific antigens of viruses, bacteria and parasites. An early example of this is the hepatitis B vaccine which utilizes yeast to produce hepatitis B surface antigen. Also, DNA from genetically modified vaccinia virus has been used to produce protective antigens for hepatitis B, rabies and malaria vaccines.36 With increasing concern regarding the possibility of a global influenza pandemic, the development of DNA vaccines whereby an individual is not given the protein antigen, but DNA encoding the antigen, is seen as a greatly improved method of delivering vaccination on a large scale.37

Monoclonal antibodies (produced from a combination of myeloma cells and antibody-producing cells from the spleen of an immunized mouse) are used in diagnostic kits, in protein purification and as therapeutic agents in cancer and organ transplant rejection. At present, monoclonal antibodies account for the largest product category of all biotechnology-derived drugs.38

Recombinant DNA technology has also been applied to the production of antibiotics, and in the development of direct-acting gene therapies, e.g. for cystic fibrosis and rheumatoid arthritis. The ‘normal’ gene is administered to patients with the aim of incorporating this ‘good’ genetic material into cells to influence the course of the disease. While there has been some success in obtaining expression of the new transgene, major problems have occurred due to the integration of the vector and further work is needed, to develop safer vectors, before this technique can be applied more generally.

Transformation processes

Transformation processes involve the enzymic conversion of one compound into another. This may involve, for example, isomerization, oxidation, hydroxylation or dehydrogenation. Examples of transformation processes include the oxidation of ethanol into acetic acid and the production of steroids, such as hydrocortisone or cortisone, from plant steroids.

Enzyme production

Enzyme production involves the isolation of useful enzymes from organisms either to use in transformation processes or for other purposes. Examples include proteases from Bacillus subtilis which are used in the manufacture of biological detergents and pectinases from Aspergillus spp., used in drink manufacture. These applications of biotechnology can be divided into four different types of process:

1. non-aseptic processes using indigenous organisms, such as in traditional wine production;
2. non-aseptic processes using specified inocula which include brewing and milk fermentation;
3. aseptic processes using specified inocula, as in antibiotic and single-cell protein production;
4. aseptic and contained processes using potentially hazardous organisms, such as vaccine production.

BIOTECHNOLOGY PROCESSES AND THEIR HEALTH HAZARDS

A typical industrial, biotechnology process involves a number of stages: inoculum preparation (for processes using specific inocula); large-scale growth of the organism in a bioreactor; separation of the organism from its growth medium; and product recovery and purification. These stages are summarized in Figure 62.2. The process may be aerobic or anaerobic, depending upon the organism used, and may be carried out in bioreactors ranging from open pan vessels to highly enclosed systems that may require mechanical agitation or aeration. Downstream processing depends on whether the product is intracellular or extracellular. Intracellular product requires extraction, whereas extracellular product is purified from spent medium (Figure 62.3) and the health hazard and effluent issues may be quite different. Extraction of intracellular product generally requires that the cells are disrupted, usually by chemical lysis or by physical disruption, such as homogenization. The potential for release of aerosols is greatest during disruption stages. The final processing stages are purification and concentration of the product, through some of the operations listed in Table 62.2.

Biotecnology processes may result in risk of exposure to biological, chemical, ergonomic, physical and other hazards.
Biological hazards

The organisms used in biotechnology processes present a number of potential hazards for consideration. These include infection, toxic effects, allergenic or other biological effects of the organisms or cells, its components or its naturally occurring metabolic products and other products expressed by the organism.\textsuperscript{39–42} Occupational exposure may occur via inhalation, ingestion, inoculation or transmission through broken skin and mucous membranes.

The effect on health of exposure to an organism depends on the route of entry of the organism, its viability, transmissibility, dose received and immune status of the exposed individual. Most organisms used in industrial processes are unlikely to cause human disease or to cause significant harm to the environment. More risk may accompany the use of non-modified organisms than genetically modified microorganisms, which are often unable to survive outside the bioreactor. However, cases of ill health among individuals involved in genetic modification work may not always be attributed to occupational exposure, leading to under-reporting. Occupational infections are not always recognized as such, especially if the resulting disease or symptoms occur commonly in the community. Reports of ill health associated with biotechnology processes are summarized in Table 62.3.

The biotechnology industry has experienced a good health and safety record. The current consensus is that the potential risks of rDNA research, development and manufacturing activities were overstated initially.\textsuperscript{11} The hazards associated with this work are similar to those associated with the organisms, vectors, DNA, chemicals and physical apparatus being used. This is supported by the fact that studies designed to test the capacity of a host organism to acquire novel hazardous properties from DNA donor cells failed to demonstrate the existence of this potential hazard, and no illness attributed to infection with a genetically modified microorganism has been reported.

Possible human health risks related to genetic modification work include:

1. Exposure to a genetically modified microorganism resulting in infection or delivery of expressed
biologically active molecules, such as enzymes, hormones or toxins to target tissues.
2. Risk of transmissible spongiform encephalopathy from exposure to modified prion genes.
3. Exposure to cloned human genes that could lead to an immune response and subsequent autoimmune disorders.
4. Exposure to a gene product, leading to induction of an immune response that could cause therapeutic complications if treatment with that product were required.
5. Respiratory sensitization related to exposure to foreign proteins, with the possibility that inclusion bodies and fusion proteins may increase the risk of sensitization.
6. Exposure to cloned oncogenic sequences or genetically modified retroviruses that could pose a carcinogenic risk.

Special consideration should be given to work with DNA-containing genes coding for potent toxins or for oncogenes. Theoretically, there is the possibility that the introduction of oncogenic sequences into a human, as a result of an occupational accident or cumulative exposure, could cause cell transformation and lead to tumour growth. No cases of this have been reported. Particular concern has been raised about possible oncogene exposure through inhalation, since the newer potential therapies use airborne viruses, such as adenovirus.

Another potential source of biological hazard is contaminating organisms present in the culture. This may be of particular concern in animal cell cultures, where viruses (retro, simian, polyoma, herpes or hepatitis), mycoplasma and prions may exist as contaminants. Tasks involving potential aerosol generation or manipulation of sharps could expose the employee to a risk of potentially serious infection.

**Toxic effects**

Toxic effects may result from inhalation of Gram-negative bacterial endotoxin. The reaction may follow exposure to the dust of single-cell protein after it has been cultured in fermenters and subsequently dried in a spray drier. Workers exposed to the end-product as a result of inadequate protective measures can develop flu-like reactions 4–12 hours later, with shivering, fever, tightness of the chest, aching limbs and cough. Blood tests reveal neutropenia followed by leukocytosis and a decline in forced expiratory volume in one second (FEV₁) has been described. These symptoms may start during the evening or the night after a day’s work, but subside by the morning or over the next day. Acute symptoms of conjunctivitis, rhinitis or cough may start immediately after exposure. Sore red eyes with a persistent discharge have also been reported. Exposed workers can be found to have precipitating antibodies to the organism, but the responses have been regarded as more likely to be due to endotoxin rather than an immunological reaction to the organism. Endotoxin intolerance can develop on subsequent challenge.

Inadequate protection against exposure to single-cell proteins (protein products developed for animal and human food (e.g. mycoprotein) or enzymes, may result in allergic effects such as asthma or contact dermatitis. Extrinsic allergic alveolitis can follow exposure to fungal spores. Type 1 immediate or anaphylactic response is a theoretical possibility after exposure to enzymes or antibiotics.

The production of biologically active products, such as hormones, interleukins and interferon, is also potentially hazardous to workers either through direct effects on health or interference with existing disease treatment.

### Chemicals

Although biological hazards are the primary focus of this chapter, it should be recognized that there are significant chemical hazards in the biotechnology industry. Potential chemical exposures may occur at many stages in the process. There are differences in the type and volume of chemicals encountered in a research and development environment and a production environment, and the levels of risk of exposure in each also vary due to differences in the way the chemicals are handled.

Growth media used in tissue cultures and fermenters consist mostly of water, inorganic salts, carbohydrates, amino acids, vitamins and other nutrients. Selective cell growth is supported by the addition of steroids, antibiotics and anti-neoplastics, e.g. methotrexate (Table 62.4), all of which pose a significant health concern, even at low levels of exposure. Chronic low level exposure to antibiotics could lead to colonization with antibiotic-resistant organisms. It may also induce or activate drug allergy, which then becomes a problem when the employee is treated with that antibiotic at a later date. Process workers are at greater risk of exposure to chemical hazards than those involved in research scale work. Tasks involved in cell culture preparation, including weighing out of chemicals, creating and agitating solutions and cleaning up spills, all present a risk of exposure.

Extraction of nucleic acids from whole tissue or tissue culture is an important preliminary phase in virtually all biotechnology processes. Table 62.5 shows a list of solvents and precipitating agents used for these purposes. Trichloroacetic acid and perchloric acid are used commonly, the latter also being an explosion hazard. Dimethyl sulphate is widely used. Certain additives can be acutely hazardous, e.g. sodium azide used to suppress unwanted bacterial growth. Cyanide salts, such as cyanogen bromide, are used with the potential release of cyanide gas, and its attendant dangers.

High-pressure liquid chromatography is used for the identification of nucleic acid components and requires the use of toxic reagents. Sequencing establishes the order of DNA pairs in a gene and can involve the use of toxic chemicals, such as dimethyl sulphate and hydrofluoric acid. Gel electrophoresis involves the use of acrylamide, but the risk of exposure can be reduced by using commercially prepared polyacrylamide gel or finished gel electrophoresis plates. Ethidium bromide, which is a mutagenic substance, is also added to electrophoresis gels, although other safer alternatives are now being used.

Sterilizing agents, such as formaldehyde, are frequently used. Potent solvent detergents, driven through by pressurized steam, are used to sanitize lines in manufacturing facilities. If this is not used in an enclosed system, inhalation exposure may cause respiratory irritation.
Ergonomic hazards

Working environments where genetic modification work is conducted range from laboratory to manufacturing plant housing large bioreactors. Employees may also work in traditional office environments and processes are increasingly computer controlled. In addition, the role of scientists has changed to the extent that much of a bioanalyst’s job may be carried out using a computer outside the traditional biological laboratory environment.

These working arrangements mean that employees are exposed to a variety of ergonomic hazards. The importance of a good ergonomic fit for staff using display screen equipment is well known. Less well appreciated is the ergonomic challenge presented by a laboratory environment. The design of safety cabinets may make it difficult to sit comfortably with a suitable work posture. Pipettes vary in weight and efficiency and do not suit all operators equally. Tasks in biotechnology laboratories are often repetitive, requiring accuracy and speed and are carried out while maintaining the upper limbs in non-neutral postures. It is thus important to carry out an ergonomic assessment of these tasks, to minimize risks to health. The increasing trend to automate sample processing will help reduce ergonomic risks.

Media preparation involves a significant amount of material handling as sacks of powdered constituents are moved around, weighed, dispensed and added to solutions. The resulting liquids often have to be moved again to storage or to other parts of the plant. Manual handling risk assessment must be carried out, training delivered to handlers and recommendations adhered to. Despite the sophistication of the biotechnology industry and the emphasis on biological and genetic modification risks, manual handling accidents and musculoskeletal ill health are leading causes of work-related ill health in the industry.

Physical hazards

Another potential health hazard in biotechnology plants is noise, resulting in a risk of noise-induced hearing loss to exposed workers. The physical hazards of steam, heat, pressure and radiation, both ionizing and non-ionizing, must also be considered. It is still not uncommon for scalds to occur, as steam is used for sterilization of fermentation vessels and lines. Other physical hazards are combustion and explosion.

Mental stresses

Finally, this comprehensive list of hazards would not be complete without the inclusion of workplace stressors. Biotechnology employees are as susceptible as any other to mental health effects from exposure to excessive pressures at work, perhaps more than some, due to the rapid pace of change in their industry. There are the added fears and anxieties related to working with genetically modified organisms and substances which have the potential to cause lasting or heritable ill-health effects. The provision of information to staff is crucial to help allay these fears. The psychological aspects of lone working or shift working should also be considered.

Environmental considerations

To render process microorganisms non-viable and to inactivate other components, the waste stream may require treatment by physical, chemical or biological methods, or a combination of these. Effluent from biotechnology processes may include growth medium components, viable and non-viable organisms, suspended solids and waste water. It will also include such chemicals as inducers, solvents, detergents, cleaning agents, buffers and alkali and acids used for pH adjustment.

RISK MANAGEMENT OF GENETIC MODIFICATION WORK

The current European approach to risk assessment for genetic modification work is based upon a classification scheme which equates the hazards to those from pathogens, assigning a genetically modified microorganism to a class which is equivalent to an equally hazardous pathogen, in terms of risk to both humans and the environment, and then assigning the same level of containment. For non-microorganisms (e.g. transgenic animals or plants) the assessment is based upon whether there is any increased risk to humans, due to the transgene, together with minimization, or avoidance in higher risk cases, of any release to the environment. In the UK, this risk assessment is mandated by the Genetically Modified Organisms (Contained Use) Regulations 2000 (as amended in 2005) and the Genetically Modified Organisms (Deliberate Release) Regulations 2002. The required process for the risk assessment for contained use is set out in the Compendium of Guidance of the Scientific Advisory Committee for Genetic Modification, which includes much helpful advice about detailed systems and considerations. The Compendium also includes limited advice on the assessment of risks for the products of ‘synthetic biology’ work.

A requirement of the Contained Use Regulations is the establishment of a Genetic Modification Safety Committee (GMSC), which should involve representatives from a range of relevant disciplines, representing both management and employees (e.g. union representatives), as well as appropriate safety personnel, while still not being too large and unwieldy. While the GMSC is specifically charged with considering and advising on all GM risk assessments, it may well also fulfil other functions, as a more general biological safety committee. The safety personnel will usually include the biological safety officer (BSO), who sometimes doubles up as the ‘competent person’ required, under the
Management of Health and Safety at Work Regulations (MHSWR), to advise the employer on safety of any GM work undertaken. However, for larger premises, where the total workload may be high, or when more specialist knowledge is required, it may be desirable to appoint a biological safety adviser to assist the BSO, as well as advising the employer.

In general, health surveillance will not be required for most GM activities and it is not a requirement under the Contained Use Regulations, although it might be under COSHH and MHSWR, depending upon the risks and benefits under particular circumstances. If a supervisory medical officer is appointed, then they would usually be a member of the GMSC, even if mainly receiving papers rather than attending meetings.

Previous regulations made a distinction between different scales of work at the risk assessment stage. This distinction has now been abandoned for the risk assessment, although it is clearly still relevant when deciding the details of the physical containment to be applied, in particular when large-scale production occurs outside usual laboratory style containment (e.g. during manufacture of GM influenza vaccine in embryonated eggs) or during clinical studies involving GM agents administered to humans in a hospital. Under the current regulations, the initial assessment is concerned to determine the relative risks to human health and the environment, considering the potential severity, likelihood of occurrence and any uncertainty. Based upon this initial assessment, the main assessment will then be aimed at reducing these factors and assigning sufficient containment measures to bring the likelihood to an acceptable probability. The GM class of the work is then determined from the containment measures required. Subsequently, consideration is given to whether these containment measures will also give sufficient protection to the lesser hazard, between human health and environment, and any necessary additional measures added. The final overall class is then reassessed, to allow for any such additional containment. The overall class determines whether it is necessary to notify the Health and Safety Executive of the particular project (initial notification of all GM centres is necessary) or even, for the higher risk classes, to seek consent before the work can be commenced.

In considering the potential hazards to human health from a genetically modified microorganism, the following should be considered:

1. Any hazard associated with the recipient strain of microorganism, particularly whether it has the potential to enter human cells or establish an infection in human hosts. Usually disabled host strains are employed, but this is not always the case and sometimes the wild-type host might be sufficiently pathogenic that even a disabled strain would still present a significant hazard. In general, the starting containment considered will be that required for the host alone.
2. Any hazard presented by the vector. While this will frequently be minimal (e.g. when the vector is a non-mobilizable plasmid which requires to be transfected into a bacterium), at other times the vector may be a virus with the potential to enter human cells and even insert into the genomic DNA, posing potential hazards not only from the genes which it contains, but also from the possibility of insertional mutation in the human genome. Examples of potentially hazardous vectors include any lentiviral, or even viral, vectors containing the enhancer of gene expression derived from woodchuck hepatitis virus.
3. Hazards associated with the genomic insert. Often the inserted gene will code only for a harmless protein, which is to be produced in bulk for subsequent purification, but on occasion the inserted DNA itself, or its product, might be harmful. Hazardous DNA will include potentially oncogenic sequences, since these have been shown to be capable of causing increased tumours (e.g. when rubbed on to the skin of mice).
4. Hazardous products from the inserted gene. These could include potentially hazardous RNA, such as siRNA targeted against tumour suppressor proteins (which would be potentially oncogenic if expressed in a human cell), and hazardous proteins, either because they are toxic or else have a physiological function (e.g. allergens, cytokines, growth factors or oncogenes).
5. Possible modification of the pathogenicity of the host microorganism. Obvious examples include pathogenicity-determining genes from a related microorganism (e.g. adhesion factors or transport factors) and any gene whose product might lower the susceptibility of the host to the immune system.

Assessment of potential hazards to the environment is less systematized, as clearly factors of the local environment are relevant, e.g. if the potential target for harm from the genetically modified microorganism is not in the immediate locality the likelihood of hazard may be substantially reduced. Risk assessment is carried out by assessing both the consequence of the hazard and also its likelihood separately, and then combining these to obtain an overall risk assessment. Among the factors which need to be considered are:

1. Any hazard associated with the recipient strain of microorganism, considering whether it might either infect or compete with any organism naturally present in the environment. Usually disabled host strains are employed, but this is not always the case and sometimes the wild-type host might be sufficiently pathogenic or dominant that even a disabled strain would still present a significant hazard. In general, the starting containment considered will be that required for the host alone.
2. Any hazard presented by the vector. While this will frequently be minimal (e.g. when the vector is a non-mobilizable plasmid which requires to be transfected into a bacterium), at other times the vector may be a
virus with the potential to infect a host present in the environment.

3. Hazards associated with the genomic insert. Often the inserted gene will code only for a harmless protein, which is to be produced in bulk for subsequent purification, but on occasion the inserted DNA itself, or its product, might be harmful.

4. Hazards associated with products from the transgene. These will usually involve consideration of whether any protein product might be harmful to any species present in the environment.

The consequence and likelihood of hazard are combined, to produce an overall assessment of risk, as shown in Table 62.6, and additional containment measures are considered until the risk to the environment is 'low' or 'effectively zero'.

Once the appropriate containment measures have been determined for the more important of the human health or environmental risk, any additional measures necessary for the other risk are added, and then the appropriate GM class is determined from the containment measures.

The containment measures necessary for genetically modified microorganisms depend upon the scale of the work. Those for small scale (i.e. laboratory scale) activities are the same as those for different hazard group pathogens and a number of the main ones are summarized in Table 62.7. In the case of GM plants, the risk to the environment will almost always outweigh that to human health and the main assessment will be that necessary to protect the environment, paying particular attention to the possibilities of dispersal, whether of pollen or seed. In consequence, the health risks are usually negligible, unless some product of the plant poses such a risk, including potential allergenicity giving rise to hay fever symptoms.

For the majority of activities involving GM animals, the primary consideration is the potential of harm to the environment, should it be able to escape and become established in the environment (e.g. by breeding and passing on its transgene(s)), and the risk to human health is similar to that posed by the wild-type animal. The issues of containment are very different, with a range in sizes from farm animals to small invertebrates requiring very different consideration. In the case of laboratory animals, the methods employed for their maintenance in a barrier unit, to ensure their pathogen-free status, will be fully sufficient to ensure that the likelihood of escape is negligible, and the risk to the environment effectively zero.

The containment measures required by the risk assessment should be adequate to protect a worker of average susceptibility. However, additional consideration should be given to anyone who might be more vulnerable, particularly those on immunosuppressive therapy (e.g. under treatment for rheumatoid arthritis or following a transplant) or who are otherwise immunosuppressed. A wider category for whom special consideration should be given is women who are, or might be, pregnant or breastfeeding. Most low class GM work will not present any specific risks to such women, or their child, but consideration should be taken if work is planned with any host known to have adverse effects, or any transgene which codes for any agent which is suspected of affecting the fetus or newborn child.

An important aspect of risk assessment is the communication of any hazards which are found to the relevant members of the workforce, so that they have a good appreciation of why the containment measures are necessary, together with appropriate training so that they can use these measures for their own, and their colleagues’, protection.

### HEALTH SURVEILLANCE

Health surveillance was a prominent risk control measure in the past when the health risks arising from genetic modification were considered to be uncertain. National guidance in several countries promoted highly prescriptive health surveillance procedures, with a hierarchy of measures linked to categories of containment levels. However, with growing experience of occupational health outcomes showing little evidence of health problems related to genetic modification work, it is clear that these traditional measures have been out of proportion to the risks to health.

The role of health surveillance has been revised in recently updated guidance, such as that produced by the Scientific Advisory Committee on Genetic Modification in the UK in 2007. The emphasis has been placed on determining appropriate health surveillance procedures based on a risk assessment of the likelihood of health effects resulting from
exposure to all the potential hazards involved in genetic modification work. Health surveillance is likely to be appropriate when all of the following criteria are fulfilled:

1. An identifiable health effect may be related to exposure.
2. There is a reasonable likelihood that the disease or effect may occur under the conditions of the work.
3. There are valid techniques for detecting indications of the disease or health effect.

The purpose of any health surveillance programme could be to collect baseline information to assist in the identification of subsequent ill health, identify health factors which are likely to increase vulnerability or susceptibility to exposure-related health effects or permit early detection of such effects. Additional aims could be to evaluate the efficacy of control measures or provide data for subsequent epidemiological study. There is also an opportunity to communicate health risks and to counsel employees about any health concerns.

Decision-making on the indications for, and content of, health surveillance programmes should be made by an occupational physician who is experienced in this field and who is involved with the organization’s biological safety committee that has responsibility for reviewing risk assessments of

genetic modification work. If health assessment procedures are indicated, an occupational health nurse can perform these and obtain advice from the occupational physician overseeing the programme.

**Low risk genetic modification work**

For work with genetically modified microorganisms that present no identifiable risk to human health, it is unlikely that there will be any indication for health surveillance. However, health surveillance may still be appropriate if there are identifiable health effects related to an allergenic response to the genetically modified microorganism or to toxic effects from expressed products.

It may still be appropriate to conduct an initial health assessment to identify individuals who may be at greater risk because of pre-existing illness or an underlying medical condition. The aim of such an assessment would be to consider the need for additional control measures or to identify adjustments to allow the individual to carry out the work with tolerable control of health risks. The following factors may require special consideration:

- relevant medical history, such as a history of asthma or recurrent infections;
- health problems which reduce the efficacy of barriers to infection, such as disorders of the skin, respiratory tract and alimentary canal;
- reduced immune competence, including treatment with immunosuppressive therapies;
- treatment with antibiotics, in particular those used in the work, or systemic steroid therapy and other treatments that could increase susceptibility to infection.

**Higher risk genetic modification work**

Health surveillance may be indicated if there is likelihood that any of the following potential health hazards may result in exposure-related health effects:

- infection, particularly with modified viruses which exhibit altered tissue tropism, reduced susceptibility to therapeutic agents or where conventional immunization would result in reduced protection;
- oncogenic or tumorigenic sequences that could give rise to a risk of carcinogenesis if incorporated into human cells;
- modified prion protein genes that could cause transmissible spongiform encephalopathy;
- biologically active substances expressed by genetically modified microorganisms, such as enzymes, hormones or toxins;
- cloned human genes that may lead to an immune response and subsequent autoimmune disease;
- substances that are asthmagens.

There is a range of health surveillance procedures that could be applied. Periodic enquiry about respiratory symptoms and lung function assessment would be an appropriate method of surveillance if occupational asthma were assessed to be a foreseeable health effect. For lower risk situations, providing information about relevant symptoms and encouraging self-reporting may be all that is indicated.

Biological effect monitoring could be used to detect antibody to the genetically modified microorganism in use, either to establish immune status prior to exposure or to detect seroconversion after a period of potential exposure. Immunization may be indicated for work with certain organisms. In the past, immunization with smallpox vaccine was recommended for work with modified strains of vaccinia virus, but there would be few circumstances now when this would be indicated as a result of a risk assessment of work with this virus. Maintaining records of exposure may be an appropriate method of health surveillance for work with oncogenic sequences where there is likely to be a long latency period between exposure and possible carcinogenic effects.

**Storage of serum samples**

Long-term storage of serum samples taken prior to exposure as a baseline reference has been widely practised in the past. The idea was that if antibody responses relevant to the genetically modified microorganisms being handled were subsequently detected, the baseline sample could be tested for comparison. However, there are few circumstances when the health benefits to the individual justify conducting such an invasive procedure and the implementation of the Human Tissue Act 2004 in the United Kingdom reinforces the view that this practice should be restricted to situations where consideration of the risk assessment for the work indicates a justifiable health or social benefit to the individual.

Previously, it was believed that the immunological response to exposure to a genetically modified microorganism or an expressed product could cause confusion during diagnostic tests for infection with the same or a related microorganism. Examples include expressed HIV proteins, where antibodies to these proteins form the basis of serological tests for HIV infection; however, previously held concerns regarding the impact that having submitted for HIV testing could have on an individual's life insurance are no longer valid. In 2005 in the UK the Association of British Insurers implemented new practice that ensures that applicants will not be penalized for having taken an HIV test and are not required to declare negative tests nor will occupation be used to assess HIV risk. In general, there is only likely to be an indication for baseline serum storage when the current diagnostic tests would have difficulty distinguishing true infection from immunological response to a related protein, or acute from chronic infection states, and where such confusion could have substantial health or social consequences. The usefulness of the baseline sample is of limited medicolegal value, however,
when one considers the implication of the window period that an employee could be in at the time of submitting a sample.

If serum storage is practised, then it is important that the purpose of the procedure is explained to the employee and informed consent obtained. It should be emphasized that the individual is only consenting to the sample being stored and that subsequent testing would only be conducted with the individual's express consent, even after the individual has left the organization where the sample is stored. A sample of approximately 5 mL of serum should be labelled to allow later identification of the donor and stored in a secure freezer at –20°C or below, with arrangements made for dealing with sample salvage in the event of freezer malfunction. The period of long-term storage before discarding the sample should be agreed with the donor. It is unlikely that there would be advantages in storing such samples for longer than 40 years. As can be seen, a multitude of practical and legal considerations regarding ensuring cold custody, informed consent, maintenance of accurate registers, notification to the occupational health department of staff leavers and disposal of samples need to be weighed in the balance prior to embarking on any programme of serum storage.

Medical contact cards

In the past, issuing medical contact cards to employees involved in genetic modification work with higher hazard genetically modified microorganisms was common practice. The rationale for doing so was to alert other medical personnel to the possibility of occupationally acquired infection and provide details on how to contact someone at the employing organization who would be able to give the clinician information about relevant biohazards. In practice, however, there is the likelihood that employees may lose or not carry their cards and as any occupationally acquired infection is unlikely to present with unconsciousness or an acute confusional state, this practice would seem to be of limited benefit. Any unusual symptoms not readily diagnosed by standard means would lead to a thorough assessment that would include a complete occupational history, thus yielding the required information.

Health records

Health records should be maintained of all health assessments conducted as part of any health surveillance related to genetic modification work. Records that contain clinical information must be held in confidence by healthcare professionals.

Records of exposure may also be indicated for work which involves higher hazard microorganisms, prion proteins or oncogenic sequences where there is known to be a long latent period of many years between exposure and the onset of ill health related to infection or carcinogenesis. These records should include personal identifying information, details of the nature of the hazards, the dates when the work started and finished and information that links the record to the relevant risk assessment and any exposure monitoring data. Such non-clinical records can be maintained by the employer. The records could also be used to provide retrospective information on health and related exposures for epidemiological investigation.

CONCLUSION

The clinician may be puzzled at the contrast between the complexities of biotechnology with its surrounding myriad of regulations and control measures and the dearth of data on ill health in the scientists and production workers involved. The industry is perceived to have a good health record, but, to be able to demonstrate the absence of a problem or to provide early warning of an unforeseen health hazard in this novel and rapidly expanding technology, it will be important to ensure that health surveillance measures based on sound theoretical considerations, including epidemiological studies where appropriate, are maintained. The challenge for the future will be to ensure that any potential hazards to human health or the environment are controlled to the satisfaction of employees, health and safety professionals, regulatory authorities and, ultimately, the general public.

Key points

- The field of biotechnology has an excellent health and safety record, but consideration must be taken of associated traditional risks such as chemical, physical and ergonomic.
- Work with genetically modified microorganisms is highly regulated and occupational health practitioners should familiarize themselves with relevant legislation and guidance.
- Health surveillance activities should be risk-based and outdated practices such as routine serum save discontinued.
- The field of biotechnology is developing rapidly and the risks posed by emerging technologies such as nanotechnology are as yet not fully characterized.

Introduction to work and stress

According to Hayward,¹ stress derives from the Latin word *stringo* (*stringere*), meaning to bind or draw tight. It entered the English language in the fourteenth century, when it referred to physical hardship and later, a form of injury. It was not until the seventeenth century that the word began to refer to an inner state.¹ Its modern usage to describe a combination of harmful environmental pressures and pathological physiological responses was popularized in the research work of the biochemist Hans Selye (1907–82). The notion that the body's response to the environment might have adverse health consequences, especially on the heart, was proposed by the famous clinician Sir William Osler (1849–1919).¹² Experimental evidence on the effects of stress emerged in the laboratory work of the physiologist Walter B Cannon in the 1930s, when he showed a range of physiological responses, such as adrenaline release and cardiac arrhythmias, in response to external 'strains'.¹ These concepts, part developed by pioneers in an era that preceded modern scientific medicine, took firm root with the public and the medical profession.

Readers turning to *Hunter's Diseases of Occupations* for authoritative guidance on stress disorders arising out of work will find the following three chapters covering the topic from separate, but overlapping, angles: a review of the evidence base, the reflections of a psychiatrist on the psychosocial aspects and a clinical psychologist’s perspective on intervention. Stress at work manifests in many different ways, but occupational physicians should have little difficulty in recognizing the 'work-stress victim' described by Lipsedge and Calnan. William Blake’s ‘dark, satanic mills’ may have finally receded into history in high-income nations, where in this age of globalization the entrepreneur employer is seen less as a villain than as the wealth creator we desperately need. However, employees in almost all employment sectors complain increasingly of such problems as overwork, or fear of making mistakes, or of being marginalized, bullied and harassed, to the point of intolerable distress. These three chapters agree on at least two things: first, that the evidence on the management of individuals presenting with stress at work is still controversial, and second, most employees who have work-related distress do not need to be medicalized. In the chapters by Glozier and colleagues, and Lipsedge and Calnan, the mental effects of exposure to life-threatening trauma and involvement in warfare as part of work are also described, along with the medicolegal minefield of post-traumatic stress disorder.

INTRODUCTION

The main aim of this chapter is to identify the cultural and psychosocial influences on the illness behaviour of employees with problems that manifest under the title of ‘work-related stress’. Much of the previous work on the relationship between work and stress has tended either to focus on the social epidemiological factors, which put workers at risk of stress-related ill health, or has adopted a psychological approach and focused on the personal characteristics of the worker and their influence on the perception of threat and the ability to cope (see Ref. 2). What appears to have been neglected is the link between the two and how aspects of the structure of the working environment to do with social relations that affect health need to be incorporated into the psychiatric assessment of the individual. This psychosocial perspective combines occupational psychiatry and medical sociology and anthropology and is illustrated with case examples.

THE DISCOURSE OF WORK STRESS

The theoretical perspective adopted here provides a general framework for understanding the arguments and explanations which are presented for the relationship between work-stress and sickness absence. It draws, at least in part, on cultural sociology as it focuses on the cultural construction of the ‘epidemic’ of work stress and the creation of the social identity of the ‘work stress victim’. The argument runs as follows: The ‘popular’ discourse of work stress suggests that the labour process is being intensified and making greater demands on the worker, which may lead to poor mental and physical health. The apparent increases in strain and tension across workplaces are claimed to be due to changes in work characteristics, such as technological innovation, introduction of new managerial techniques, greater job insecurity or increases in working hours. These changes in the organization and character of work are increasingly conceptualized in terms of the ‘medical’ category of stress which emphasizes their consequences for the physical and
mental health of the individual worker. There are essentially two strategies for addressing the work stress 'epidemic'. The first emphasizes strengthening the individual through stress management techniques and therapeutic interventions, such as counselling or medication. The second focuses on job redesign as a means of reducing job strain, although even here the emphasis is still on health and safety at work.

The reaction to problems at work depends mainly on how employees interpret their experiences, and how they decide to respond. However, employees do not make sense of their experiences in a vacuum, rather they make sense of their personal experiences by relating them to a broader pattern of assumptions and expectations. This broader pattern, according to Wainwright and Calnan, might be referred to as the 'discourse of work stress', and it acts almost as a guide to action, or at least as a pre-existing framework within which experiences can be made sense of and decisions about future action can be taken. The discourse of work stress is an informal body of social knowledge built on a mixture of lay experience, professional and academic opinion and media representations. It tends to reflect current social and structural arrangements and is, therefore, historically specific. This argument, however, has a further dimension in that it suggests that work stress is not entirely mediated at the level of consciousness or cognition. Over the life course, social experiences become embodied or as Wainwright and Calnan propose 'become written on the body' in the form of learned emotional and physiological responses which can later be triggered independently of conscious assessment. Unaware that these reactions have been 'learned' since childhood, it is taken for granted that they represent a 'natural' limit on the body's capacity for endurance and resilience, further reinforcing the belief that work stress is basically a biomedical reaction to the excessive demands and strains of working in the current cultural context.

The work-stress discourse can be interpreted as an example of the medicalization of a social problem, i.e. that adverse experiences at work which were previously seen as political or industrial relations issues are increasingly falling into the domain of medical jurisdiction. Medicalization operates at a number of different levels with varying degrees of medical professional involvement. The work-stress discourse provides a conceptual framework for defining and understanding the problem in medical terms. Yet this medicalization process may also be evident at the institutional level where doctors can control access to and legitimate sickness absence and benefits and at the interactional level where they treat and diagnose those who consult them for work-related problems.

There is a range of different approaches to medicalization, but the more recent ones have emphasized the way medical discourse might influence self-identity in a positive rather than a repressive way. Thus, the new self-identity of the work-stress victim might offer an accessible framework for making sense of and responding to, not just adverse experiences at work, but what appear to be their emotional and physiological manifestations. It not only provides a seemingly 'scientific' explanation of lived embodied experiences, it also offers a range of strategies for action: therapies and sick leave for some, exit from the workplace through early retirement on medical grounds for others, and for a few the opportunity to seek financial redress through the courts.

The adoption of the identity of a work-stress victim is a choice and thus the question is how far the discourse of work stress which appears to dominate public debate about changes in work at the macro level has been taken on by workers at the micro level. Evidence from studies which explored the processes by which employees come to recognize adverse experiences at work as health problems and the extent to which they turn to medicalized solutions for dealing with these problems, suggest that the stress discourse is salient to workers (both men and women) when they are discussing adverse experiences at work, and that it is used to make sense of a wide range of experiences, from low morale and low job satisfaction, through to embodied manifestations, including physiological signs and symptoms. Moreover, the assumption that workers passively accept medical solutions, such as medication and counselling, was shown to be inaccurate and consultation was a way of getting sickness absence rather than treatment (for example, Ref. 3).

... he (the doctor) said, 'there are two ways of handling this, we can either give you some time off work, or, I can give you some medication, something to take.' And I said, 'I didn't want to take anything,' so he signed me off work for a week. And he said; 'come and see me in a week and we'll see how it goes' (p. 185).

And the doctor was just a means to an end to get a sick note because I wasn't fit enough to work. I didn't feel that the doctor herself actually talked to me and helped me. At the time I couldn't continue to work (p. 181).

While some workers adhered to medical labels and followed an illness pathway which led to exit from the labour market through early retirement on medical grounds, others contested the medicalization process and resisted seeking professional medical help. The value attached to personal resilience coupled with the reluctance to adopt the self-identity of a work stress 'victim' appears to be an important factor in determining resistance to the medicalization process (for example, Ref. 3):

Interviewer: How did you feel about going to the doctor with that kind of problem?

Pathetic basically, you should be able to cope with life, shouldn't you, be stronger willed and get on with everything (p. 183).
you feel you’re letting yourself down because you haven’t been able to cope. You feel that you have an image that you have to maintain. I’ve told a few close friends and the rest you tend not to talk to about it (p. 183).

A range of alternative strategies for addressing problems at work was identified, including informal mechanisms of support, ‘emotion work’ and informal relaxation techniques. In a related study of arm pain, contrary to mechanisms of support, ‘emotion work’ and informal relaxation problems at work was identified, including informal mechanisms of support and employers to their condition. Some of this reticence stemmed from a fear of being seen as a trouble maker and others, who felt unable to discuss their condition at work, were more likely to feel this way because of the ‘age factor’:

I’m just very conscious of my age and I work with a lot of young people, and I just don’t take time off of work ... I’ve got a TENS machine for my back and I sit and work with my TENS machine on (A1217).

Why was there opposition or resistance to medicalization? Wainwright and Calnan suggest that the answer seems to lie in the extent to which becoming a work-stress victim entails relinquishing control over one’s mental life. Agency, or the ability to actively engage with the world as a conscious actor, depends fundamentally upon mental competence. To be unable to cope with the demands of a stressful job and to seek medical advice, is to give up one’s identity as an independent social actor where being able to work is a fundamental part of social identity. The ability to cope with stressful life events without using medical therapy has traditionally been viewed as a positive personal trait, but the negative side of valuing the capacity to withstand pressure is that those who fail to cope are stigmatized as weak or inadequate. Hence, the reluctance among the informants to change arises from both the disruption of the moral/political order that binds the employee to the organization and from the apprehension and uncertainty caused to their sense of identity, security and self-worth. Sickness absence on the grounds of work-related stress is interpreted here as an oblique form of resistance, a covert acting out of indignation and anger. This, as the previous theoretical discussion suggested, is no easy or lightly taken option given the moral imperative to be resilient, to be able to cope and continue to work.

We would argue that paradoxically the new identity reinforced with a medical label (disorder or ‘syndrome’) can become a strategic tool to redress the balance for those employees who feel undervalued, exploited or discarded. The quest for a diagnostic label and the performance of a culturally standardized sequence of events and actions has the characteristics of a ‘culture-bound syndrome’. The necessary conditions for a culture-bound syndrome are a specific configuration of social expectations and a template of how to behave when oppressed. Culture-bound syndromes are local patterns of time-limited behaviour, specific to a particular culture, which while regarded as undesirable, have a problem-solving function for the dislocated individual who is not held to be aware or responsible in the everyday sense (p. 290).

In the workplace, the employee who feels humiliated, whose dignity has been affronted or who feels that his work is over-controlled, is denied what Scott calls ‘the ordinary luxury of negative reciprocity; trading a slap for a slap, an insult for an insult’ (p. 23). Being treated with respect and dignity might be more important at work than financial reward (p. xii). When an individual is wronged by a person of inferior status they feel contempt, when the offender is of the same rank the victim becomes angry, but when a person is treated badly by a superior they feel bitterness and resentment, which can become the state of chronic embitterment recently described by Tom Sensky.

In his monograph, Happiness and Unhappiness in the Workplace, Warr has defined the key characteristics of any job which lead to greater well-being and self-validation. These include opportunities for personal control, skills use, variety, clarity of role, social interaction, status, support, security and equity, as well as amount of pay.

These ingredients are perceived to be lacking in the modern workplace, as in Franz Kafka’s description of a large open-plan office:
People were criss-crossing the middle of the floor, in all directions, at great speed. No one offered a greeting, greetings had been abolished, each one fell into the tracks of the man ahead of him and kept his eyes on the floor, across which he walked to make as rapid progress as possible (p. 34).

Kafka

Employees’ complaints about stress often reflect feelings undervalued and powerless within an organization. Subjective well-being is undermined by a perception of organizational injustice and where there is thought to be a breach of the psychological contract. (This is defined as a set of expectations specifying what the individual and the employer expect to give and receive from each other in terms of rights, privileges, duties and obligations) (p. 149).

Pinder found that ‘systemic injustice’, i.e. the perception of unfairness within the organizational context, tends to induce fear, resentment, hopelessness and sadness (p. 122). Anger and hatred towards superiors were common in employees who felt they had been treated unfairly, especially if there had been an element of public humiliation (p. 123). ‘Employees who feel locked into their jobs have limited constructive means for dealing with their frustration and, as a result, are more likely to resort to either aggression or displaced aggression in their jobs’ (p. 125).

Pinder (p. 277) describes what job dissatisfaction feels like: ‘It often carries feelings of gloom and despair, sometimes anger and resentment, sometimes futility’. He adds that ‘withdrawal in response to job dissatisfaction can take the form of tardiness, absenteeism and turnover, as well as passive compliance and minimal effort’ (p. 278) and that the ‘perception of unfair or unjust treatment by employers is a major cause of theft, sabotage, violence at work, absenteeism and lateness’ (p. 313).

When the subordinate takes sick leave because of a breach of the psychological contract, they might be adopting a political strategy to redress the imbalance in the power relationship between employer and employee, by embodying a ‘hidden transcript of the weak’ (p. xii), which covertly expresses their resentment and frustration. ‘Oh my Lord’, he thought, ‘If only I didn’t have to follow such an exhausting profession! On the road, day in, day out. The work is so much more strenuous than it would be in head office, and then there’s the additional ordeal of travelling, worries about train connections, the irregular meals, bad food, new people all the time, no continuity, no affection. Devil take it!’ (p. 88).

Historically, subordinates have disguised their resentful opposition by resorting to tactics such as foot-dragging and dissimulation which Scott describes as the ‘infrapolitics of the powerless’ (p.xiii). ‘a substitute for an act of assertion directly in the face of power’ (p. 155).

In his novella about Bartleby, the indolent scrivener, Herman Melville describes the predicament of the benign employer in the face of his employee’s repeated refrain: ‘I would prefer not to’. ‘Nothing so aggravates an earnest person as a passive resistance … mortified as I was at his behaviour, and resolved as I had been to dismiss him when he entered my office, nevertheless I felt some superstitious knocking at my heart, forbidding me to carry out my purpose and denouncing me for a villain if I dared to breathe one bitter word against this forlornest of mankind’ (pp. 17–26).

**Susto and the sick role: a way out?**

From a sociological perspective, the resort to sickness absence by employees with seemingly minor symptoms and distress is an example of both strategic manoeuvring and of illness behaviour. Taking sick leave is one of those conditions identified by Robert Edgerton which are ‘culturally recognized and named as brief periods during which the temporarily ill, intoxicated, bereaved or possessed person is expected to behave in ways that would ordinarily be prohibited’ (p. 49). In advanced industrial societies, being on sick leave starts off as a temporary status which exempts people from their ordinary obligation of economic productivity (p. 6). When the powerless individual is enmeshed in a situation that he cannot control, the passive appeal of helplessness affords room for manoeuvre and negotiation with management.

As Brown has asserted (p. 39), ‘some people with the same symptoms and conditions as others choose widely disparate ways of dealing with their symptoms or conditions’. **Susto** is an example of the well-known ‘sick role’ as defined by Parsons and Fox which provides a socially sanctioned exemption from the challenge of everyday responsibility and which is fashioned in accordance with the ‘dominant social elements of medical knowledge’ (p. 37). As with stress in the West, **susto** is a culturally shaped idiom of distress. Medical anthropology recognizes that bodily and psychological complaints are used as metaphors of personal, social or occupational stress, ‘which give the sufferer a little more leverage in negotiating for a less difficult work situation …’ (p. 27). Sometimes these temporary conditions can become long term, and evolve into eligibility for incapacity benefits and eventually early retirement on the grounds of ill health.

Among the Zapotec of the Oaxaca Valley of Mexico, **susto** (‘fright sickness’) exempted the afflicted person from onerous duties for a limited period of time, before resumption of normal responsibilities. The ‘clinical presentation’ of **susto** includes unrefreshing sleep, low mood, lack of drive, energy and motivation, poor appetite and neglecting one’s appearance, together with feeling overwhelmed by routine tasks and non-specific aches and pains. This amalgam of complaints is found throughout rural Latin America and is attributed to ‘soul loss’ in which the person’s spiritual element departs from their body. The victim has generally felt powerless and trapped in a stressful situation where they cannot meet social or personal
obligations. Susto provides a socially respectable escape hatch from intolerable circumstances, by affording respite from normal social responsibilities.

Becoming an *asustado* appears to be a more or less conscious choice. Its potency in mobilizing privileges derives from the folk belief that susto, like hypertension and even stress in the West, is potentially fatal.30 The status of *asustado* is arrived at through group negotiation, with cues provided by neighbours. Entitlement is sometimes challenged because not all temporary conditions that have the potential to provide exemption actually have clear criteria for entitlement and the claim for exemption has to be negotiated (p. 49).23 As Edgerton points out (p. 74), exempting conditions such as grief, illness, intoxication and spirit possession ‘can be readily exaggerated, prolonged or faked altogether’. He asks, ‘Was someone really possessed, truly drunk, honestly grief-stricken?’ In our society, a sceptical benefits gate-keeper might ask, ‘Is this person genuinely sick and disabled?’ or is this a case of ‘strategic opportunism?’ (p. 53).23

**WORK STRESS AS A CULTURE-BOUND SYNDROME**

The culture-bound nature of workplace stress reactions is illustrated by the epidemic of possession states described in Malaysian factories in the 1970s.

In one ethnographic account,31 foreign-owned electronics factories enlisted single Muslim women from village communities. They lived in hostels at some distance from their rural homes. These young women were closely supervised on the factory floor by male managers from a different ethnic background. Their electronic assembly work was repetitive and monotonous and caused eye strain. The employees were motivated to work in these factories by the prospect of earning enough money to send to their families and to pay for their own further education. This was an attractive alternative career to traditional arduous physical labour in the rice fields. However, despite the attraction of regular wages and a degree of independence from the constraints of traditional village life, there were sporadic outbreaks of possession. These dramatic, but generally short-lived, episodes were characterized by sudden screaming and falling to the ground with violent convulsive movements.

A common theme was having a vision, while in the lavatory and especially when menstruating, of a Tamil male supervisor peering at the employee (both the toilet zone and menstruation are liminal and associated with pollution).32 Several fellow workers would typically then see the same vision, collapse and make violent movements with their limbs. Work on the assembly line would be halted and production targets sabotaged.

At first, management called in *bomohs*, traditional healers, to exorcise the possessing spirit. The local interpretation of these bouts was that the factories had been built on virgin forest land which had offended and displaced tree spirits. These vengeful spirits were now possessing and punishing the factory workers.

Some possession cases proved to be refractory to priestly intervention and so company medical officers were invited to examine the afflicted workers. They made a diagnosis of mass hysteria and prescribed psychiatric drugs, mainly benzodiazepine tranquilizers. These biomedical interventions were only partially effective and some of the possessed women, after further episodes, were dismissed on medical grounds and returned to their villages.

In a foreign-owned factory in Malacca manufacturing trainers, there were 40 outbreaks of ‘mass hysteria’ in 1977–78 among poorly educated, badly paid female workers.33 The hysterical behaviour included convulsions, aggression and apparent loss of consciousness. This behaviour was attributed by the employees to spirit possession due to violation of moral codes. Management labelled this as ‘hysteria due to superstition’. Again they encouraged local traditional healers to carry out exorcisms at the factory water tanks. Private interviews with an anthropologist revealed a number of grievances: resentment about low wages, lack of subsidies for bus fares, strict and closely supervised work regimes, restricted leave and alleged harassment by male supervisors. The women expressed feelings of powerlessness, exploitation and job insecurity. Their wish to join a union had been thwarted.

In both cases, the Malay cultural disapproval of open display of anger prevented these workers from verbalizing their grievances and their resistance to management took an oblique form.34

Chew35 who was director of the industrial health department in the Ministry of Labour in Singapore discusses the management of outbreaks of hysteria among factory workers in Malaysia. ‘These mass hysteria episodes were treated like an epidemic disease of bacteriological origin. (p. 50)’ Control of contagion was attempted by isolating the identifiable cases from the general factory population and injecting them with chlorpromazine. Isolation was required since they were considered to be ‘infectious’. It was recognized that psychological factors were important and it was also concluded that as a long-term preventative measure ‘a key factor seems to be education and raising the level of immunity in the susceptible community by “inculcating” the right notions and giving basic facts to eliminate superstitious beliefs’ (p. 53).35 There is no reference to conflict in the workplace. In this public health approach which was based on the principles of containing a microbial epidemic, tranquilizers were administered to control the activity of the disease in the victims.

In Ackerman and Lee’s study33 of a spirit possession event at a shoe factory in Malaysia, the authors emphasize the factory’s policy of strong anti-unionism. The managing director had instructed management to listen for rumbles of discontent and indications of collective organization among the workers, whose leaders were to be identified and dismissed immediately to deter any would-be organizers. They describe episodes of violent convulsions, loss of consciousness,
incoherent mumblings and aggressive behaviour among groups of Malay female workers which were interpreted as spirit possession. Fellow workers attempted to hold them down, applying cooling agents to their foreheads and accompanying them home after they had calmed down. Other workers were afraid to approach them in case the behaviour was contagious. The afflicted workers were all female. The managers had few complaints about the female production workers’ job performance and discipline, but the male workers presented continual problems of insubordination and theft. Management were perplexed by the outbreaks of possession and did not hold these women workers responsible for their disruptive behaviour which on occasion led to the closure of the factory. The authors elicited antagonism towards management and both male and female workers’ dissatisfaction with the incentive system and work conditions, but this antagonism was not perceived by either the workers or the management as a significant causal factor in the occurrence of possession. Thus, the assumed supernatural influences in the factory were not explicitly linked with the workers’ grievances, i.e. the outbreaks of mass spirit possession and the resentment of the workers were perceived as two unrelated domains.33

From the perspective of medical anthropology, these outbreaks of possession in factories in the industrializing world can be interpreted as follows:

- As with other culture-bound syndromes,36 the stylized behaviour has a shared meaning which articulates a personal predicament and represents a conflict, in this case the opposition between employer and employee.
- The culturally shaped resistance to pressure from managers has both a personal expressive meaning for the individual and an instrumental function.
- The resistance draws on locally available beliefs in possession which mainly afflicts non-dominant people, i.e. women of low status. As in other situations of frustration, ‘the principal is able to adjust his or her situation by recourse to mystical pressure’.37 Such spiritual affictions ... are to be found in circumstances where other secular means of ventilating grievances or pursuing vital interests are blocked, or very restricted’ (p. 89).38 This sideways recourse to transcendental action mobilizes the ‘power of the weak’,39 invoking supernatural (or biomedical) pressure which permits personal adjustment of the situation and reduces frustration.
- Possession tends to occur during a visit to the factory lavatory. This is a liminal place invested with potency because of the contrast between purity and dirt. A woman’s vulnerability in the toilet is enhanced if she is menstruating which is also associated with notions of pollution and danger.
- Furthermore, the recurrent theme of being spied on by hallucinated foreign male apparitions reflects the subordinate position of the female workers who are under close surveillance by male supervisors of a different ethnicity.

- Malaise due to the demands of working in an electronic assembly plant and a shoe factory provoking a sequence of ‘symptoms’ followed by traditional folk labelling and exorcism has parallels in the West, where the therapeutic quest for relief from work-induced medically unexplained symptoms often shifts from the biomedical to New Age methods: acupuncture, reiki, bioenergy, amygdala retraining, ‘healing’. Chinese herbal medication, multivitamins, reflexology, natural food remedies, Light Bath, vibration therapy, geodetic force analysis, massage and cranial osteopathy.

**BENIGN SURVEILLANCE**

The tension between productivity and employees’ subjective well-being has been a core issue of industrial psychology and psychiatry since the early twentieth century.40 'Alex’, the Daily Telegraph business pages strip cartoon for July 28, 2008, provides a good example of the stress discourse. A senior executive at Megabank asks the bank’s stress counsellor if anybody from his department has consulted him recently. The stress counsellor replies that although his services are paid for by the bank, the names of the employees who consult him and the matters discussed have to remain strictly confidential. The executive replies, 'But I have decisions to make about the running of my department and I need to be forewarned if any of my team is cracking up or losing the plot …'. He adds, 'I mean I wouldn’t want to fire a guy and waste a payoff on him if he was already planning to quit …’. The stress counsellor refuses to breach professional confidentiality and a day or two later he himself is made redundant.

Close surveillance in the workplace is familiar in the West40 and even extends to toilet breaks. Thus, Gillian Howard in the Law Society Manual on drafting employment contracts writes, 'When you take lavatory breaks during the course of your working day, you are required to report to central office at the time of starting and finishing the break. This is required for safety reasons so that management knows where you can be located in the case of any emergency or safety issue’ (p. 127).41 According to an American Postal Workers’ Union official, supervisors have the right to order emergency psychiatric examinations for employees who have ‘increased bathroom use’ or become ‘argumentative’.42 In these cases, the surveillance aspect is mitigated by the expressed concern for health and safety.

Psychological interpretations of sickness absence have inspired a number of management solutions over the past 100 years or so.40 These approaches have attempted to work on the subjective experience of the private self, i.e. to socially organize and manage thoughts. Under the French insurance company AXA’s ‘My Budget Day’ initiative, employees are given an hour off during a working day to check their financial planning and use the company’s website to contact brokers, consultants and advisers to develop personal budget plans. The scheme was introduced by
AXA to improve relations with staff and to raise morale. The programme, interestingly, also helps managers to check whether money worries are affecting staff (the group human resources director describes the scheme as the scheme as an employer’s financial web-based ‘health check tool’). This initiative is included in the employee’s benefit programme (Daily Telegraph Business, Appointments section October 30, 2008, https://mybudgetday.axa.co.uk).

The programme has helped morale and reduced absenteeism and staff turnover and managers have reported an improvement in performance when employees were less worried about their personal finances. After the ‘My Budget Day’ in 2007, employee turnover rates fell from 12.8 to 11 per cent, while absenteeism which AXA uses as a ‘stress indicator’, fell by 10 per cent to just over 3 per cent.

DEFINING ENTITLEMENT

The sick role concept has long been criticized for having limited explanatory power for accounting for the social position of chronically sick people as it applies mainly to acute, physical short-term illness. Of more relevance is the way it might be used to control deviance by providing a set of rules, responsibilities and obligations which circumscribe eligibility and access.

The Employment Appeals Tribunal in the case of Morgan v Staffordshire University furnished practical guidance on the type of evidence needed to ‘prove’ that an individual is suffering from a mental impairment. For organizational and legal purposes, ‘stress’ is often too nebulous a concept and there is a requirement to produce a more focused diagnosis using WHO ICD-10 categories (Morgan v Staffordshire University43 cited in D’Auria et al;44 see also Jamdar and Byford45).

A diagnosis involves reified definitions of disease into which professionals fit their observations. This implies legal endorsement for medically ‘organizing’ a mishmash of disparate feelings, emotions and complaints to create a coherent entity46 by a process of mapping reported symptoms onto available cultural models of illness and healing.47

As Brown observes ‘… physicians are confronted with what is often an “unorganized illness” and a conglomeration of complaints and symptoms which may be unclear, unconnected and mysterious. Their job is to understand and interpret that material in order to arrive at an “organized” illness’ (p. 39).48

However, although employment tribunals require specific medical diagnoses, categorical diagnostic classifications such as depressive disorder or anxiety states obscure the cultural shaping of symptoms. As Horwitz49 points out, the basic assumption of the diagnostic framework is that the presence of sufficient particular symptoms, regardless of their cause, indicates an underlying disease. In reality, distress takes the form of generalized and non-specific symptoms which reflect expected reactions to challenging situations, unhappiness, frustration, demoralization and dissatisfaction (pp. 14–15).49 Psychological and psychosomatic ‘symptoms’ develop as a reaction to a taxing social environment, such as problems in the workplace, but these symptoms are often appropriate flight or fight responses of the autonomic nervous system to challenge or threat, rather than evidence of specific disease entities or of an underlying mental disorder (p. 14).47 Psychological symptoms of distress overlap across many diagnoses and lie on a spectrum of abnormality. As Kirmayer50 writes (p. 331), ‘Some milder forms of distress are coterminous with everyday emotions …’. Anxiety is on a continuum with worry and apprehension, and depression merges with grief and a sense of loss. It can be difficult to distinguish demoralization from depression. Demoralization often stems from lack of a sense of personal control in jobs where there is close supervision, reduced autonomy and little participation in decision-making (pp. 184–5).51

Entitlement can be falsely claimed. ‘Someone skilled at strategic manipulation of the rules may successfully exaggerate the extent to which he is ill, emotionally distressed or intoxicated in order to claim the exemptions from responsibility that these conditions provide’ (p. 53).23 Psychiatric labels are a readily available source of mitigation and exculpation.52 Clinical decisions about the presence of psychiatric disorder are somewhat subjective and are prone to influence by the social context, despite the ‘technical rationality of the standard diagnostic systems’ (p. 220).53

Case 1

A commercial property surveyor threatened a colleague in their office whom he suspected of making suggestive remarks to his girlfriend. He stormed out of the office, called at his doctor’s surgery on his way home and was given a certificate for ‘work-related stress’. Subsequently, a private psychiatrist submitted a report that he was suffering from mixed anxiety and depressive disorder (ICD-10, F41.2)54 and was not fit to attend a disciplinary hearing. It was this specialist’s opinion that his patient was ‘unlikely to recover from his anxiety with depression unless the disciplinary charges are withdrawn’.

INCAPACITY BENEFIT CLAIMS AND SICK NOTES

Doctors are more minded to provide certificates to patients with a psychological problem.55 The Health and Safety Executive has reported that work-related stress is now the most common cause of working days lost as a result of occupational injury and ill health.56 The American anthropologist, Allan Young, has commented that, ‘When faced with a diagnosis for which he has equally convincing reasons to believe that either his client is sick or he is not sick, the physician finds that the professional and legal risks are less if he accepts the hypothesis of sickness’ (p. 15).57
Doctors have acted as gatekeepers to the benefit system since the 1911 National Insurance Act. They control access to the Department for Work and Pensions. Sick leave is discussed with between one and six patients per doctor session, but only a proportion may be regarded as genuinely unfit for work on medical grounds. Family practitioners find consultations about sick notes problematic because of the threat to the doctor–patient relationship from a perceived conflict of roles and a suspicion that patients will ‘doctor-shop’ to obtain a sick note. Doctors might feel coerced into writing sick notes. Many doctors issue certificates on demand, either on the grounds of speed or of the doctor knows best, while an equal number said they would not work regardless of the doctor’s opinion. The ‘the doctor knows best’, while an equal number said they wanted a passive role in the decision-making process, i.e. the doctors themselves showed resistance to participation in a perceived flawed bureaucratic system. ‘There seemed to be a code or language of sick notes developed by general practitioners which fulfilled three purposes: to preserve patient confidentiality, to communicate with other agencies, and to deliberately misuse or sabotage the system by the use of vague diagnoses. Participants described writing “malaise”, “debility”, and TALOIA (“there’s a lot of it about”), producing meaningless statistics’ (p. 89). The authors comment that the gate-keeping role is effectively sabotaged by the strategy of acquiescence to every patient. Doctors do not wish to jeopardize the doctor–patient relationship by confronting patients over sick note requests (p. 89).

A study of sickness certification by 67 doctors in Scotland found that the system was largely patient-led and most of them wanted a ‘sick certificate on demand system’ (p. 91). The doctors themselves showed resistance to participation in a perceived flawed bureaucratic system. ‘There seemed to be a code or language of sick notes developed by general practitioners which fulfilled three purposes: to preserve patient confidentiality, to communicate with other agencies, and to deliberately misuse or sabotage the system by the use of vague diagnoses. Participants described writing “malaise”, “debility”, and TALOIA (“there’s a lot of it about”), producing meaningless statistics’ (p. 89). The authors comment that the gate-keeping role is effectively sabotaged by the strategy of acquiescence to every patient. Doctors do not wish to jeopardize the doctor–patient relationship by confronting patients over sick note requests (p. 89).

The chief medical officer to the Department for Work and Pensions has challenged the view that doctors ‘should simply accede to the patient’s wishes without any negotiation’ (p. 461).

FITNESS TO ATTEND DISCIPLINARY HEARINGS

Medical support for a claim of unfitness on mental health grounds to attend a disciplinary hearing is not uncommon. ‘Withdrawal from everyday social responsibilities is made socially acceptable through some means of exculpation usually through mechanisms of biophysical determinism’ (p. 298). The mystical power of biomedicine as “external” justification for individual action, and the negotiated “space” it affords seem relevant to those other situations in which the patient enacts a "pas de deux" with the doctor. Such as requests for sick notes on the grounds of work-related stress.

Employers might suspend the disciplinary hearing because of fear of litigation and failure in their duty of care. In the case of Deadman v Bristol City Council, the Court of Appeal decided that an employer is liable for stress caused to the employee during a grievance or disciplinary investigation if it is reasonably foreseeable that the investigation might cause personal injury (Howard, personal communication, 2008).

Nevertheless, in most cases, employees should be able to participate in disciplinary hearings, unless they are effectively unfit to plead. Fitness to attend disciplinary hearing requires answers to the following questions which are based on standard fitness to plead criteria:

- Does the employee have the ability to understand the allegations made against him or her?
- Does the employee have the ability to distinguish right from wrong?
- Is the employee able to instruct a friend or a lawyer to represent their interests?
- Does the employee have the ability to understand and follow the proceedings, if necessary with extra time and written explanation?

It is recognized that a protracted delay in attending a disciplinary hearing is likely to increase the probability of a normal reaction to stressful events (anxiety, low mood, insomnia and diminished concentration) becoming more severe (Staley, personal communication, 2009).

If necessary the hearing can be held at a neutral location or the employee can provide written submissions to be considered in their absence or send their representative to speak for them or ask their representative to read out their statements. Alternatively, they could attend a telephone or video conference from their home with the hearing taking place in the office (Howard, personal communication, 2008).

ADVERSE WORKPLACE EVENTS AND TRAUMA

Fraudulent or exaggerated claims to be suffering from an exemption condition are only likely to be successful when there are widespread examples of genuine disability to act as a template. Post-traumatic stress disorder (PTSD) is a well-known model which provides the litigant with a specific incident as the cause of emotional distress (see Ref. 68, for incontrovertible work-related examples). Alexander lists the circumstances which foster the inclusion of ‘imaginary and/or deceitful’ complaints in the illness category. These include ‘monetary gain from disability insurance, workmen’s compensation, private medical insurance and litigation; interpersonal gain – sympathy, attention, assurance of personal importance, excuse for inept or unsuccessful
personal performance; [and] freedom – sanctioned release from onerous responsibility, from work and employment …’.

Thus, there may be ambiguities over the attribution of personal agency with dispute over whether illness behaviour is ‘pragmatic’ or the result of trauma, whether it is volitional or the expression of disease (p. 26).67

A sophisticated typology of adverse events and their context has been developed by Brown et al.70 and applied in a very large survey by Kendler et al.71 Specific aversive experiences in the workplace are familiar precipitants of adverse psychological reactions. These events include public humiliation which in the workplace is often a ‘put-down’ which is defined as rejection or direct verbal attack by a person in authority. Events in which the subject themselves brought about the put-down are associated with a marked sense of shame and personal failure.71 Another familiar workplace situation is entrapment when the individual feels that unpleasant circumstances will persist or even get worse with little or no possibility that a resolution can be achieved. Of particular relevance to the Walker v Northumberland County Council72 case is a failed positive event which is defined as an ‘event which suggests that a fresh start went disastrously wrong within one to two weeks, leaving the person stuck in a situation as bad as or worse than before, with seemingly no way forward’.71

WORKPLACE PHOBIA

Amorphous feelings of humiliation, helplessness, shame, insecurity and distress are shaped and organized by culturally available tools into culture-specific nosological entities, especially depression, anxiety, adjustment disorder and ‘phobia of the workplace’. Just as shyness has been transformed into the psychiatric category of social phobia73 and unhappiness into depression,74 so an aversion for the workplace is now medicalized as a phobia.

Case 2

Frustration, humiliation and entrapment might make the prospect of returning to work intolerable.

A sales manager who had not achieved his targets because of a failure in the supply of his company’s products was unjustly criticized and humiliated by his boss. He went off sick with ‘anxiety and depression’. After months of cognitive-behavioural therapy (CBT), he felt much calmer and was less miserable but any mention or thought of his workplace triggered off intense worry and discomfort. The occupational health department recommended mediation with the employer to facilitate a graded return to work, but the patient’s private psychiatrist submitted a report invoking ICD-10, F40.2. He stated that his patient’s intractable ‘specific phobia of the workplace’ constituted a permanent barrier to any contact with his employers and that early retirement on medical grounds was the only solution.

Case 3

A 53-year-old chartered accountant in Stirling had been on sick leave for the previous four years. He went off sick when he felt severely stressed in his office after a heated confrontation with a colleague. He had recently reluctantly taken on additional managerial duties, but felt unable to cope. His ‘breakdown’ at work followed several days of irritability, poor concentration, unrefreshing sleep and worry about his future. He obtained a significant score on a depression self-rating scale, the PHQ 9-Health Questionnaire (the threshold for ‘caseness’ on this scale is very low) and the doctor made a diagnosis of mixed anxiety and depressive disorder (ICD-10, F40.2).

ICD-10 sounds a helpful note of caution in its annotation about anxiety with depression. This category is one of the most common diagnoses provided by GPs on Med 3 certificates for work-related stress. The description emphasizes that the category refers to a mixture of comparatively mild symptoms which are commonly seen in general practice settings. ICD-10 adds that ‘many more cases exist among the population at large which never come to medical or psychiatric attention’ (ICD-10, F41.2).75

A cognitive-behavioural therapist elicited the patient’s lifelong aversion for his own profession. He had only become an accountant because of his parents’ insistence. Despite his lack of passion about his career, he had succeeded in becoming a partner in his firm, but the requirement to take on managerial duties had been the last straw. The cognitive-behavioural therapist constructively recommended mediation with his partners to allow him to start a carefully graded return to his fee-earning work, while being spared any managerial duties. However, his general practitioner intervened, predicting that the very thought of even visiting his office would be bound to precipitate a relapse. She concluded that he would never be able to attempt any rehabilitation to work because this would only cause his health to deteriorate alarmingly. In the doctor’s opinion he had to give up his profession altogether on the grounds of his refractory psychiatric illness which had failed to respond to CBT and to all the latest antidepressants. As the occupational psychologist, Bob Grove, has written,76 CBT is not a magic bullet. CBT will not work if the workplace situation and relationships remain toxic or if the employee is in the wrong job.

DEPRESSION, ADJUSTMENT DISORDER AND SICKNESS ABSENCE

As Derek Summerfield points out,7 ‘the term “depression” tends to be used without qualification as if it was settled that we were always referring to a freestanding biologically based disorder’ (p. 161). Apart from a small number of very severe cases (suffering from what used to be called ‘melancholia’), ‘there is no reliable demarcation of depression from ordinary unhappiness or misery …’.
It is a mistake to conceptualize normality and mental illness as dichotomous, i.e. as states of mind which are not distributed along a continuum. 'Depression' is a pervasive term which is applied to a variety of states of unhappiness and misery, including grief at a loss, demoralization, frustration, low self-esteem, disillusionment and finally a depressive illness which is assumed to have a biological basis.

In terms of DSM-IV, a distressed individual achieves 'caseness' if they experience more than the minimum number of symptoms in specific categories. The arbitrary nature of this diagnostic system is most apparent in the distinction between a severe reaction to bereavement and depressive illness. As Arthur Kleinman shows in Rethinking psychiatry: From cultural category to personal experience,77 'An anthropological sensibility regarding the cultural assumptions and social uses of the diagnostic process can be an effective check on its potential misuses and abuses' (p. 17).

The widespread belief that depression is under-recognized at the primary care level (prompted by the Royal Colleges of Psychiatrists and General Practitioners Defeat Depression Campaign)78 has led doctors to prescribe more readily. However, there is now evidence that there is almost no difference between the effects of drug treatment and placebo at moderate levels of depression.79

As a study of psychiatric drug advertisements has shown, advertisements tend to individualize negative reactions to the workplace by ignoring the situation which provoked the distress.80 Messages in these advertisements reinforce the view of distress that there must be pathology within the individual. The advertisements imply that the work context is either irrelevant or is an unchangeable situation to which the afflicted person must accommodate.

Psychotropic medication is presented as the panacea for the problems of adjustment to a stressful work environment.80 Moving emotional distress out of the context of work and into the employee’s neurochemistry diverts attention from factors in the workplace that might require challenge and alteration. With the current emphasis on cognitive-behavioural therapy as an alternative cure-all, the identification of ‘faulty cognitions’ and ‘dysfunctional attitudes’ can amplify the ‘decontextualization’ described by Kleinman and Cohen80 so that a person’s problems are defined as internal rather than external, individual rather than environmental, ‘psycho’ rather than ‘social’, with the option of adding antidepressants as a ‘bio’ solution if both belt and braces are required.81

Adjustment disorder is a disputed diagnosis because of the blurred distinction between the varied manifestations of adjustment disorder and normal adaptive reactions.82 Casey et al. point out that ‘transient depressive responses to stressful events are increasingly regarded as illness requiring specific intervention’. Furthermore, ‘a low threshold for making a diagnosis of depression propels an individual towards a specific therapeutic approach. Distress and disorder remain conflated in clinical practice, and among the research communities we continue to medicalize the emotional vagaries of the human condition’ (p. 480).

For the anthropologist and psychiatrist Arthur Kleinman, the increasing articulation of life problems as mental health conditions leads to a ‘misguided search for magic bullets for complex social problems’ (p. 38).27 Kleinman also refers to the ideological influence of the modern medical scientific and technological programme which tends to convert suffering into a technical problem: ‘Suffering is “euphemized” and distress is “medicalized” as a psychiatric condition, thereby transforming an inherently moral category into a technical one’ (p. 35). He adds that psychiatric diagnostic systems provide far-reaching administrative and legal definitions of ‘what is a problem and how it should be treated’ (p. 39).27

In their critique of DSM-III and its successors, Kirk and Kutchins53 write, ‘The precise nature of a client’s trouble is frequently ambiguous, its causes obscured by a lifetime of personal experiences, environmental stresses and psychological confusion’ (p. 226).53 However, psychiatrists may feel compelled to construe suffering in terms of a distinct nosological category rather than an existential response.

The symptoms of depression, of anxiety and of post-traumatic stress disorder are mostly subjective and they can be recited in a checklist fashion in the context of sickness absence, disciplinary hearings, applications for early retirement and litigation for compensation. These conditions are now amazingly common, with one in six of the adult population of the United Kingdom currently suffering from ‘crippling depression’ and chronic anxiety, according to the Depression Report published by the London School of Economics, Centre for Economic Performance.83 One million people are in receipt of incapacity benefit because of mental illness, which accounts for 40 per cent of all disability, both physical and mental.83 According to this report, poverty is a less significant cause of unhappiness than mental health problems. To address this problem, the proposed expanded psychological therapy service requires an extra 10 000 therapists to treat 800 000 people a year.

There is an increasing tendency for the normal and expectable consequences of stressful circumstances, which include low mood and worry, and which are a universal response to unpleasant situations, to be defined as mental illness. A low threshold for diagnosing clinical depression leads to the labelling of normal emotional states as illness. As Parker points out, ‘The gravitas of the term “major depression” gave it a cachet with clinicians … and helped patients get medical insurance cover’ (p. 328).84

Regier et al.85 warn that patients might receive a label of depression when in fact they are having ‘appropriate homeostatic responses which are neither pathological nor in need of treatment’. For Crossley,46 Mental distress is predefined in western culture by the discourses of psychiatry whose reach has extended beyond the realms of professional cliques into the domains of everyday discourse. Psychiatric schemas and practices enjoy widely taken-for-granted status. As such, they shape perceptions/conceptions of the
lay public, some of whom will experience psychological difficulties first hand in relation to either self or significant others and may thus categorize self and others from the psychiatric point of view (p. 162). 7

In theory, to qualify for ‘caseness’, these psychological difficulties have to be disproportionate to the trigger in terms of intensity and duration after the causative stressors have disappeared, but as Horwitz points out (p. 31): 49 ‘disproportion can only be defined according to social judgements of the normal range of responses to various stressors in particular contexts’. In practice, the widespread use of psychiatric nomenclature to describe common reactions to personal problems in specific social contexts has contributed to the escalating number of people claiming incapacity benefits on the grounds of stress-related illness. The ready availability of these scientific-sounding diagnostic categories (which necessarily lack confirmatory laboratory and imaging evidence) contributes to ‘the technological process of transforming a person with an ambiguous complaint into a client with a defined mental disorder’ (p. 222). 31

Furedi 72 describes the pervasive influence of the therapeutic culture, and the ever-expanding medicalization of adverse emotional experience, while Dalrymple laments the replacement of the concept of unhappiness in modern life by the word ‘depression’. ‘Of the thousands of patients I have seen, only two or three have ever claimed to be unhappy, all the rest have said they were depressed. This shift is deeply significant, for it implies that dissatisfaction with life is itself pathological, a medical condition, which it is the responsibility of the doctor to alleviate by medical means … A marvellous pas de deux between doctor and patient ensues: the patient pretends to be ill and the doctor pretends to cure him (p. 9). 78

In the encounter between client and traditional healer in francophone creole society, the patient resorts to an explanatory system which absolves him of personal responsibility by identifying an external cause for his bad behaviour. The anthropologist Massé questions whether the afflicted person is ‘lying’ when he proposes to the healer that he is the victim of a hostile spirit, while the highly paid quimboiseur actively colludes with this mitigating interpretation. 89 As Kirmayer 50 writes (p. 335), ‘The microdynamics of the negotiated encounter of patient and practitioner are embedded in larger political and economic systems that sanction some forms of distress while others are punished, suppressed or even made unthinkable’.

POST-TRAUMATIC STRESS DISORDER

The choice of the diagnosis of post-traumatic stress disorder (PTSD) as a cause of emotional distress has strategic advantages over the diagnosis of depression. With depression there may be a series of causes for the individual’s distress, whereas the diagnosis of PTSD implies that all the litigant’s psychological problems arise from one specific incident ‘and not from a myriad other sources encountered in life’ (p. 85). 90 Dr Henry Field has written that it is virtually impossible nowadays to study a medicolegal report prepared by a psychiatrist or psychologist instructed on behalf of the plaintiff in personal injury litigation where it is not concluded that he or she is suffering from PTSD. 91

The fact that litigation might be based on a trivial incident is an affront to the survivors of truly horrific experiences, such as rape, torture or terrorist attacks. DSM-IV rightly requires the victim to have experienced intense horror, fear or helplessness in a life-threatening incident and any allegedly traumatic event that does not meet this criterion must be discounted. In the occupational health setting, one meets employees who claim to be suffering from intrusive imagery, avoidance behaviour and symptoms of autonomic arousal in the absence of a single acute overwhelming life-threatening trauma. 48

The possibility of benefits or of compensation can have a pathoplastic effect after relatively minor injuries or disabilities. Allan Young in Harmony of illusions (p. 17) 92 cites Herbert Page, consulting physician to the London and Western Railway Company whose monograph on railway accidents identified a proportion of victims with minimal or invisible injuries whose recovery was retarded: ‘The knowledge of compensation … seems almost from the first moment of illness to colour the course and aspect of the case, with each successive day to become part and parcel of the injury in the patient’s mind, and unwittingly to affect his feelings towards and his impressions of the sufferings he must undergo …’ (pp. 255–6, 261). 93, 94

Case 4

A bus driver who had been rebuked by his line manager threatened to deliberately crash his vehicle. He claimed that he was suffering from PTSD after seeing a friend being decapitated by a roadside bombing in Iraq. It transpired that he had never actually served in a war zone.

The diagnostic entity of PTSD was invented in 1980 by advocates for veterans of the war in Vietnam working with anti-war psychiatrists. Ben Shephard, the military historian, rebukes psychiatrists for medicalizing the human response to stressful situations and for creating a culture of trauma which is undermining resilience (p. 57). 95 Shephard decry the unitary concept of trauma which groups together under a common label a very wide range of stressors. ‘Any unit of classification that simultaneously encompasses the experience of surviving Auschwitz and that of being told rude jokes at work must, by any reasonable lay standard, be a nonsense, a patent absurdity’ (p. 57). 95

In a comprehensive review of the unreliability of the PTSD diagnosis, Rosen and Davison warn about the trivialization of PTSD by ‘criterion creep’, the fallibility of self-reporting in the context of litigation, the routine use of checklists and of coaching by legal advisers, and ‘parroting’
or ‘echo attribution’ in which ‘a false sense of validity is gained by attribution to a prestige source [a psychiatrist or psychologist] what is nothing more than an echo from the original communicator’ (p. 94).96

RESILIENCE

There has been a tendency to neglect resilience in response to catastrophic events, such as the destruction of the World Trade Centre97 and the July 2005 London bombings.98 Between 11 and 13 days after the London bombings, 31 per cent of Londoners reported one or more symptoms of ‘substantial stress’ relating to the attacks,99 but follow up seven to eight months later showed that the figure had fallen to 11 per cent.

As the psychologist, Bonanno100 has shown, many people exposed to violent or life-threatening events show a significant degree of resilience that should not be interfered with by clinical intervention. His review of the published research shows that most individuals exposed to loss or violent or life-threatening incidents do not exhibit chronic symptom profiles and that very many, if not most, show significant resilience. He cites Ozer et al.,101 who found that while 50–60 per cent of the population of the United States was exposed to traumatic stress, only 5–10 per cent develop PTSD. Many individuals exposed to violent or life-threatening events might show evidence of short-lived PTSD or subclinical stress reactions, but these tend to abate over the course of several months.

The redoubtable Mr John Eke showed great fortitude in 1898 when the express train whose Westinghouse brakes he was adjusting left Kings Cross Station unexpectedly while he was under a carriage. He clung to the base of the carriage until the first stop which was at Grantham, where he climbed out on to the platform. After a restorative cup of tea with the station master, Mr Eke returned to London to go back on duty.102

Case 5

A 40-year-old man working in a safety-critical occupation went off sick with ‘stress’. He was complaining of dizziness, backache, irritable bowel, poor sleep and nightmares. The doctor made a diagnosis of PTSD. He was found to have specific work-related issues which included representing his union during stressful strike negotiations, victimization by his manager because of the strike and investigation of an incident which caused friction with some of his colleagues.

His employer proposed a graded and supervised non-safety-critical return-to-work package which would have been viable and included the suggestion that he should be spared trade union duties which had led to his stress at work problems in the first place. On receipt of this proposal, the employee’s psychosomatic symptoms became more severe.

Case 6

Sometimes, there is a combination of personal factors and an un congenial work setting which acts as a deterrent to returning to work. A security guard in a risky area who had been subjected to intimidation on several occasions took sick leave on the grounds of work-related stress and PTSD. His wife from whom he was separated and who worked for the same employer and on the same site, was suing for divorce. In addition to his aversion to meeting her at work, the employee’s solicitor warned him to remain on incapacity benefit because otherwise his wife would be entitled to a more generous settlement in the ongoing financial dispute resolution.

As Horwitz94 observes, ‘When symptoms are classified without regard to their causes or to whether they indicate a mental illness, there is no limit on the sort of conditions that could enter the new diagnostic manual. Chronic dissatisfaction with life could be renamed “dysthymia”; distress arising from problems with spouses or lovers could be called “major depression” … a symptom-based approach has the dual advantage of providing a seemingly objective and factual basis for diagnosis and of including any entity that mental health professionals currently treated’ (p. 73).49

WORK OVERLOAD, DISTRESS AND SICKNESS ABSENCE

Overwork outside the control of the individual is a common complaint and is widely reported as a cause of work stress.

Case 7

A health service manager had three admissions to a private psychiatric clinic. Each admission lasted four weeks which reflects the maximum length permitted by private medical insurance. (The fact of a psychiatric hospital admission does not necessarily reflect the severity of the condition because the threshold for admission to the private sector is much lower than in the NHS. This patient’s personal crisis would not have warranted voluntary inpatient treatment within the NHS.)

He was found to have a tendency to overwork and he was having to cover for a colleague who was on long-term sick leave. During one of his hospital admissions, he was invited by his employer’s occupational health department to attend for review. However, his doctor provided him with a letter stating that such an assessment would be detrimental to his recovery.

After many weeks of sick leave, the doctor reported that he could not return to work because of residual problems which included poor concentration, feeling in a state of limbo about his job and ‘not feeling up to a return to work
as yet’. The non-medical obstacles to his return to work had not yet been addressed and he continued to experience understandable feelings of apprehension, worry and uncertainty about his future with some loss of self-confidence, pessimism and distractibility because of the challenging prospect of finding a new job in the present economic climate.

COUNSELLING IS NOT A SUBSTITUTE FOR MEDIATION

It is important not to medicalize these common emotions and attitudes which are entirely understandable in the circumstances of work overload but which do not in themselves constitute a disease. Furthermore, it is essential to address the causative problems in the workplace and the provision of personal counselling is not a legally sanctioned substitute for this.

Case 8

Mrs Daw was a payroll integration analyst with 13 years of outstanding service, employed by Intel. She developed a depressive illness which was attributed to her excessive workload. Her reporting lines were confused and it was difficult to prioritize the demands of her different managers. She eventually won an award for personal injury caused by stress at work, but her employer appealed on the grounds that she had failed to use their external confidential counselling facility. The Court of Appeal concluded that the counselling would not have attenuated the risk of her breakdown since it would not have reduced her workload, which was the only way the employer could provide a safe working environment. The Court of Appeal held that the provision of counselling was no substitute for putting in place measures to reduce Mrs Daw’s workload (Howard, personal communication, 2008).

INCIVILITY IN THE WORKPLACE

The targets of incivility often feel alienated and become less committed to the employing organization.

Case 9

A plumber went off sick from work with ‘stress-related depression’ after finding that his managers were giving him more work than he could cope with and imposing unrealistic deadlines. He had been rebuked by his line manager who had sworn at him in front of colleagues. He presented to his doctor with feelings of humiliation, anger and ideas of taking revenge. The doctor made a diagnosis of depression and he was prescribed various antidepressants and saw three different psychiatrists. He was reluctant to return to his job. A professional mediator attempted to work out a reconciliation, but it emerged that there was a financial disincentive to return to work and the company was not prepared to take him back until his doctor reported that he was completely symptom-free. By that time, he was taking out a compensation claim against his employer for causing his work stress-related illness. The principal precipitating and maintaining factors were his grievance against his employers. He felt overwhelmed by anger and resentment, but his doctor described him as suffering from anxiety with depression. He was referred for cognitive-behavioural therapy, but the therapist felt that because of the unresolved conflict with his employer he would not be able to return to work for the foreseeable future. (Organizational injustice increases the effects of psychosocial health risks on sickness absence.) He became entrenched in the sick role and both he and his medical advisers interpreted his frustration and anger in medical terms. He consulted his solicitor who felt that following the case of Barlow v Borough of Broxbourne, he would find it difficult to establish that the employer had been in breach of its duty to take reasonable care to ensure that he did not suffer psychiatric injury as a result of work-related stress, because it had not been foreseeable that he would suffer such an injury. He had previously coped perfectly well with his workload, the instances of swearing were not numerous and he had never reported ‘symptoms of stress’ and had not used the employer’s counselling service.

RESENTMENT AND SICKNESS ABSENCE

The interpretations that employees make of their working conditions have a crucial role in determining psychological well-being.

Case 10

A middle-aged executive had a very public falling out with her chief executive officer. She went off sick with a diagnosis of stress-induced depression. She was noted to have loss of self-esteem combined with anger and resentment at the way she had been treated. Her doctor elicited mild depressive symptoms, but over the following months she developed fatigue and lack of physical and mental energy. She had a long course of acupuncture with a Chinese medicine practitioner, who had identified a weak pulse and prescribed adrenal gland extract. She had also had reiki healing, reflexology and cranial osteopathy. This individual had excellent qualifications and an outstanding professional track record, but so far no attempt had been made to encourage her to resume her career with another
employer. There was no objective evidence that she had been treated unfairly and her perception that she had been victimized would be insufficient for successful litigation on the grounds of work-related stress, since the judgement in Ian Richard Paterson v Surrey Police Authority. In that case of a demoralized estate manager, the court concluded that the cause of his anxiety and depression was how he considered that he had been treated by his employer, rather than any breach of duty by the employing authority. During the trial, he evinced a strong sense of grievance about a perceived challenge to his personal worth to the organization, for which he had worked conscientiously for 26 years.

**THE POSITIVE ROLE OF MEDIATION**

The powerless individual enmeshed in an uncontrollable situation at work is afforded room for manoeuvre by the dominant biomedical symbolism of ‘work stress’ with its passive but potent appeal of helplessness. The mystical power of biomedicine affords negotiating space to the disaffected employee.

However, long-term sick leave is demoralizing and stigmatizing and it induces its own morbidity. A large power company, EDF, has developed a constructive way of redressing the imbalance which might otherwise push employees into the psychodrama of protracted sickness absence. They provide a negotiating forum, the facilitated round-table meeting, which employees with stress are invited to attend within a couple of weeks of going off sick. The participants include the employee and their representative, their line manager, together with representatives from human resources and occupational health.

The agenda is to ascertain the obstacles to a return to work and to negotiate practical solutions to the familiar precipitating problems of work overload, conflicting demands, lack of control over work, poor social support, ambiguity in management and work role, conflict with colleagues and tension between work and the demands of the family.

The round-table meetings take place in a supportive environment which helps the employee and the manager to understand each other’s interpretation of the particular work issue and to agree a way forward. There is constructive discussion about rehabilitation and agreement to reasonable adjustments that are acceptable to all parties.

The round-table system is one ingredient of a comprehensive intervention which is primarily educational and avoids medicalization and which has significantly reduced both sickness absence and early retirement on medical grounds. The programme is proactive and the aim is to create a risk-free way in which an employee can seek help when they feel under pressure or develop the psychophysical feelings of distress. The company has circulated all the employees with information leaflets on the early identification of these ‘symptoms’.

When employees return to work they are given a carefully graded re-entry and are provided with support and regular two-way appraisals focusing on the employee’s adjustment and their work priorities. The incidence of work-related psychological ill health was reduced by 63 per cent over the three years following the introduction of this programme. This innovative round-table approach is in line with the Institute for Employment Studies’ conclusion that ‘improved communication, co-operation and common agreed goals between employers, employees, occupational health providers, and primary care professionals can result in faster recovery, less re-occurrence of ill health and less time out of work overall’.111

The success of this company’s programme also shows the importance of the employer, the doctor and the occupational health professional asking, ‘What are the barriers to recovery and return to work that this person is experiencing?’ (p. 291).12

Unfortunately, there has been no published systematic assessment of the mediation/round-table model – see for example, Workplace interventions for people with common mental health problems112 and What works at work?111

**GOVERNMENT POLICY ON INCAPACITY BENEFIT AND GETTING BACK TO WORK**

In recent years, there have been a number of UK Government policy initiatives, aimed at getting people back to work. These policies are linked to a concern with the high level of uptake of Incapacity Benefit (IB) which appears to relate to the period between 1979 and 1995 when the number of recipients of Invalidity Benefit (IB) rose dramatically. However, the number has begun to fall of late at the latter period of economic growth since the 1990s recession. Men are more likely to be claiming incapacity benefit than women and these male claimants have been characterized as almost all having some kind of health limitations; only a quarter say they cannot do any work; half would like a job, but fewer than one-in-ten are looking; health was the main reason for job loss in only half of all cases, although age, skills and qualifications would anyway expose them to unemployment. However, there is also evidence of a rising number of women claimants and the explanation for this increase is similar to that of men, i.e. hidden unemployment, those who could be expected to have been in employment in a fully employed economy. Other reasons for the marked increase in the uptake of IB might include the political need, at least at that time, to keep the number of registered unemployed at a low level. The concern for policymakers is not just that IB rates are high and therefore costly, but that the benefit might be being used by those whose intention is to malinger and avoid work, rather than by those who are genuinely incapacitated by health problems. There is thus a moral
element (a kind of ‘moral hazard’) to this policy of trying to ensure that IB is only available to those who are deserving of it.

The Pathways to Work programme, which was implemented throughout the country in 2008, is central to the government’s IB reforms, which distinguish between those with severe health problems who are incapable of work and those with less severe problems who, with appropriate help, have the propensity to return to work.113–115 This programme requires all new IB claimants to attend a work-focused interview (WFI) with an IB personal adviser. Those with severe medical conditions or deemed likely to return to work without support are exempt from further WFIs, others must attend up to five more WFIs. The other elements of the Pathways programme are optional and according to recent reports not well used.115 They comprise the Choices package – a range of interventions aiming to improve labour market readiness and opportunities, including the New Deal for Disabled People and the Condition Management Programme; the Return to Work Credit; In-Work Support, and the Advisers’ Discretionary Fund.

The Pathways programme has been introduced to promote employment, and to address psychosocial obstacles to return to work by therapeutic means. Those who refuse to participate in WFIs face benefit sanctions, while those who return to work receive the Return to Work Credit. Interventions, such as mentoring and job coaching, appear to aim to try to address the harm of being on long-term benefits to personal and social identity.

These proposals are the outcome of policy deliberations about the inappropriate uptake of IB which has led the government to set a target of one million IB recipients returned to work by 2015,114 although this target figure appears to have increased in more recent policy documents.115 These IB reform policies aim not only to reduce the number of new people applying for benefit, but also to encourage long-term recipients to go off benefits and back into paid employment.

Recent analysis suggests that these target figures may be untenable as there are marked geographical variations in the distribution of incapacity claimants and thus attainment of these targets depends on an accelerated revival in the economies of the North, Scotland and Wales.118

Is the programme effective? The limited evidence currently available suggest it might have some advantages for new IB claimants,119 although the impact of the Pathways programme on existing IB recipients appears to be small.120 However, further evidence is needed before the effectiveness of the Pathways initiative of returning long-term IB recipients to work can be fully assessed.

More recent policy has been less influenced by concerns with rising levels of unemployment and more with reducing those on IB, although this may change in the current economic climate. Thus, following on from the Pathways programme a new, more stringent assessment, the Work Capability Assessment (WCA), was introduced in 2008 for new IB claimants, to assess their eligibility for the Employment and Support Allowance (ESA) which will replace IB. Again, this aims to distinguish between applicants according to their capacity for work, with the less impaired assigned to the work-related activity group who will be expected to prepare for return to work, while the more severely disabled will receive a higher rate of benefit, but will still be able to volunteer for back-to-work support. These new initiatives, like the previous ones, combine ‘stick and carrot’ measures with pragmatic policies which intend to address some of the psychosocial barriers which hinder people returning to work.

A more recent White Paper, building on this policy, has been published115 on the reform of the benefit system where the expectation is that most people on out-of-work benefits, such as ESA, will look for work and the proposal is for all existing IB claimants will be reassessed using the WCA. Early evidence117 suggests that the vast majority (two thirds) of new applicants for benefits such as the ESA are being rejected at the WCA stage, although it is not clear what the consequences of this have been and if this has led to higher levels of those returning to or retaining employment.

**SUMMARY AND CONCLUSION**

This chapter has attempted to show how emotional distress is often translated into an idiom of suffering which is used to empower the employee who feels helpless.

The cultural and social construction of grievance in the workplace organizes negative feelings into psychiatric diagnoses. However, diagnosis is an imperfect means of representing psychological distress, disaffection and demoralization. The sociologists Mirowsky and Ross challenge this medicalization of distress. ‘Psychological problems are real but are not entities. They are not discrete. They are not something that is entirely present or entirely absent without shades in between. They are not alien things that enter a person and wreak havoc. Nevertheless, psychiatrists often speak of depression and other psychological problems as if they are discrete entities entering the bodies or souls of hapless victims. An imagery of detection follows from such language of discrete entities. The psychiatrist detects the presence of an entity, determines its species and selects an appropriate weapon against it. This categorical language is the legacy of nineteenth century epidemiology and microbiology. A person is diseased or not. The disease is malaria or not, cholera or not, schistosomiasis or not. A language of categories fits some realities better than others; it fits the reality of psychological problems poorly (p. 11).’51

It is increasingly clear that psychiatric assessment in these cases should be taking into account the problem of...
the medicalization of grievance and of a sense of injustice. A typical sequence is:

A loyal, hardworking employee is not given an informally promised promotion/bonus.

Confrontation with manager.

Employee feels very upset.

Employee goes off sick and sees doctor and mental health professionals, who reconceptualize anger, resentment, demoralization and a sense of injustice and of grievance.

These thoughts and feelings are translated into ICD-10/DSM-IV terms as anxiety/depression, adjustment disorder and even PTSD. Grievance and disciplinary proceedings and litigation help to crystallize the medicalization in terms of the impact of harassment/constructive dismissal.

The individual is rarely vindicated or might win a pyrrhic victory.

Mental health professionals become the employee’s advocates with a mission to protect the patient from a return to the perceived noxious environment of the workplace.

Long-term incapacity with a ‘phobia’ of returning to paid employment. ‘The thought of going back to work brings back all my symptoms.’

Referral for cognitive-behavioural therapy which often fails to assist a return to work because of the therapist’s advocacy role.

Long-term sickness absence with certificated ‘work-related stress’.

This chapter has identified the cultural and psychosocial influences on the illness behaviour of sufferers with work-related problems and the case studies have illustrated the complex and diverse circumstances that lead people to seek sickness absence from work. It is therefore questionable whether the package of measures and standardized assessments proposed in recent government policies will be sufficiently personalized and tailored to individual needs to effectively rebuild people’s confidence and identity for them to be attracted back to work.

Key points

- The epidemic of work stress-related sickness absence is interpreted in terms of medical sociology and anthropology.
- The distress of aggrieved, disgruntled and demoralized employees who feel powerless and exploited at work is commonly labelled as a morbid condition.
- Understandable human reactions (frustration, humiliation, disappointment) are often located within the psychiatric diagnostic systems (ICD-10 and DSM-IV).
- Entry into the sick role can be a form of passive resistance by employees which affords temporary relief and exemption, but which is self-defeating in the long term (e.g. so-called ‘phobia of the workplace’).
- As a constructive alternative to the medicalization of everyday distress, we propose mediation and the resolution of grievances between employee and employer in the form of round-table dialogue and conflict resolution.

ACKNOWLEDGEMENTS

We wish to thank Gillian Howard LLB FFOM(Hon) for suggestions about cases and Charles Stewart and Roland Littlewood of the Department of Anthropology, University College London for discussions about epidemic possession states. We also wish to thank Samantha Durrell for her skilled and patient preparation of the manuscript. Thanks to Dr David Wainwright from Bath University for his contribution to the development of the ideas on the epidemic of work stress and policies on sickness absence. Finally, thanks to Dr Margaret Samuel and Dr William Mitchell of EDF.

The term ‘work-related stress’ can be misleading and seems to have become a generic label describing a range of mental health problems in the workplace. Commonly experienced mental health problems in the general adult population fit into a continuum of distress ranging from formal diagnoses (including disorders of mood and behaviour, such as depression, panic disorder, phobias and eating disorders) to varying levels of non-diagnostic emotional distress. Thus, many individuals who do not have a condition that fits into a formal psychiatric diagnosis can nevertheless experience marked emotional distress which may also reduce their ability to function, including at work. Indeed, it may be argued that emotional distress, even at subdiagnostic levels, may impact with the most significance in many occupational settings where high levels of physical and/or intellectual performance are required.

In addition, there is continuing confusion on what constitutes work-related mental ill health, and also inherent problems in understanding its mixed aetiology, including how or if the work environment has had an impact in a given individual. This level of uncertainty makes responding to and planning effective interventions difficult, even if the individual has clearly diagnosable mental health needs.

In light of all this, it can be useful to adopt a psychological approach that considers:

- the benefits of developing a biopsychosocial case formulation of an individual’s mental health needs, which includes both diagnostic and psychological perspectives;
- the merits of using this process as the basis of an intervention plan;
- the use of direct or indirect psychological interventions as part of this plan.

This chapter will argue that psychological management can be helpful in reducing employee emotional distress and thus improve mental health in the workplace. It advocates that a case formulation approach is needed, which may then lead to either indirect and/or direct psychological interventions. Five case examples are used to support this argument and the chapter concludes by drawing attention to important issues, such as the limitations to psychological interventions, the value of prevention and the importance of the relationships between health providers, employee and employer.

Mental health at work: psychological interventions

ADRIAN NEAL
health problems, such as panic disorder, adjustment disorder, complex grief, agoraphobia, generalized anxiety disorder, health anxiety, social phobia, obsessive compulsive disorder, eating disorders and phobias. The treatments currently practised, depending upon the condition, are interpersonal therapy, cognitive analytic therapy, dialectical behaviour therapy, eye movement desensitization and reprocessing, and brief psychodynamic therapy. Evidence is also emerging to indicate that mindfulness-based cognitive therapy can be helpful for people who experience reoccurring moderate clinical depression. Psychological therapies can also contribute in the management of patients with complex mental health problems, including borderline personality disorder, psychosis and non-chronic bipolar disorder.

It is reasonable to suppose, in the light of these recommendations in the general population, that some of these methods may be applicable to the mental health problems that arise in the workplace. However, before it is possible to recommend psychological therapy in this context, caution is needed to ensure a tailored approach, including an acknowledgement of the potential role of the work environment and employer. Interestingly, it is this ability to tailor psychological interventions to the individual that makes them so potentially useful in a range of settings.

CASE FORMULATION: MAKING SENSE OF PEOPLE’S DISTRESS

Formulation is a tool used by clinical psychologists and many psychotherapists to conceptualize the difficulties of the individual, and as a rationale from which to frame the psychological intervention. The majority of contemporary case formulation literature comes from the cognitive behavioural tradition which has its roots in 1950s’ behavioural models of aberrant behaviour and in particular functional analysis. Case formulation was seen as an alternative to psychiatric diagnosis aiming to identify and describe problems, thus allowing an intervention to be designed which would directly address the maintaining mechanisms of the problem.

Beck modified traditional behavioural models by putting increased emphasis on the role of internal events, such as thoughts and emotions, and developed CBT along with Albert Ellis. Case formulations from a cognitive behavioural perspective soon incorporated different levels of thoughts, and detailed how they interacted with emotions and behaviours to both trigger and maintain emotional distress. CBT approaches and case formulation have widened lately to include a biopsychosocial matrix that incorporates a range of biological, psychological and environmental or social factors. Biopsychosocial-based case formulation has thus evolved into a broad and inclusive clinical tool. Case formulation is viewed as the cornerstone of clinical psychology in the United Kingdom, and although not all clinical psychologists are exclusively cognitive behavioural in their theoretical orientation, with many having an integrated approach, there is wide acknowledgement that the process of case formulation is central to understanding an individual’s problems and thus developing effective interventions.

A formulation framework

Formulation begins as soon as the clinician receives information about their potential client(s). From this point, it may be helpful to use a simple framework to guide and organize information. The five P model is a widely used generic cognitive behavioural formulation framework useful in all clinical areas. The framework requires information to be organized around five key areas, namely: presenting issues, precipitating issues, predisposing problems, perpetuating factors and protective factors, which are described in more detail below. The five P framework facilitates the identification of a wide range of information, allowing the clinician and client to develop a current and working conceptualization of the key problems, and thus begin to see hypothetically how they may be best addressed.

PRESENTING ISSUES

Identifying the individual’s key current problem(s) is a primary task in the assessment, often these are linked to distressing and current emotions or behaviours. The ideal situation is to generate a list of clearly identified problems, even if they are not going to be addressed directly. It is useful to try and quantify these problems and anchor them in behaviour (e.g. I feel low in mood, I struggle to motivate myself and I avoid work). Providing clear examples of the problems helps to target future intervention, is useful as a measure of outcome and also illustrates the individual nature of the problems and how they may be connected.

PRECIPITATING FACTORS

Precipitating factors can be difficult to identify as not everyone is aware of what might have triggered their current problem(s). In addition, some precipitating factors may not be only recent events, but can be seen as related to past experiences, as is often the case in post-traumatic stress disorder. Hypothetical precipitating factors may also need to be identified, and these can be internal (thoughts, memories, feelings or physical sensations) and/or external (environmental).

PREDISPOSING FACTORS

Establishing a coherent model of a person’s problems is enhanced by the identification, even hypothetically, of predisposing factors, which often consist of highly individual interactions between life experiences, personality traits and biologically based factors, including, one could argue,
temperament, cognitive structures (beliefs), emotions and relationships. For many people, it is often helpful to explore their past to find related factors and events which can help give some meaning to their current distress.

PERPETUATING FACTORS

A useful way of understanding these is to consider the relationship between the factors which maintain and perpetuate the cycle of distress, and which can be internal or external to the individual, or a combination of both. Of all the perpetuating factors, the ‘experiential avoidance’ of distress seems to be the most commonly identified across most mental health problems. Put simply, if an individual tries to avoid distress, or any experience that for them triggers distress, they are likely to experience a negative reinforcement of the problem.

For example, a woman felt highly fearful following an experience of breathing difficulty and believed she was at increased risk of choking, thus possibly dying, if she had any future breathing difficulties. If she were to experience being short of breath, she may well perceive this as the beginning of another choking episode, become fearful and then try to avoid any situation that triggers similar physical feelings. Over time, she successfully avoids ‘risky’ situations, but her fear actually increases.

In this example, avoidance-based coping plays the primary perpetuating factor in the person’s catastrophic beliefs and predictions. Likewise, problems can also be in part maintained by external factors, such as financial difficulties, issues with family, friends, workplace and other environmental factors over which they may have minimal control.

Within the cognitive behavioural literature, there are disorder-specific maintenance patterns, particularly in anxiety problems. For example, with panic disorder and health anxiety, there is a characteristic over-vigilance for bodily changes, and for post-traumatic stress disorder, there is an active avoidance of stimuli that trigger distress.

PROTECTIVE FACTORS

Often overlooked when trying to identify and plan how to approach emotional problems, protective factors can be very useful to client and clinician, both in the formulation process and also during the intervention. Protective factors are best framed as a person’s strengths. These can be seen as factors that have protected them in the past, helped them to cope, or have acted to prevent them from experiencing even more distress than they are currently. As such, these are often highly individual and should be considered carefully as internal resources, such as humour, which could also be used as a means to avoid, as well as cope, and thus actually be a perpetuating factor in one instance and yet a protective factor in another.

The recent review of the resilience literature by Atkinson et al. provides a useful overview of the psychological construct and its role as a protective factor. In their review, the authors identify a number of characteristics considered to be protective. These include having purpose, pragmatism, being able to goal plan, optimism, hope, good self-esteem, perceived control, flexibility and distress tolerance. The authors urge caution and add that this list is not exhaustive and other factors, such as biological, and chance are probably also important in making a person resilient.

Overview of the formulation process

The process of formulation, particularly if guided by the five P model, can offer an invaluable resource for both client and clinician. In addition to being useful in creating a framework to understand a problem and plan for intervention, there is an emerging literature looking at the impact of the formulation process itself on outcome. Although early, there is a growing recognition that formulation is an important process as it helps form a collaborative therapeutic alliance. Indeed, for some individuals the formulation process is all the intervention they require.

Another aspect to consider and include in a formulation process are the accepted attributions that form part of the social and workplace milieu. These will differ from one work environment to the next and may differ between the type of work undertaken, e.g. information technology, medical, research, manufacturing, construction, etc. Attribution style based on attribution theory is significant as it forms the basis of the individual’s expectations of his employer and colleagues, and points to why the employee might have different values and expectations to their employer. An attribution style will help determine personal responsibility, role, and what an individual thinks they deserve. Formal industrial action, ongoing antagonistic relationships, sabotage, conflicts and bullying between employer and employee will be linked to the attributions of those involved.

FORMULATION-BASED PRAGMATISM: DIRECT AND INDIRECT PSYCHOLOGICAL INTERVENTIONS

There are many models of brief psychological therapy which focus on direct work with adult populations. The most documented and commonly used within clinical psychology in the United Kingdom currently include: CBT, interpersonal therapy, cognitive analytic therapy, Gestalt, humanistic and psychodynamic. These models typically centre around two individuals, a client and a clinician, identifying problems, agreeing goals and developing a therapeutic relationship. Although sharing common themes, the content, organization and nature of the stages of therapy will differ between models. Interestingly, these differences appear to be slowly becoming smaller as the trend towards briefer time-limited models develops.
Although traditional psychosomatic models tend to focus on working directly with one adult, there are number that allow for working with the individual indirectly. Systemic models often encourage teamwork and working with more than one individual (e.g. a family) and are commonly seen in child and adolescent mental health services. More recently, traditional one-to-one models have been broadened to integrate systemic ideas, allowing the psychologist to work towards helping an individual through others within the system. In occupational settings, this may involve working with human resources, occupational health services, general practitioners, managers and even colleagues where necessary. As with traditional direct methods, indirect methods need to be based on a clear understanding of the problems, and have a formulation anchored in psychological theory.

Before embarking on a psychological intervention, it is important to consider, in the formulation process, what the aims are to be, how achievable they are and whether they are compatible with the needs of the referrer. This is a particular issue for occupational health services as returning an individual back to health in order that they may return to work may not, in some instances, be ethical or indeed realistic, particularly if the work environment has in some way played an active part in the development or maintenance of their problem. Psychological interventions are more likely to be of help if these issues can be acknowledged early on.

The following case studies illustrate effective direct and indirect psychological interventions within different occupational health settings.

**Case 1**

Alan, a 48-year-old medical doctor, was referred by the occupational health service of the hospital where he practised. Alan reported feeling highly anxious, self-conscious, lacking in confidence and low in mood, although he was not apparently clinically depressed. All of these symptoms impacted on him negatively at work and he worried about them leading to a reduction in performance. His symptoms seemed to have developed over a period of a few months following an incident at work where he had made an error during a surgical procedure. The error was identified and corrected; however, Alan was temporarily suspended from surgical duties until an internal investigation had been carried out. Alan reported experiencing regular and distressing flashbacks to the events surrounding this incident and seemed to be stuck in a pattern of rumination.

The referral had asked for an assessment with treatment recommendations; however, it soon became evident that formal treatment was not necessary and that an extended assessment with an active formulation would be sufficient.

The generic cognitive behavioural formulation identified that most of Alan’s distressing emotions were, at least to begin with, normal reactions to a difficult event (e.g. anxiety, fear, guilt, concern, shame). What appeared to have developed, however, was a number of distress-maintaining patterns that seemed to have evolved as a consequence of how he had tried to cope with his distressing emotions. Alan had experienced marked anticipatory anxiety at the thought of running into colleagues who might know about the incident, so he had tried to cope by avoiding situations he considered to be ‘risky’. As a result he changed his route to work, worried about the journey beforehand and arrived at work anxious. This anxious state triggered further anxiety as he worried that he might make a mistake, or that his anxiety would be seen by a colleague who might comment critically. The worries he had about being viewed negatively by others steadily increased, as did his efforts to cope until he felt he needed help.

Based on the formulation, a self-directed behavioural exposure programme was devised, and anxiety-based psychoeducation recommended. He later reported that the formulation process had allowed him to see his main problems more objectively, and to then feel able to address the self-maintaining mechanism of his anxiety, which he learnt were both understandable and changeable.

**Case 2**

Heather was a 43-year-old woman with 25 years’ experience of working for her employers. She had recently taken a new role as team leader, a role she was well experienced in and qualified for, but she was struggling. Heather was referred by the occupational health department who explained in a referral letter that ‘she was low in mood, felt on edge and unable to cope’.

During assessment, Heather explained that she was experiencing a ‘crisis of confidence’ and marked low mood, as well as other symptoms of moderate clinical depression. She explained that she had felt this way in the past, but had recovered quickly. She had been feeling this way for ‘too long’ and it was impacting on her ability to perform. Heather stressed how important it was that she should do her job well and explained that as a woman in a predominantly male work environment she could not afford to ‘slack’. In addition to her low mood, she reported feeling marginalized and unfairly treated which is why she, in her eyes, had had angry outbursts.

Heather’s low mood seems to have been initially triggered following an undermining comment from a colleague. This comment had suggested that Heather’s team were underperforming. It was Heather’s perception that this colleague wanted her role and that she was vulnerable. Normally, she would have been able to cope, but Heather explained that she was feeling increasingly vulnerable as the project the team were tasked with was simply too complex to do well. She felt a sense of failure in spite of the impossibility of the task.

Heather admitted that she was a perfectionist and that things had to be just right or she felt uncomfortable.
She had a reputation at work of being a hard worker, and always seemed to succeed. Faced with a task that was impossible, she began to feel low and vulnerable. The formulation identified, along with her protective factors (determination, creativity, drive and confidence) that she was also dependent upon success to support her self-worth. Thus, failing to maintain her standards posed grave risks to her self-worth. We also recognized that her perfectionism seemed to have its origins early in life. She experienced many physical problems as a child, but she was able to excel academically. She had also learnt that to be favourably viewed by those around her, she had to succeed. Thus, not to succeed was both unfamiliar and, from her perspective, highly frightening.

The intervention was highly pragmatic and aimed primarily at helping her cope with her day-to-day, work-related distress, and slowly she started to recover from her depression. Based on direct cognitive behavioural-based work, the focus was on identifying and adapting beliefs that underpinned her drive to be perfect (e.g. ‘If I can’t succeed I am a failure, no one likes a failure’), activity scheduling, increasing her distress tolerance, and being more able to directly communicate her emotions to others, rather than waiting until she felt uncontrollably angry. She was also helped to link present emotions, beliefs and behaviours to relevant past experiences. The collaborative relationship was vital as she felt a deep sense of shame for appearing to fail.

Later, it transpired that she had been right and her colleague had been trying to take her role, which was curiously reassuring to her as she no longer felt threatened, but consoled herself that at least she could still judge human nature.

**Case 3**

Julia was a 34-year-old woman who worked as an administrator in a university records department. She reported experiencing high levels of anxiety at work which impaired her ability to function. She also reported feeling low in mood. Julia was referred from the occupational health service, and during the initial assessment presented as highly distressed, she struggled to make eye contact and reported that she felt unable to cope and she believed that colleagues wanted to get rid of her. It seemed that Julia’s anxiety had been getting worse over the past few months and that she had, in her opinion ‘always been sensitive to criticism’. Following a critical annual appraisal, Julia had found her anxiety increasing, her capacity to cope reduced, and had eventually gone off work sick.

The formulation process suggested that she had a predisposition to feeling negatively evaluated, and although never having felt this scared before, she had often felt uncomfortable with others. Compounding matters further, she had also experienced severe stress-related alopecia that had further increased her self-consciousness.

The formulation further indicated that she was experiencing heightened social/performance anxiety underpinned by the belief that others would be critical and that she could not cope alone. Julia also explained that as a child her stepfather had been highly critical of her. It seems that these old experiences had had a direct effect on her developing self-worth and had also played a role in the formation of her beliefs about the criticalness of others. Following the annual appraisal, and to cope with feeling vulnerable due to a fear of further negative evaluation, Julia isolated herself, slowly disconnected from her social network, and reduced her assertiveness at work. Over time, her sleep deteriorated and she began to feel ashamed and highly self-conscious, and avoided more aggressively. In addition, she began to feel hopelessness having realized that she would probably struggle to find another job.

Although Julia struggled with the assessment, she was offered a cognitive behavioural-based intervention for her social anxiety. Her aims were to feel ‘stronger’ and return to work, and also to be able to make an active choice about staying in her current job. The intervention also involved close liaison with occupational health professionals and her line manager in planning her return to work. The intervention focused on helping her to feel more confident in identifying and challenging her primary negative predictions around negative social evaluation.

We used the formulation process, then behavioral experiments, to do this over a number of weeks. At the same time, we developed a graded exposure hierarchy combined with activity scheduling to increase her out of work positive experience. Julia kept records of her work and successes as evidence of progress and as a basis for supporting more compassionate self-beliefs. Julia also became aware that she was responding defensively to perceived and not necessarily actual threats. However, it was vital she accepted that at one time in her life she had needed to protect herself from actual threats. This was an important message to convey as it helped her feel less ashamed of her lifelong avoidant behaviour, which was once highly adaptive and protective, even if it acted to maintain her anxiety.

After 14 sessions, Julia successfully improved her understanding and management of her anxiety, increased her social network and confidence. She returned to work and finally resigned some months later with the confidence that she could find another job.

**Case 4**

Mary was a 35-year-old computer programmer referred from the occupational health department for help in dealing with anger at work, depressed mood and generally struggling to cope. She also had a history of self-harm and had recently been to Accident and Emergency having deeply cut one of her wrists with a broken wine glass.

During the assessment, Mary struggled to recognize any thoughts or feelings that might shed light on her problems.
from a cognitive behavioural perspective. She also reported long-standing problems with obsessional behaviour, restrictive eating and drinking alcohol. It quickly became clear that alcohol consumption preceded her risk behaviour, particularly at weekends. Mary identified her anger as a key problem and also explained she felt powerful feelings of guilt. These problems seem to permeate all parts of her life and negatively impacted on work, as there was a risk of her being disciplined and possibly made redundant.

In order to understand Mary’s problems, the formulation needed to expand to include the cognitive analytic therapy (CAT) model.15 The CAT model is a time-limited, integrative model incorporating cognitive, behavioural and psychodynamic components. CAT has been found to be a useful model for problems which have a chronic dysfunctional relationship component and where strong emotions are regularly activated. The evolving reformulation (CAT uses the idea of a reformulation, as opposed to formulation) suggested that Mary’s overwhelming negative emotions (anger and guilt) were connected to her relationship with her parents, particularly her father. Interestingly, she also relied on her father to give her a lift into work each morning and described ‘starting the day on edge’. The reformulation also suggested that she drank to avoid feeling strong emotions, but that it was also an indirect way of punishing her parents. This strategy, however, simply promoted conflict and critical behaviour in the family. Mary also explained that she hated going to her parents for a meal on Sunday, but felt compelled to. It was at these dinners that she would often drink too much, return home and self-harm.

The reformulation guided the 16-week long direct intervention in a number of ways. First, it allowed Mary to observe her unhelpful patterns and see how they were maintaining her very serious problems and distress. Second, it seems to have given her permission to make some simple behavioural changes, such as getting the bus to work, and becoming more assertive with her parents, so she began to politely decline her parents’ offer of a Sunday meal, thus avoiding becoming angry and feeling guilty. Mary also began to accept that she could not change her parents, but that she had a choice to change how she reacted. At work, her mood improved. The anger outbursts decreased and she was generally happier – as were her managers.

Case 5

Tim was a 56-year-old laboratory technician who had worked for a university engineering department for 26 years. Tim was referred from the occupational health department having been off work for six months with ‘stress’.

At assessment, Tim reported high levels of anxiety, mostly around feeling overwhelmed and physically weak, and not being able to cope with the demands of the job or indeed those of his day-to-day life. He reported that these symptoms had been getting worse since going off work sick.

Before going off work, Tim had had been ill with a cardiac problem and was undergoing tests. Psychological assessment revealed that Tim had been feeling increasingly stressed at work for at least four or five years. He reported changes in the work environment, management structure and job description that had left him feeling unsupported and at times unclear as to what his role involved. He added that his job used to be very important to him, as it provided structure and predictability, as well as enjoyment and a sense of achievement. He also explained that his wife was now ill and that he was very worried about her.

Much to his doctor’s surprise, Tim’s problems seemed to have worsened while off work. Rather than having time to recover and regain his confidence, his anxiety had deepened and he had become clinically depressed. It also became clear that he had stopped all forms of exercise for fear of setting off a ‘heart attack’. He had subsequently invested a great deal of energy in trying to ‘think himself better’ in the form of ruminations, checking (scanning his body regularly for signs of danger, e.g. increased pulse rate) and he avoided anything that reminded him of his work or which triggered increased anxiety/low mood.

In addition, before going off work, Tim had been assessed for an autistic spectrum disorder, and been given a diagnosis of high functioning autism. While this diagnosis made sense to him and his doctor, it seemed to add to his sense of feeling overwhelmed, particularly as his work colleagues upon hearing the news had started to treat him differently.

Following the assessment and early formulation, Tim was offered a cognitive behavioural-based intervention and realistic goals were planned. These included: developing new ways of understanding and managing his anxieties, feeling more pleasure and less overwhelmed, and finally returning to work. The formulation suggested that he had gradually grown to feel increasingly overwhelmed at work as he had struggled to manage organizational changes. This was perhaps linked to his autism and the fact that he had done the same job for so long. Feeling overwhelmed meant he struggled to cope with the daily worries which soon became too much. His heart problems were just the final stressor and triggered an acute stress reaction. The time spent off work seems to have led to an avoidance (and hypervigilance) based maintaining cycle, which had led to a worsening of his distress.

The intervention focused on both direct and indirect work. Working directly with Tim using a cognitive behavioural framework, he was able to understand that his anxiety and depression was based on catastrophic predictions about his health and ability to cope in general. He also found that his avoidant coping style, i.e. rumination, active avoidance and hypervigilance were making him worse. This led to a graded exercise exposure programme under advice from his doctor, who was liaising with the cardiology department. Working with occupational health, a carefully graded return to work was planned and a clearer job description was negotiated. Occupational health also
established an effective line of communication between Tim and his line manager which allowed Tim to feel listened to and more in control. He eventually returned to work successfully and negotiated a new role in his old department after being off for nearly nine months.

Case studies: A summary

These five case studies draw attention to the importance of systematically formulating an individual’s psychological needs before embarking on a treatment plan. They also highlight the individual nature of mental illness. Most importantly, these cases illustrate the potential helpfulness of both formulation and psychological interventions, particularly when carried out in transparent coordination with other professional carers, and those working on behalf of the employer.

CONCLUSIONS

As mentioned previously in this chapter, there is not always a clear or even helpful relationship between employer, occupational health provider, psychologist and employee. It is important, therefore, to include these factors into any formulation process as they may have direct impact on the aims and outcome of any intervention and may also impact on client confidentiality.

Formulations are hypothesis based and remain ‘work in progress’ with no absolute declarations or truths. At best, they are helpful hypotheses which help individuals make sense of their problems, at worst they are a rigid, reductionist and patronizing list of a person’s problems and do not contribute to recovery. However limited a poor formulation might be, it at least does not have the same stigmatizing potential as some psychiatric diagnoses, e.g. schizophrenia or borderline personality disorder. The potential normalizing effect of the distress-focused biopsychosocial formulation can help engage those individuals who feel stigmatized by the thought that they may have a mental illness and therefore avoid seeking help.

It is not hard to imagine a situation where an employer sends an anxious or depressed employee to occupational health, who then discovers that aspects of the work environment are directly linked to the individual’s distress. This was similar to Heather’s (case 2) experience. The formulation may reveal that there is little that can be done to change the individual and what is recommended is to change the environment. This can be very frustrating for all involved, especially if the employer disagrees or is actively attributing blame to the employee. This is a particularly difficult situation if the core problem is linked to ongoing bullying, harassment, disputes or relationship problems in the workplace. In these instances, there needs to be clear communication between professional carers involving the client, and an agreement about what is in the best interest of the employee, both ethically and clinically.

Where a work environment is psychologically toxic and thus part of the identified problem, the health professional should raise the issue under the duty of care of the employer. Occupational health practitioners have an important role here, but as advisers they may have limited ability to change the work set-up if the employer resists. In these cases, there is an ethical responsibility to raise the issue with the client and help them make the best informed choice they can: in Julia’s situation (case 3) one of the aims was to help her regain her confidence so she could leave the job. It is important to be as open and pragmatic with clients as possible in order to facilitate their recovery and alleviate their distress.

Finally, it is important to raise the limitations of psychological therapies. Therapies should be chosen for a specific purpose by individuals who are competent in their ability and knowledge base. Psychological therapies and techniques have the potential to cause harm if used inappropriately. Referrers to psychologists should be aware that choosing a specific type of therapy, planning its individualized structure and ensuring quality is complex and often only possible after specialized training and ongoing supervision. Likewise, even CBT, in its many forms, can cause harm in the hands of an incompetent practitioner. It is important for practitioners and referrers to be aware of the contraindications to therapy, ongoing risk factors and the realistic limitations of psychological treatment so as not to give false hope to those in distress.

Key points

- Mental ill health, including ‘work stress’, can be conceptualized as being on a continuum of emotional distress ranging from mild to severe and enduring.
- A biopsychosocial model of emotional distress is highly relevant in the workplace, given the range of diverse factors that may have an influence in any one case.
- A problem-focused formulation can inform psychological, systemic and medical interventions in order to reduce emotional distress in the workplace.
- Psychological interventions need to be pragmatic, realistic and supported by collaborative relationships between invested parties.

Work and psychiatric disorder
Work and psychiatric disorder: an evidence-based approach

NICK GLOZIER, MAX HENDERSON, NEIL GREENBERG AND SIMON ØVERLAND

INTRODUCTION

This chapter will concentrate on the relative effect of work and its context upon psychiatric disorders, particularly those most commonly encountered in the working population (including depression and anxiety). It will then outline the impact of psychiatric disorder on functioning in the workplace, before evaluating the current knowledge on the value of health promotion interventions. Given the effect of different health, social and employment systems between countries, this review will concentrate on the United Kingdom and other northern European literature.

The UK government Foresight Project on Mental Capital and Wellbeing identified the importance of nurturing the ‘mental capital’ of a nation to maintain economic and social prosperity. Meanwhile, reports from the UK and other OECD (Organization for Economic Cooperation and Development) countries have also highlighted the problem of tackling the association between psychiatric disorder and the workplace.1–4 One of the most important ways in which psychiatric disorders affect the lives of sufferers and their families is on their functioning in the workplace5 and on their losing employment and receiving disability benefit.6 At the same time, the public view work and ‘work stress’ as a primary, and increasing, cause of their ill health.7 The body of literature on work stress is now substantial, with numerous definitions extending from well-being and resilience to stress and depression.

Finding a way through this forest of data is a major challenge.

One issue that recurs repeatedly in evaluating the literature is that there is no standard definition of ‘employment’ or ‘work’. It is often unclear whether a given rate refers to competitive, sheltered, voluntary, part-time or full-time employment, what time-frame has been used for measurement and how far definitions require sustained attendance at work for people to be categorized as employed. Also, there is often only scant mention of what sort of work people were engaged in outside specific occupational settings and whether this was for an open market rate of pay. The majority of reports do not explain how they have dealt with women who are working in the home, who may be classified as employed, as well as voluntary workers and students. These deficiencies make interpreting and comparing results from different studies difficult or impossible.

EFFECT OF WORK UPON THE DEVELOPMENT OF PSYCHIATRIC SYMPTOMS AND DISORDER

The potential experiences at work that might be related to poor mental health are legion. These have been postulated to range from discrete events, such as personal injury and witnessing disturbing events, through intermittent but repetitive events, e.g. bullying, encounters with aggressive
or threatening clients in public services, through to more consistent job characteristics, e.g. physical discomfort, both overly onerous and overly undemanding roles, social support, perceptions of organizational injustice and imbalances between the efforts expended and the reward received. Some of these may be related to particular occupations, organizations or types of work, others to actual or perceived experience and all are impacted by a range of factors operating outside work.

Objectively assessed occupational risks

**OCCUPATION**

Surveys of occupations which would seem to carry a high chance of exposure to stressful events and violence, unsociable hours, shift work and many other features considered to constitute a ‘toxic’ working environment, consistently report levels of about one-quarter to one-third of respondents meeting criteria for psychiatric disorder. These levels have been determined, most usually, through studies in which respondents have reached a cut-off point on a screening tool. Examples of such studies include front-line ambulance staff and paramedics, police, other hospital staff, doctors, and veterinary practitioners. In such studies, the prevalence of ‘stress’ in members of the occupational group are compared to the prevalence of psychiatric disorder, ascertained through interview in a rigorously sampled population-based study, such as the National Psychiatric Morbidity Survey in the United Kingdom or the National Comorbidity Survey in the United States. These studies get good publicity and are popular with the respective professional groups and unions, yet frequently suffer from poor response rates, different methods of determining disorder (self-report measures often derive higher prevalence rates than interview-based studies) and little information on the context that may lead to response bias. For instance, it is quite possible that the answers to a ‘stress’ survey may differ from identical questions asked in a ‘well-being’ survey. It is important to remember that prevalence estimates obtained in different groups using different study designs cannot be directly compared. Therefore, such studies are unlikely to provide a valid answer to the question of whether one group has a higher prevalence of psychiatric disorder compared to other occupational groups.

Attempts have been made to use broader based surveys to identify occupations in which employees are more or less likely to develop common psychiatric disorders. Using a large self-reported database, ambulance workers, teachers, social services, customer services (call centres), prison officers and police reported poorer than average scores on psychological well-being and job satisfaction measures. More robust data come from population-based data in the United States. These studies get good publicity and are popular in high income countries have shown two consistent patterns. First, not having a job is worse than having any type of job, although less so in a period of high unemployment. This was confirmed recently in a pan-European study. Second, suicide registers consistently suggest that healthcare workers are the only occupational groups consistently associated with raised suicide rates after adjusting for other known risk factors. For instance, among those who have previously been admitted with psychiatric disorders, minimal associations between occupation and suicide are observed except for doctors, who are at almost four-fold greater risk. This presumably reflects access to the means of suicide (drugs) and knowledge of how to use them. Some have suggested knowledge of the consequences of chronic illness or the effect of having people so dependent upon them as explanations. In others, the risk may be due to economic factors, such as the transient nature of some occupations predisposing to periods of being unemployed and being in receipt of low income. Within such groups, however, the same risk factors operate for being vulnerable to suicide as in the rest of the population – psychiatric or personality disorder and previous deliberate self-harm being the most prominent.
The oft-quoted association of suicide with another large group with access to lethal means, farmers and farm workers, is less consistent with both positive and null associations, although veterinarians have high levels, presumably for similar reasons to other health professionals. Groups such as the police and other front-line public sector workers have similar rates to the rest of the population. Much of the apparently high suicide rates in certain occupations are due to lower death rates from other causes. Beyond this, it is difficult to make out a common job pattern, although Sanne et al. suggest a strong effect of low skill use occupations being associated with depression in men suggesting job selection. Certain people are drawn to certain jobs, for example, there is a stronger relationship between a simple global measure of intelligence with future occupational level than the multitude of specific aptitudes often tested in the psychological selection processes used by many organizations. Late adolescent personality characteristics also play a strong role in determining future occupation and attainment, with ‘alienated and hostile adolescent’s … personality dispositions leading them to work experiences that undermine their ability to make a successful and rewarding transition into the adult world’. 

### POSITION IN THE ORGANIZATION

Within many workplaces or jobs, there is a hierarchy between higher and lower grades. A consistent finding is that those in lower status jobs have higher levels of psychological distress. In the Whitehall II study, this association was not explained by poorer mental health leading to employment grade changes (social causation), but rather supporting a selection into certain grades by factors that are also risks for psychiatric disorder. The association with workplace position in fact appears stronger than broader objective measures of socioeconomic position in society as a whole. Subjective measures of socioeconomic status also have a strong effect, bolstering the idea that workplaces perceived to have flatter hierarchies may be less likely to engender negative health effects.

### HOURS WORKED

Long hours and overtime have also been linked to psychiatric disorder in some studies (e.g. Ref. 34), which can receive media attention. However, the most comprehensive literature review in the area showed that fewer
than half of all longitudinal studies demonstrated any negative impact of long hours, indicating a need for more understanding and better determination of what long hours mean rather than a simplistic ‘more work = bad’ approach.

**PSYCHOSOCIAL WORK ENVIRONMENT**

**Job strain and effort–reward imbalance**

Men are disturbed not by things, but by the view which they take of them.

Epictetus (AD 55–135)

Two major models have emerged to describe the psychosocial work environment – both are determined by an individual’s perception of their environment. In the ‘job strain’ model the ‘demands’ of work are contrasted with the level of control (‘decision latitude’) an individual has over how they work. ‘Job strain’ is said to occur when high demands are associated with low decision latitude. Later, a third dimension was added to the model, namely, perceived social support at work, and was combined with the other two dimensions. Hence, a high-strain job in the context of low social support should produce the worst effects on health. This situation created the ‘demand–control–support’ or ‘iso-strain’ model. The second model is the ‘effort–reward–imbalance’, in which stress responses are believed to occur when effort expended at work is not matched by rewards in terms of pay, self-esteem and sense of achievement.

Both job strain and effort–reward imbalance were shown to be associated with psychiatric disorder in numerous cross-sectional studies, e.g. Ref. 38. When objective, rather than self-reported, assessments of work demands are included, the association between the psychosocial work environment and psychological morbidity is attenuated. Adversely perceived changes in these stressors, particularly control, are associated with future increased and longer spells of absenteeism.

A meta-analysis of prospective studies from both Europe and North America showed that there was consistent evidence for similar effects of job strain (summary OR 1.8 (95 per cent CI 1.1–3.1)) and effort–reward imbalance (summary OR 1.8 (95 per cent CI 1.4–2.3)), in predicting later psychological symptoms, termed ‘common mental disorder’, that was not explained by response bias (the tendency for certain individuals to report things more negatively). The individual components of these models, i.e. demands, decision authority and support, showed smaller but still significant effects of increasing the likelihood of later psychological distress by about 1.3 times. The effects were less strong generally among women than men.

When the outcome of a clinically defined diagnosis of depression is used, the evidence is less convincing. Bonde identified seven studies where the risk of later depression was determined using a validated interview. The two studies assessing demands provided conflicting results of no or a strong association. There was no association of decision latitude on its own. The combined measure of high job strain (high demand and low control) did produce an effect, particularly in men, with a relative risk in the 1.5–2.5 range. A second systematic review in the same year with the same objectives identified a slightly different, but generally overlapping, set of studies. This review concluded that there were consistent effects of job demands upon the development of depression with relative risks around 2.0, but conflicting results with respect to decision latitude. Social support at work was associated with a decrease in risk for future depression, as all four studies identified showed that high social support reduced the risk of future depression. Both of these latter reviews suggested less of a gender difference. One important point was the observation of a ‘very strong’ publication bias with only one negative study published which was attributed to a positive secondary outcome.

Another recent study across 11 large companies has bolstered the observation of the deleterious effects of people reporting either high strain or so-called ‘passive’ (low demand, low control) work stress patterns leading to later onset of prolonged sick leave for depression, particularly for men, a negative effect of low control for both genders, but failed to show any protective effect of social support. A young birth cohort showed that higher levels of psychological, but not physical, job demands, poor support and low decision latitude (high strain) were associated with a recent onset of well-defined major depressive disorder and generalized anxiety disorder in 32 year olds. Previous studies have highlighted the importance of adjusting for prior disorder given the social causation effect. Finally, recent Canadian work has shown that those exposed to chronic high job strain developed depression at twice the rate (8 per cent) as those with consistently low strain (4 per cent) and those who reported a change from high to low job strain had a risk of major depression similar to those exposed to persistently low job strain. This would reinforce the idea that reducing an individual’s perception of strain may have a positive impact on the risk of depression.

While the study of the perceived psychosocial work environment has deepened our understanding of the nature of the relationship between the individual and his work, the models have limitations. The reliance upon self-reported data is either a hindrance or the ‘core of the issue’ depending upon the viewpoint as it incorporates beliefs, perceptions and attitudes to work. More work is needed on validating methods of assessing work demands and the way in which the perceptions of demands and decision latitude are filtered or modified by individual factors, such as personality, temperament and previous experience. The literature has concentrated upon depression and depressive symptoms with little emphasis upon anxiety. Bonde’s review demonstrated that not one of the 16 papers accounted for all common potential confounders of
demography, life events/family demands, personality, previous disorder, chronic disease and family history. The similar findings of associations across widely varying measurements of both stressor and psychiatric disorder, with no apparent trend towards greater effect of early versus late onset (unlike other life event work), and the huge variation in outcome prevalence, led him to suggest that much of the association may represent bias and confounding.

Other specific elements of the psychosocial work environment have attracted research attention and seem important clinically.

**Bullying (mobbing)**

Despite two decades of intense work on workplace bullying and studies demonstrating significant personal, organizational and societal sequelae, the field is somewhat hampered by lack of an agreed definition. The prevalence varies enormously depending upon the definition, but tight definitions of bullying consistently produce a figure of around 5 per cent.49–51 Broader definitions of unwanted acts can lead to much higher rates, e.g. 40 per cent52 or even 50 per cent.53 The most comprehensive review in the area54 used a definition of ‘prolonged and repeated hostile behaviours conducted by at least one person toward one or more individuals when they are unable to resolve their workplace conflicts in non-hostile manners and can cause health problems for victims and affect their performance’. As can be seen, the definition of risk factor includes the outcome and so anyone experiencing such behaviour who does not endure a health or performance effect is not bullied by definition. Thus, the bullying occurs as a transaction between external behaviour and individual perception, much as with other psychosocial risk factors. Whether or not intentionality is a defining characteristic of bullying has been the subject of some debate. Keashly and Jagatic55 argue that intent constitutes a key element of bullying and emotional abuse. On the contrary, Zapf et al.56 point out that it would be difficult to include intentionality as a feature of bullying, given that intent may prove difficult to verify. There does, however, appear to be one consistent criterion which is the rule of thumb that the unpleasant behaviour must happen at least once a week for at least six months57 to be classed as bullying. Despite a great deal of interest, conceptual articles and the presence of numerous websites on bullying and whistle blowing, the systematic review by Moayyed et al.54 found only 37 analytical papers, of which only seven met a moderate threshold of quality. Six of these were case control as probably befits such an outcome. A consistent finding was that those with certain personality and stress characteristics (lower levels of assertiveness and extraversion, higher levels of depressive symptoms) were more likely to report being victims of bullying at a later date. There were no consistent effects of gender, although men tended to be bullied by men, and women more likely to be bullied by women, potentially reflecting the gender-segregated composition of many work environments. In the only cohort study, less than half of those reporting bullying did so over the two-year time period, but this group had much poorer outcomes, being four times more likely to develop depressive symptoms.48 Bullying has also been associated with insomnia57 and a range of other health indices, although once again hampered by tautological definitions and cross-sectional study designs with their inherent biases. One interesting observation is that people who report observation of the bullying of others have poorer mental health themselves, which may suggest either the presence of wide organizational issues or support the view that those with low mood perceive actions and workplaces in a less favourable light.58

**Trauma and violence in the workplace**

There is no a priori reason to presume that an experience of trauma or violence, that might be psychologically disabling in other areas of one’s life, should not be so if experienced at work. While most people who experience such an event will experience short-lived symptoms, such as distress, insomnia, anxiety or unhappiness, only a minority will develop a mental health disorder. Responses to traumatic events have been suggested to comprise one of five groups with the first being by far the most common:

1. The normal stress response characterized by intense intrusive recollections, numbing, denial, feelings of unreality and arousal. If more severe and prolonged, this forms the adjustment disorder of the ICD.
2. Acute stress disorder/reaction which is characterized by feelings of panic, cognitive disorganization, disorientation, dissociation and severe insomnia, and infrequently paranoid or truly psychotic reactions, and difficulty in work and interpersonal functioning.
3. Uncomplicated post-traumatic stress disorder (PTSD). Where PTSD does occur, it usually has an onset within a month of the event. While PTSD may persist for months or even years, a substantial number of PTSD cases resolve without the need for formal intervention.
4. PTSD, comorbid with other disorders, is more common than uncomplicated PTSD and is usually associated with disorders such as depression, alcohol/substance abuse, panic disorder and anxiety disorders.
5. Personality change as a result of catastrophic experience which is suggested to be the result of exposure to prolonged, or in some cases highly intense, traumatic situations.

Some have suggested that other disorders, such as depression, are more common sequelae of traumatic events. For example, Fullerton et al.59 studied the development of depression among rescue workers who were
exposed to dead bodies and physical danger and who gave assistance to survivors in disaster situations. The study observed the rescue workers for one year and found a three-fold increase in the risk of developing depression of 3.5.

A significant critique of the field in ascribing PTSD to an occupational cause, has been that the occurrence of ‘a stressful event or situation of an exceptionally threatening nature, which is likely to cause pervasive distress in almost anyone’ (the criterion A event necessary for a diagnosis) is common. The proportion of adults who report having experienced at least one such traumatic event includes the majority of people in the United States (61 per cent of men, 51 per cent of women), suggesting that many have suggested it does not provide a specific aetiology for a disorder. The association between exposure to trauma and the development of symptoms of post-traumatic stress is not fully understood. It involves a complex interplay between factors related to the trauma, neurobiology and psychosocial influences. All of these determine an individual’s vulnerability or resilience to developing PTSD as a result of exposure to a traumatic event. Certain sociodemographic factors, such as sex, age, ethnicity and income, have also been shown to be associated with vulnerability to developing PTSD.

The majority of studies addressing work-related traumatic events has focused on specific occupational groups that obviously carry a much higher risk of experiencing such events, i.e. military, ambulance, fire and police staff. Surveys of emergency service personnel find a sizeable minority of fully operational employees who screen positive or meet criteria for PTSD. For example, in UK ambulance personnel between 5 and 20 per cent of paramedics still working screen positive for PTSD. There is an extensive literature which suggests that many employees experience horridous events but do not develop PTSD. Our survey of London ambulance staff in the aftermath of the July 2005 London bombings suggested that the prevalence of PTSD as found on a screening tool was similar to that in the general population (2–3 per cent), with a higher prevalence of 6 per cent in those involved in the bombings directly. The failure to find substantially raised levels in emergency services suggests either that affected staff rapidly leave the service or that people joining such organizations self-select for resilience.

In the field of military operations, there are extensive texts best referred to, such as the PTSD Compensation and Military Service report. Cohort studies of military personnel deployed in Iraq and Afghanistan suggest a three-fold elevated incidence of PTSD among those reporting combat exposures of around 8 per cent. As above, there are vulnerability factors – those with poor physical and mental health prior to deployment being the most likely to develop PTSD for any given level of combat exposure. In United Kingdom, Gulf War veterans of low rank and leaving the service were the strongest determinants of poor mental health, with little effect of either pre-deployment training or post-deployment leave. Studies which have looked at more recent operations found that among UK troops, about 4 per cent of the force, whether deployed or not, reported symptoms of probable PTSD, although troops engaged on combat duties reported higher rates (6 per cent), suggesting that increased ‘toxic’ exposure may well have a significant, albeit small, effect upon PTSD rates.

A primary source of traumatic events outside the emergency services is violence at work which is more common in those working in the public sector: health and social work professionals. According to the British crime survey, 0.9 per cent of employees had been physically assaulted while they were working, a similar number threatened and 0.5 per cent of workers said that worrying about workplace violence had a ‘great deal’ of impact on their health, and 2 per cent said that it affected their health ‘quite a bit’. Despite increasing attention, the reported rates in this frequently repeated survey have actually been falling since 1995.

A major issue besets the field of post-traumatic distress disorder and violence in medicolegal settings. If two people experience the same DSM-IV or ICD-10 criterion A event, yet only one goes on to develop a disorder, only this person is compensated for this experience with sickness absence, pension or some other form of social compensation. There has long been a suggestion that the presence of compensation claims can prolong the course of the disorder as seems to be the general pattern following a range of injuries. The United States veterans’ review suggested that compensation was not a barrier to help seeking, but did not address the issue of whether it was a disincentive to recovery. However, as shown by the rates of PTSD specific to trauma experienced at work in occupational groups, the presence of such a disorder does not preclude employment even in front-line operational posts. Work into the factors preventing the onset of PTSD and enabling well-trained people to continue being gainfully employed, e.g. by tackling the stigma associated with help seeking, are major foci of attention in the area.

Given the apparent lack of specificity of a traumatic event as a cause, the numerous vulnerability and resilience factors and the role that compensation and other benefits play in the development and persistence of symptoms of PTSD (and other disorders), the disorder can be a medicolegal minefield. Future research may help to clarify matters, although with more and more experiences being considered as potentially traumatic (www.hcp.med.harvard.edu/wmhcdi/instruments_papi.php) the threshold for traumatic events is likely to be lowered, making this group far more heterogeneous.

**Downsizing and job insecurity**

In the Stansfeld meta-analysis, job insecurity appeared to have a moderate effect on increasing the risk of future psychiatric disorder, primarily in men (OR 1.3) in the two studies that assessed this, both by simply asking a yes/no
question. As with many of these psychosocial risks, the effect seems stronger in cross-sectional surveys. The effect of current job insecurity seems stronger in men and uncommonly observed in women in population-based studies. The Finnish study also followed up those who left the workplace showing that for those who found employment elsewhere, their mental health improved and was in fact better on average than those who stayed, particularly after major restructuring.

Job insecurity is noted in two main areas: first when organizations are downsizing, retrenching or rightsizing (‘making people redundant’ as it used to be called). Although there are some studies from the mid-1990s suggesting positive health benefits during downsizing (e.g., Parker et al. in general, the remaining workforce appears to be consistently and negatively affected. One interesting observation is that the perception of job insecurity mediates the relationship between actual likelihood of being laid off, e.g. being given warning notices or having members of one’s team laid off, and psychological problems. This has also been suggested to be mediated through longer hours and work intensification across a range of countries and industries and occurs despite the observation that those still employed tend to be a healthier group than those who lose their jobs. Chronic job insecurity seems to have a particularly strong effect. In a large Scandinavian study group, the 4783 employees who worked in organizations undergoing change, but kept their jobs after downsizing, were at a higher risk of being prescribed psychotropic drugs (rate ratio 1.49, 95 per cent CI 1.10 to 2.02 in men and 1.12, 95 per cent CI 1.00 to 1.27 in women) than the 17600 not exposed to downsizing. The association of downsizing was strongest with hypnotics among the men and with anxiolytics among the women. Older workers, those more committed to their employer and potentially male gender were identified as riskier groups for the psychological effects of downsizing. Others have identified racial factors potentially indicating forms of discrimination or stigma.

The other major area of job insecurity occurs in what is called ‘contingent’ or ‘precarious’ employment. This term reflects the growth of flexible workers, such as fixed-term employees and workers without an employment contract in many OECD countries. These employees are more likely to have mental health problems on recruitment, particularly poorer mental health, and also to develop mental health problems later. This effect is not explained by part-time, as opposed to full-time work, but rather contract type. In many OECD countries, contract workers constitute a sizeable minority of the workforce. As this practice spreads, there will be more work on this area of insecure employment and the broader impacts on health both within organizations and society. Although some have suggested that increased focus on performance has reduced the tolerance of staff with health problems, the job market over the early part of this millennium was such that many with mental health problems re-entered employment.

The effect of the recent economic downturn is likely to be felt most acutely in this group.

Stigma and discrimination

People with psychiatric disorders are among the stigmatized and the workplace is an important source of discrimination. The ‘concealability’, attribution of blame and perceived unpredictability are key components of this work-placed risk. Individuals with psychiatric disorders are less likely to enter the job market and, if they do, they are more likely to be underemployed, employed in low status or poorly remunerated jobs, or employed in roles which are not commensurate with their skills or level of education. Many more have entered employment over the past few years of economic growth, but often in contingent and flexible roles. They then become harder to identify and study, and are overlooked in reports where only data from the primary labour market are analysed. The flexible and short-term nature of these positions may be attractive to those returning to the workforce following a prolonged absence, but this comes at a price. Positions in the secondary labour market are often unstable, poorly remunerated or open to exploitation. Short-term employees have weaker legal protection, and poorer opportunities for training and career development. They frequently report being denied opportunities for training, promotion or transfer. Others have been dismissed or forced to resign. Baldwin and Marcus identified over 5 per cent of workers with a psychiatric disorder who had been laid off, fired or told to resign because this fact became known. Furthermore, those returning to work following a psychiatric disorder come under far greater scrutiny, such as vigilance for, or overinterpretation of, symptoms, or more requests for further information from doctors than those returning after an apparently physical disorder. There is, however, a spectrum of views – depression is better tolerated than psychosis, and individuals are viewed more charitably if they are taking medication, better still if they are not currently ill.

When it comes to disclosure of a mental illness to an employer, most high-income countries have antidiscrimination policies and laws obliging employers to accommodate people despite health problems. The presence of such laws has made people aware of these processes, but covert discrimination is hard to detect and tackle. As such, a challenge for those with psychiatric illness is if, how and when to disclose this to an employer. Many patients are reluctant to disclose their psychiatric history fearing being treated differently or having their job offer withdrawn, often with good reason. The Shaw Trust, a UK disability charity, recently conducted telephone interviews with CEOs, directors and human resources officers in 500 businesses of different sizes. A huge majority (89 per cent) believed that they did not have anyone with a diagnosis of mental illness working in their organization at present.
Furthermore, 80 per cent believed that ‘potential employees should disclose mental health problems prior to recruitment’, but when asked if they would employ someone with mental health problems, only one-third reported that they would (compared with 62 per cent for physical health disability). In terms of what drives these discriminating views, work with human resources managers suggested these were based less on an expectation that those with a history of psychiatric disorder would take more time off, rather that they would be worse at their jobs. Disclosure is therefore often delayed until a ‘good impression’ has been made. In trying to keep problems secret, employees may be less likely to seek appropriate support from occupational health, be reluctant to be seen taking medication or to seek time off for hospital or therapy sessions.

Emerging concepts

There has been a slew of very recent studies examining other psychosocial risks. Initial results suggest that employees with low workplace social capital, both vertical (lack of respectful and trusting relationships across power differentials at work) and horizontal components (lack of trust and reciprocity between employees at the same hierarchical level) increase the odds for newly diagnosed depression and antidepressant treatment by 30–50 per cent compared to their counterparts with high social capital at work. Poor team climate and other group level indictors can also impact upon the mental health of employees, as can perceptions of organizational injustice and unfairness.

Psychosocial risk factors at work and physical disorders

The contribution of many of these psychosocial occupational risks to more physical disorders has been addressed. There are a number of reviews in pain conditions which generally show a tendency for higher job strain to be associated with development of back pain and neck/upper limb pain. Working longer hours is associated with a range of adverse physical health outcomes. Recent evidence suggests that long hours also make cognitive function decline faster in middle age. Organizational injustice and unfairness at work has been linked to cardiovascular disease and heavy drinking.

Work stressors are entrenched in the public’s perception as a cause of heart attacks, although the evidence is not consistent, e.g. Kivimaki et al. and Eaker et al. This has led to observations that it is the accumulated impact of chronic work-related stressors that are important. Certainly, chronic job strain was shown to increase the risk of recurrent myocardial infarction in a predominantly male cohort, independent of any demographic or medical risk factors. This was to the extent that the positive effect of returning to work on mortality seen over the first few years was reversed by year four. Any effect of job stressors on the health of women with cardiovascular disease has yet to be shown convincingly, although it has been examined. The potential pathways by which occupational stressors lead to physical disease are legion. Some have suggested that any effect of work stressors on cardiovascular health may be mediated by psychiatric disorder. Depression, for instance, has an independent effect upon the development of cardiovascular disease in otherwise healthy people and for poorer outcome, in particular recurrent depressive episodes, after a cardiac event. The psychiatric disorder may mediate this through health behaviours and poor adherence, social exclusion or reduced support. Cognitive models of harm avoidance, coping and self-efficacy appear useful in understanding work-related illness in pain conditions. The Whitehall II study suggested that a combination of adverse health behaviours and the development of metabolic syndrome explained a significant part of the link between work stressors and cardiovascular disease. Alternatively, linked (pro-) inflammatory and immune responses and hypothalamic–pituitary–adrenal axis dys-function are being explored as either common determinants of psychiatric and physical disorders or as the mediating paths between psychosocial risks and disease. There are whole textbooks in this emerging field of psychoneuroimmunology, but a useful introduction can be found in Ref. 117.

One emerging avenue is the impact of many of these occupational stressors, such as the effort–reward imbalance in men, long hours and organizational injustice, on sleep disturbance and insomnia. Given that similar inflammatory and oxidative stress markers are apparent in people with sleep disturbance as in mood disorders and cardiovascular disease, sleep disturbance may be one of the mediating paths by which health is affected.

Toxic exposures and medically unexplained syndromes

Another important consequence of working in high threat locations is the potential for personnel who do so to develop a ‘syndrome’ of physical symptoms which lack a consistent pathophysiological base. Such syndromes are categorized in ICD-10 as somatoform disorders and also known as functional somatic syndromes or medically unexplained symptoms. Probably the best known of these conditions afflicted, and continues to afflict, military personnel who served in the 1991 Gulf War. Although it is not clear who first coined the term, initial media reports described so-called ‘Gulf War Syndrome’ (GWS) as being clusters of either unusual illnesses in veterans or their families, such as cancers in previously fit veterans, or birth defects in veterans’ children. Soon, however, the term covered virtually any physical or psychological symptom,
alone or in combination, occurring in anyone who had served in the region. Troops from almost all coalition nations, including the United States, United Kingdom, Canada, Australia and Denmark, reported suffering from the condition. Numerous studies investigating GWS have repeatedly failed to find any definitive evidence of a syndrome that is specific to Gulf War service. Instead, studies repeatedly showed that personnel, who had served in the 1991 Gulf War, report two to three times more symptoms than those who did not, but the pattern of symptom reporting is the same irrespective of deployment to the Gulf in 1991.

Although there is no consistent evidence for a causative agent for GWS, medically unexplained symptoms were experienced by some 17 per cent of UK service personnel who served in the Gulf War. Furthermore, those who suffer from the condition remain adamant that their work was the direct cause of their symptoms and disability. The suggested candidates for causative agents are legion and include pesticides, oil fires and vaccinations. One particular substance, depleted uranium (DU), has been frequently linked to the development of GWS. However, studies of military personnel who have been injured with DU fragments, and thus indisputably exposed, have not shown them to have suffered higher levels of adverse health consequences to date. Evidence from the 2003 Iraq War has also failed to link exposure to DU with health problems in coalition forces. Another putative cause was pyridostigmine bromide (PB), which was used, in tablet form, as a prophylactic against the possible effects of some chemical weapons. However, Canada sent three ships to the Gulf, the personnel of only two of which used PB prophylaxis, yet the rate of illness was the same in all three ships.

In summary then, although multiple unexplained symptoms have been found to afflict substantial numbers of veterans of the 1991 Gulf War, those symptoms did not cluster in any particular pattern, nor has it been possible to demonstrate any definitive links with possible toxic, causative agents. The GWS legacy continues though, with a four-year follow up of UK veterans showing that the majority of those who had originally reported GWS symptoms remained unwell. Although GWS is perhaps the most well known of the military somatization disorders, it is noteworthy that similar patterns of symptoms have been found in military personnel after many other conflicts.

Moreover, the military is not the only occupation to be associated with an increased risk of controversial somatization disorders. Although these disorders go by many names, such as chronic fatigue syndrome, multiple chemical sensitivity or fibromyalgia, the constellation of symptoms, including fatigue, joint pain or dizziness, reported by those who suffer from them are similar, as are the frequent disagreements about what causes them. These conditions tend to affect people of working age (between 20 and 50 years) and are more commonly seen in women. Multiple chemical sensitivity, for instance, is said to be associated with low level exposure to a variety of industrial substances, such as smoke, pesticides, plastics, synthetic fabrics, scented products, petroleum products and paints. However, blinded trials show that in fact those who are said to suffer with this condition do not react to chemicals. A detailed review of 37 provocation studies concluded that ‘persons with MCS do react to chemical challenges; however, these responses occur when they can discern differences between active and sham substances, suggesting that the mechanism of action is not specific to the chemical itself and might be related to expectations and prior beliefs.

Another important occupational consideration in these conditions is that they have a relatively poor prognosis. For instance, the UK’s Health and Safety Executive suggests that while 40 per cent of those who suffer from chronic fatigue syndrome may improve with treatment, only few recover fully. Once these syndromes are established, occupational outcomes tend to be even poorer. Psychiatric medication, usually antidepressants, is generally not effective at treating these conditions, although comorbid depression and anxiety, which may be present in up to 50 per cent of cases, should respond to pharmacological approaches. However, there is evidence that cognitive behavioural therapy (CBT) is effective in some cases. A 2007 meta-analysis of five CBT randomized controlled trials of chronic fatigue and chronic fatigue syndrome (CFS) reported 33–73 per cent of the patients improved to the point of no longer being clinically fatigued. However, in keeping with the controversial nature of these disorders, the use of CBT has often been criticized by patients. For instance, a survey (n = 285) of CFS sufferers conducted by ‘Action for ME’ found that only 7 per cent of respondents reported CBT to be helpful, while 26 per cent reported that it made their condition worse.

In summary, such medically unexplained symptoms and the associated syndromes are generally difficult to manage in the occupational environment because of controversy about their causation, their impairing effects on function and the poor response to treatment, particularly when the cause is perceived to be the workplace.

Future for psychosocial risk evaluation

Whereas the models of job strain and effort–reward imbalance have merits, the other psychosocial working conditions identified above have uncommonly been investigated in epidemiologic studies, with the exception of responses to traumatic events. In future research, more precise measures of risk and exposure are needed including duration or the intensity of a given exposure. Such evaluation cannot be obtained by means of postal or Internet-based questionnaires alone. In addition, standardized in-depth interviews can be applied in order to gather more information on the quality and quantity of occupational risks. These observations will need to be replicated in different countries and
organizations and the relative effects of these versus other risks determined in well-conducted cohort studies that take the full range of mediators and confounders into account.

PSYCHIATRIC DISORDER AND WORK DISABILITY

Depression and phobic anxiety disorders are the most commonly identified psychiatric disorders in the workplace. These can impact upon an individual’s work through various ways: employment status, disability measured through extra effort, reduced performance, work cut-back days, poor role functioning, sickness absence and being pensioned out of the workforce on a long-term or permanent basis. Assessment of each of these outcomes is conducted in different fashions. Much of the literature revolves around cross-sectional surveys with self-reporting of both disorder and work disability. Increasingly, the literature uses observable outcomes, routine data or validates the self-reported outcomes, although similar patterns are observed and self-reporting of outcomes, such as sickness absence, appears fairly reliable.

Two apparently conflicting, but consistent, findings make determining the association of any one individual’s psychiatric disorder and work ability complex:

1. There is no direct relationship between the presence of psychiatric disorder and working, either as employment status or work performance. In the UK, for example, the employment rates of women with psychiatric disorder range from 42 per cent (phobias) to 59 per cent (panic disorder), compared to employment rates of 62 per cent overall. The comparable employment figures for men are 35 per cent and 70 per cent compared to 75 per cent overall.142 The lack of association is well described by Wikman et al.143 In this study, effectively a cross-sectional survey of people of working age in Sweden, respondents were asked to identify whether they had one or more of a range of common symptoms of illness, had a physician-made diagnosis and were identified as having been absent from work from the National Social Security Board. Each person could fit into none or any permutation of these groups. Only a minority of the population (25 per cent) had no illness symptoms. More (33 per cent) had symptoms, but had no diagnosis nor took sickness absence. Some 14 per cent had had a recent sickness absence of over two weeks, although 2 per cent of the whole population had been off sick without apparently experiencing symptoms or receiving a diagnosis (Figure 66.1).

2. In the general population, the more severe the disorder the more likely there is to be a limitation of working.144 Employment rates for those with severe psychiatric illness (who comprised some 6.5 per cent of a US population-based study145 and similar levels in other OECD countries) is between 5 and 20 per cent. This can lead to dramatically reduced earning capacity in those with more serious conditions. This was estimated to lead to approximately $27 000 per year less income for men and $9000 for women (at 2005 US dollar rates). Those with less serious conditions – who can presumably access sickness benefits, remain in work underachieving or take limited time off – were not as affected.

OCCUPATIONAL IMPAIRMENT OF PSYCHIATRIC DISORDER

What is it about a psychiatric disorder that impairs occupational functioning? As Mechanic eloquently pointed out, psychiatric disorder impairs exactly those functions most required in modern workplaces – concentration, cognitive function, energy, motivation and social interaction. One aspect often raised in clinical situations, but rarely covered in research, is that of the extra effort that those with psychiatric disorder have to put in, in order to do their work, e.g., to overcome poor motivation or anxious cognitions. Fatigue may also be one of the occupationally toxic elements of depression and improvements of energy levels are associated with improved work productivity.149 Most studies, though, have concentrated on cognitive function. Depression is often associated with impaired cognitive function, aspects of which appear differentially affected. A meta-analysis of studies from a range of patient populations showed a strong and consistent effect for an association of depression severity with executive functioning (short-term working memory, cognitive flexibility, planning and problem solving), and weaker but consistent associations with learning, immediate and delayed recall and processing speed. Scheid152 cites these as potential barriers to both high status jobs and those where there are high levels of contact with the public. There was no consistently observed association with semantic memory or visuospatial functioning. Analysis of individual items on self-report questionnaires has shown that people with
depression identified more disabilities in occupations requiring proficiency in decision-making and communication or frequent customer contact. In the European ESMED study of 21 000 people in six countries, attention and concentration and embarrassment in social situations were the mediators of the association between depression and occupational functioning. This finding has particular implications for making adjustments in allowing people to return to work following illness in that those with ongoing symptoms will experience poorer functioning and will require some degree of task modification.

Several studies have demonstrated temporal associations of work-related disability with relapse and remission in depression and anxiety. These are not just limited to clinically diagnosable disorders, but appear to exist on a continuum, with people with subclinical disorders still having a significant occupational disability. However, there is still a substantial amount of occupational disability that is not accounted for by either psychological or physical symptoms. This may be because there appears to be a time lag effect, such that occupational functioning becomes impaired some time after the onset of symptoms and resolves later than the remission of symptoms. The most important predictors of incomplete functional recovery are clinical and social, whereas personality and demographic characteristics are less important. One important observation is that those who do make a recovery generally return to their premorbid level of functioning and only those with a severe and recurrent illness experience a decline in function – an important issue in determining eligibility for disability benefit. Other relatively unexplored, but clinically relevant, issues include the impact of the disability associated with psychiatric disorder upon co-workers, for example through performance or absenteeism.

Severe mental illness such as schizophrenia, very disabling mood disorders and severe personality disorders, are dealt with predominantly by psychiatric services in most developed countries. The literature in this area over the past decade has almost exclusively focused upon rates of employment, vocational interventions with ‘competitive employment’ as an outcome and barriers to this, although much practice is still in the sheltered employment type of vocational rehabilitation facilities. In part, this reflects the consistent finding that in most OECD countries the proportion of people in paid employment with severe mental disorders, usually schizophrenia, but in some studies encompassing other psychoses, e.g. bipolar affective disorder, is very low (10–20 per cent) and has decreased over time compared to the rate of employment in the general population. Again, cognitive and ‘negative symptoms’ of lack of motivation and anergia appear to drive this work disability, rather than the more obvious psychotic experiences. Many such people are able to be employed and the spreading practice of individual placement and support (IPS) has the strongest evidence base for maintaining stable employment.

Organizational effects of psychiatric disorder

**Presenteeism**

Most employees come to work with a range of symptoms which are best not medicalized. Sickness presence, or ‘presenteeism’, describes a situation where an employee has a disorder, but nevertheless goes to work and may underperform. A number of work (e.g. time pressure and working in a small company) and personal characteristics (e.g. level of commitment to work) affect the likelihood of such presenteeism behaviour, but studies often combine types of disorder. A moment in time study showed that the decrements on task focus and productivity over a month in those with a diagnosis of depression was equivalent to two days per month absence. An alternative approach is to measure ‘work cut-back days’. Kessler and colleagues have consistently demonstrated the negative effect of both depression and anxiety, whereby people with these common psychiatric disorders experience more cut-back days than many with other chronic conditions. The more chronic, but less severe diagnoses, such as dysthymia and mixed anxiety and depression, tend to have an even greater societal and organizational impact through lost productivity and presenteeism because of their greater prevalence. Other studies confirm that the reduced productivity attributable to psychiatric illnesses is significant and that depression, of all common conditions, has the greatest negative impact on time management and productivity and is equivalent to rheumatoid arthritis in its impact on physical tasks.

**Sickness absence**

Short-term absences are by far the most common type of absence episode. The ‘causes’ of short-term absence appear to be different from longer-term sick leave. The Whitehall II study compared causes of different forms of sickness absence, and although respiratory and gastrointestinal disorders were the most common causes of short-term absences by some margin, it is likely though that the role played by psychiatric disorders is underestimated. Job satisfaction and motivation, both linked to mental ill health have been shown to predict increased short-term absenteeism for colds.

There is no agreed demarcation between short- and long-term sickness absence and this complicates comparisons between studies and countries. Although long-term absence makes up only a small proportion of the incident number of absences, it accounts for up to a third of days off and 75 per cent of absence costs. Although psychiatric disorder accounts for a small proportion of long-term absence, when it does it can be very long term and absence for this reason has a higher median cost. Once the employee has gone off sick with depression, there do
not appear to be any work characteristics which predict the length of sick leave, although lower education and, surprisingly, being the main breadwinner, do seem to be associated with longer leave.174

Returning to work

A successful return to work is the desired outcome for most episodes of sick leave due to psychiatric disorder; however, there has been little research on how best to ensure that personnel do indeed return to work. The longer someone is off sick the less likely they are to return to work. This is partly due to factors related to the initial difficulties surrounding the decision to take time off, but also relates to obstacles implementing a return to work. Fear-avoidant and catastrophizing coping strategies175 impact on the decision to leave work and are also likely to play a role in decisions on returning to work, particularly in workers who believe that their work has either caused their health problem or made it worse.176 A commonly used technique to overcome some of these problems is a phased return to work. The employee starts back to work initially part-time and gradually builds up the hours and/or days over several weeks. While being apparently sensible, there is little evidence to suggest whether such an approach is the best one to use and, if so, in which circumstances.

Decisions about when to return to work are made more difficult by issues of timing – when is someone who has been off work with a psychiatric disorder ready to go back to work? Although obtaining reports from treating physicians is common practice, the only study of liaison between the employer and the employee’s treating physicians found that doing so actually increased the time to return to work in those with psychiatric disorder, although communication between employer and employee only, had a positive effect.177 There is also no standard way in which an individual moves through the ‘stages’ or ‘phases’. Should the employee increase his hours in a preordained fashion decided at the start or should the increase depend on how well he is performing, or his level of symptoms? In many physical disorders, where the natural history of this aspect of recovery is relatively well understood, these dilemmas may be less important, but recovery from psychiatric disorders is less predictable, and might not fit into a rigid protocol. The attitudes of the individual’s co-workers and resentment over covering their work or perceived underperformance might also play a role in making the return to work a success.178 These effects appear even greater in those from minorities, compounding the discrimination.179

Ill health retirement and disability pensioning

In both the United Kingdom and many OECD countries, psychiatric disorders have now overtaken musculoskeletal disorders as the most common cause of ill health retirement and disability pensioning.2,180 This rise has not occurred due to a fall in the prevalence of musculoskeletal disorders – they have just increased more quickly. Furthermore, this rise in benefit claims for symptom-related disorders does not reflect a similar rise in the incidence of such disorders in the population which have remained fairly static over the same period, suggesting a lowering of the severity at which retirement is awarded. More research is needed to discover what lies behind this discrepancy, but it seems probable that it has been brought about by a greater acceptance of psychiatric disorders on the part of claimants and their doctors. Even then, the true impact of psychiatric symptoms may be underestimated. A large prospective study found that anxiety and depression were strong predictors of ill health retirement awarded for physical disorders.181 The same was found for insomnia, which only in rare cases is denoted as a cause for disability pensions.182

The evidence about the health impact of ill health retirement is mixed – some studies show an improvement over time.183 However, this apparent improvement might instead be a return to normal after a temporarily increased level of symptoms around the time of being awarded the disability pension.184 Given the potential harmful social and individual effects, it is surprising that many who are awarded ill health retirement for psychiatric illness report not having received treatment for it.185 Nonetheless, several studies, most notably of health service employees in the UK, identify that a large minority of people supposedly retired for a (semi-) permanent incapacity are back in work a year later.186

Burnout

Burnout is defined as a ‘prolonged response to chronic emotional and interpersonal stressors on the job’ and is a widely used term in occupational psychology and even a qualifying ‘diagnosis’ for accessing social welfare benefits in some countries, such as Sweden.187 The concept is almost universally measured by one or other version of the originator’s assessment: the Maslach Burnout Inventory (MBI), the primary version of which has 22 items. The three key dimensions, as postulated by Maslach, are of ‘overwhelming exhaustion’, ‘feelings of cynicism and detachment from the job’ and ‘reduced effectiveness/ accomplishment’. There is an extensive literature associating burnout as an outcome of a range of negatively perceived work experiences. However, Wieclaw has identified conceptual and measurement difficulties with this concept, including the challenging issue, from an occupational health and preventive perspective, of providing convincing evidence of the relationship between burnout and specific occupational exposures.188 There are strong correlations of burnout with psychiatric disorders, such as depression and anxiety, and personality traits like neuroticism and job satisfaction (from −0.40 to −0.75). The questions in the
measure itself ask the respondent to attribute their response to their job which, it is argued, establishes that ‘burnout is a problem that is specific to the work context, in contrast to depression which tends to pervade every domain of a person’s life,’187 regardless of conflicting evidence showing the substantial contribution of non-work factors if assessed, e.g. life events.189 This study of medical students also highlights problems with the term being used as an end point. Nearly 50 per cent of the medical students were already classified as ‘burnt out’ yet the vast majority will go on to long and productive careers in the same area. Recent work has shown that once labelled burnt out, someone has a greater risk of permanent disability in Finland even accounting for baseline diagnosable disorders.190 While burnout is not a psychiatric disorder, and unlikely to become so in DSM-V or ICD-11, establishing the concept’s utility and validity as potentially a mediator of work-related stressors and disorder is warranted.

**Comorbidity of physical and psychiatric disorders**

Psychiatric disorders are often comorbid with physical illness. Attributing sickness absence to a single physical ‘cause’ ignores the multiple factors that contribute to the process. The propensity for those with psychiatric disorders to have periods of absence ‘… not necessarily the type diagnosed as nervous’, has been recognized for at least 80 years.191 Many cross-sectional studies have shown higher unemployment or poorer occupational functioning in people who have comorbid depression and anxiety. For instance, the presence of a comorbid depression192 and anxiety193 is associated with greater degrees of work disability across all pain-related conditions.

For those who are employed and experience an episode of physical illness, even accounting for the physical impairment arising from that condition, the presence of mental ill health, usually defined by some cut-off point on a scale, has a deleterious impact upon returning to the workplace. Glozier et al.194 showed that for the 20–25 per cent of people who have a stroke while of working age, over half return to work by six months. However, those with mental ill health were less than half as likely to return, even after adjusting for levels of physical disability and other factors. Similar findings have been shown after myocardial infarction.195,196

**WHAT INFLUENCES THE INTERFACE OF OCCUPATIONAL RISKS AND PSYCHIATRIC DISORDER?**

Most research into the effect of work characteristics upon the development or exacerbation of psychiatric disorder has focused either on the nature of the work or the nature of the disorder. As shown in Chapter 64, Work, stress and sickness absence: a psychosocial prespective (p. 804), a host of contextual factors plays a role in shaping these influences. More recent work has demonstrated the proximal effects of an individual’s cognitive processes as the mediator between external factors and occupational dysfunction. Karasek and Theorell,36 Marmot197 and Stansfeld et al.39 have all alluded to the role of such individual perceptions, which have been extensively studied in the field of musculoskeletal disorders, but less so in psychiatric disorders. What might influence such perceptions is difficult to study, but a range of related personal factors are important determinants of psychiatric disorder and are candidates for mediating the effects of work upon mental health.

Job satisfaction is strongly associated with mental health in meta-analyses,198 as are many aspects of perception and personality.199 These derive from a combination of temperament, mainly genetic, and a range of early experiences. Using lifecourse data, Henderson et al.200 have shown that teachers’ ratings of temperament in childhood and even whether the child’s father was off sick were also strongly predictive of work disability in adult life, over and above accepted predictors such as IQ and education. This suggests there are early life influences upon health behaviours which affect the likelihood of an individual to take sick leave.

Individual perceptions on work functioning are influenced by a number of other contextual factors, the most notable being balancing demands between work and other aspects of life. Appreciation of this by researchers (lagging behind clinicians) has shown that such factors as perceiving an imbalance between work and family/personal lives was strongly associated with current mood problems in both genders and in anxiety in women, even making allowances for standard work stress measures,201 a gender effect seen elsewhere.202 In some cases, a specific home life pressure actually makes some people more likely to come to work.165

The interaction between work factors, the individual and their psychiatric disorder can best be understood using a dynamic model whereby individuals are seen as active agents making decisions about their status along a ‘sickness journey’ as shown below. This accords with what is called the ‘voluntaristic’ aspect of sickness behaviour in an occupational setting.203 It provides a framework for thinking about how to manage an individual with psychiatric symptoms in a specific context as there will be a host of influences on the cognitive factors underlying each decision. Certainly tackling the cognitions that determine these decisions has been shown to improve such occupational disability as return to work after myocardial infarction.204

This dynamic model (Figure 66.2) suggests that an employee’s perception of their symptoms and health occurs in a specific context leading to the person actively making a decision about their work status. The journey starts with perceiving sensations or feelings as symptoms of illness that may or may not have an effect upon function. Any reduced function can be expressed as either taking
leave from work or presenteeism. The decision (point 1) on which of these two options to take will, as shown above, be affected by a range of factors, e.g. personality (conscientiousness, for instance), background culture of working, organizational (team structure or flexibility) and social characteristics (level of unemployment), as well as perceived severity. Most countries allow some period of self-certified absence after which a doctor’s confirmation is required. The decision to seek (point 2): this is also multifactorial and includes such factors as ease of access, benefit systems and perception of how likely the doctor is to concur with the patient. After a period of time on some form of sickness benefit, a decision has to be made upon returning to work – of either the original role in some form – full or modified (point 4) or of moving to another role, or seeking the more permanent support of a disability...
pension (point 3). These time periods, ease of access, level of support, etc., vary dramatically across countries, as do even the diagnoses allowable for compensation. It is the understanding of this sickness pathway that underpins much of what professionals in the field do (Figure 66.2).

**WHAT CAN BE DONE IN THE WORKPLACE?**

While it is clear that workplace factors have a moderate role in the development and perpetuation of psychiatric disorders, and that the public health impact of psychiatric symptoms on occupational outcomes is enormous, it is unclear how governments, insurers, employers and health services should respond. The most striking feature of the research to date is the paucity of high quality studies addressing these questions. There are also differing views from reviews of the same literature, potentially dependent upon the views of the authors and the rigor of the review criteria which make any recommendations difficult.

**Primary and indicated prevention through organizational interventions**

A common conclusion from the epidemiological studies of psychosocial risk factors is that one or more of the identified factors should be tackled to prevent later psychiatric disorder. While there have been some examples of simple changes in the workplace, such as in the pattern of shift work, leading to lower levels of distress, a recent systematic review concluded that there was currently insufficient evidence to judge the effectiveness of any specific organizational changes. Graveling et al. identified a range of participatory approaches to changing organizational practices in 11 studies, fewer than half of which showed a positive benefit upon ‘mental well-being’. A systematic review of organizational interventions to improve employee control could not identify a single randomized controlled trial (RCT) in this field of study. A small majority of the studies showed some benefit and two studies which ran concurrently with redundancies reported worsening health. An interesting observation from a second review by this team suggested that task-restructuring interventions increasing team working had minimal or no effect and that working in autonomous groups in fact caused deterioration in the psychosocial work environment, with resulting health effects. Interventions that did manage to improve employee control appear to have a positive effect, but the processes by which this is achieved have not been identified, making any replication of the study very difficult.

Educating and training individual managers about psychiatric illness and the potential importance of job strain through web-based or more traditional formats, although attractive, does not seem to reduce either job strain or psychiatric illness when evaluated. One intensive 40-hour programme did appear to have a beneficial effect, suggesting a major commitment was needed to make an impact.

**Primary and indicated prevention through individually focused interventions**

Alternative approaches have focused on the individual worker, rather than the work environment, with interventions aimed at increasing an individual’s ability to cope with stressful work situations. Two separate systematic reviews have concluded that the heterogeneity of individually focused prevention programmes and the limited methodological quality prevent any definite recommendations being made. Nevertheless, both reviews reported that the majority of stress management programmes have a modest or short-term impact on a range of variables associated with individual distress. Other reviews have concluded that interventions which reduce psychological distress among workers will also reduce levels of sickness absence. A meta-analysis of 48 experimental studies agreed that individually focused interventions designed to reduce or prevent psychological consequences of occupational stress tended to be more effective than organizational interventions, and that cognitive behavioural therapy had the best evidence for effectiveness. New linked interventions, such as acceptance and commitment therapy (ACT) may have a role in reducing psychiatric disorders in employees via increasing their acceptance of undesirable thoughts and feelings. A similar review in healthcare workers suggested a positive effect of individual interventions, generally cognitive and behaviourally based, on ‘stress and burnout’.

A number of employers have instigated general ‘healthy lifestyle’ programmes to improve employee health and, presumably, occupational performance. Undertaking regular exercise and maintaining a healthy weight may help prevent psychiatric disorders, but no reliable studies have been able to demonstrate that exercise programmes in the workplace reduce levels of psychiatric illness. There is, however, some evidence from observational studies that workers in sedentary jobs who engage in regular strenuous leisure-time physical activity outside the work environment, have a lower risk of sickness absence due to psychological complaints.

**Screening and treatment of established cases of psychiatric disorder**

Health screening is an established part of risk management in many larger organizations. A large trial demonstrated that screening for depression in the workplace, followed by a systematic programme of telephone outreach and care management (encouraging employees to enter appropriate
treatment and monitoring treatment quality) resulted in decreased symptoms, higher job retention and more hours worked. There is also some theoretical evidence that screening programmes may be cost-effective for purchasers.211

Established guidelines on the treatment of depression and anxiety222,223 are based on the broad research evidence from primary and secondary care trials. However, few of these trials have measured occupational outcomes. It is therefore difficult to assess the occupational benefits of interventions recommended in such guidelines, particularly as symptom improvement does not necessarily correlate with return to work.

The Cochrane collaboration has published a systematic review of all randomized controlled trials of work or worker-directed interventions for depression.224 The authors identified 11 studies, involving 2556 individuals, which evaluated the effectiveness of a range of pharmacological and psychological interventions. They concluded there was no evidence that medication, enhanced primary care or psychological interventions have any impact on the amount of sickness absence taken by depressed individuals, although the interventions might have been effective in reducing symptoms. For instance, employers changing an employee’s tasks seems to have a positive effect upon depressive symptoms, while reducing hours or tasks, changing department and sending people on courses had no such effect.174 A recent meta-analysis showed that while a range of different treatments can cause significant reductions in symptom severity, the associated gain in labour output was only a third as large as the reductions in symptoms,225 an observation that does not bode well for any future economic analyses. The apparent lack of an effect of standard treatments on occupational outcomes suggests that additional specific interventions addressing return to work issues may be needed. When occupational health practitioners are available, training them in cognitive behavioural approaches such as graded activity, can result in employees returning to work more rapidly.226

Employee assistance programmes (EAPs) or counselling services are commonly provided by many organizations and these usually use relatively unstructured psychological support offered on a voluntary basis, delivered by individuals from a range of professional backgrounds. An English Appeal Court ruling in 2002 suggested the provision of a counselling service was likely to satisfy an employer’s duty of care, which may have led many employers to implement a counselling scheme as a form of ‘insurance’ against stress at work claims.227 In a 2001 systematic review, the British Association of Counselling and Psychotherapy claimed such counselling could reduce sickness absence,228 although the poor quality of studies included, including no RCTs, has been highlighted.229 Workplace counselling may be helpful for some, but better quality evidence is needed to guide further use of this intervention.

Population-based interventions

Interventions at a societal level, such as improving mental health literacy,230 have been credited with increasing help seeking and treatment for psychiatric disorders. Such campaigns may have a role in tackling the occupational consequences of disease and health promotion advocated as a method of reducing the impact of work stressors on psychiatric disorder.231 In 1997, a public health campaign was undertaken in Victoria, Australia, which aimed to educate the population on the importance of staying active and remaining at work when they suffered back pain.232 Interestingly, a later evaluation of those physicians who claimed to have a special interest in the management of back pain showed that these physicians were most likely to advocate bed rest and avoidance for acute low back pain contrary to recommendations.233 Such potential pitfalls to this approach are also highlighted by Coggon,234 who suggested that the back pain epidemic of the 1970s and 1980s was partly a result of the very interventions aimed to make workers aware of the risk of harm to their backs.

CONCLUSIONS

Over the past two decades, there has been an accumulation of evidence that both objective and subjective characteristics of workplaces are associated with increased risks of psychiatric disorder and mental ill health. None of these have been demonstrated to be sufficient in their own right to cause these disorders, not even catastrophic life-threatening trauma. As with many epidemiologically identified ‘risk factors’ for disease, demonstrating that interventions designed to reduce these risks actually improve health has proven a far more difficult task. Reviews of a range of approaches have yet to demonstrate any repeatable significant impacts of organizational interventions despite their widespread adoption. Individually focused interventions show more promise in improving mental ill health, although how these are to be delivered has yet to be adequately defined. However, the notion that attempts to improve health in an occupational setting actually brings tangible benefits to an organization seems to have been widely accepted with little evidential support.

The lack of a one-to-one correlation between occupational risk factors and psychiatric disorder means that other factors are required for the development of a disorder. These include genetic predisposition, personality, early life events and brain development, substance misuse, and stressors such as illness and other demands, e.g. family, caring and financial. Conversely, there is also no one-to-one relationship of the presence of psychiatric disorder with an inability to work: most people with the common illnesses work and many of those with more serious illness would like to, although the number who do is woeful. We suggest that the increasing levels of work-related disability
(a social construct) across OECD countries, without a demonstrable rise in the population prevalence of these conditions, indicate that there are a range of social factors that are having a major impact. It may be that, at one level, a reduction of stigma and increased health literacy may lead to workers being more accepting of psychological conditions, while the actions of media, professions, employers, unions and government in perpetuating occupationally related mental ill health as a disorder is potentially understated. Much of the public perception of the complex interplay of work and mental health is based upon a relatively poor, or at times non-existent, evidence base upon which to base occupational and medicolegal practice and policy, yet the societal costs of dealing with these conditions are staggering. Understanding the complexity of this topic may be helped by viewing the individual employee as an active agent who makes decisions about their ability to work in the context of their symptoms and perceived stressors, which in themselves are influenced by the medicolegal and sociocultural context in which they reside.

Key points

- Psychiatric disorder has been increasingly attributed to work-related causes and designated as a reason for work disability over the past two decades without any observable change in overall prevalence of these disorders.
- There is little consistent evidence for any independent effect of occupation or profession upon psychiatric disorders when compared to other measures of inequality, such as grade and income.
- There is moderate evidence that a range of perceived psychosocial stressors, including job strain, effort–reward imbalance, perceived bullying, job insecurity and organizational injustice, are associated with psychiatric disorder and mental ill health.
- A range of personal factors, such as early experience of sickness behaviour, personality and education, and contextual factors, such as medical, legal and social security practices, have at least as strong an effect on the expression and development of work-related psychiatric disorder as work and occupational characteristics.
- Successful interventions need to identify how best to balance individual and organizational needs and should view an individual as an active decision-making agent in determining their work and health-related behaviours.
- Persuasive evidence for the effectiveness, and especially cost-effectiveness, of workplace interventions is generally lacking.

Substance abuse and the workplace

JONATHAN D CHICK

INTRODUCTION

This chapter explores for clinicians the relation between substance abuse and health and performance at work. It also considers clinical management of substance abuse, company policies that may be available to help abusers and implications for the occupational physician. Numerous substances are abused, including cannabis, cocaine, opiates and benzodiazepines, but the most common in the working population is alcohol, which is the main focus of this chapter.

DEFINITIONS

Employees with a substance misuse problem can be defined as those whose regular or intermittent use of a substance or mix of substances repeatedly interferes with their work, or the work of others, their job performance or their ability to work, their relationships with colleagues or clients, or their health.

As in the general population, alcohol-related problems in the workplace can be considered as: heavy drinking, acute problems, chronic effects and dependence on alcohol. These overlap in different people in different ways (Figure 67.1). Dependence is a state in which an individual experiences difficulty controlling the intake of the substance, and experiences withdrawal symptoms on reduction or cessation of intake. An affected person may move in and out of periods of dependence. The syndrome tends to be reinstated if, after a period of abstinence, the individual begins to use the drug again.

The terms ‘drug addict’, ‘alcoholic’ and ‘alcoholism’ are still widely used, and usually connote chronic excessive use of the substance, either regular or periodic; an admitted or an inferred difficulty in controlling when and how much is consumed; and usually the experience of social or medical problems (Figure 67.2).
WORKPLACE PROBLEMS RELATED TO ALCOHOL

Work competence and safety

The acute effects of alcohol are chiefly those of a central nervous system depressant, leading to impairment of reasoning, perception, reaction time, balance and coordination. In some drinkers, in the appropriate social setting, a transient disinhibition gives the feeling of enhanced interpersonal communication and well-being. This is partly due to culturally defined expectations. However, in this state, decision-making, operating machinery, driving and other skilled activities are compromised.

Even before the burgeoning of UK alcohol consumption in the late 1900s, surveys found that 24 per cent of company executives in a variety of organizations and 14 per cent of manual workers in alcohol production industries admitted to occasional impaired work efficiency due to drinking in the preceding six months. The dose-related effects of alcohol on motor/perceptual skills and judgement have been shown in American drivers. A blood alcohol level of 60 mg/dL (produced by approximately two consecutive pints of 3.5 per cent alcohol by volume beer, i.e. 4 UK units, where 1 unit contains 8 g ethanol) doubled the risk of involvement in an accident compared with drivers with no alcohol in the blood; levels of 100 mg/dL (consumption of 7 units) and of 150 mg/dL (consumption of 10 units) were associated with increased risk of six and 25 times, respectively. Laboratory experiments show that risk-taking increases and perceptual decision-making skills decline to begin at blood alcohol levels as low as 25–50 mg/dL. After a major train accident in California, a survey of drinking among railroad workers revealed that more than 33 per cent of employees reported seeing a co-worker drinking on duty in the preceding year and 20 per cent reported seeing a colleague too drunk to work.

Workers seeking medical attention after an accident often refuse a blood alcohol test. Thus, estimates of the role of alcohol in industrial accidents are very approximate. In an autopsy study of cases where the death certificate recorded ‘injury at work’, 9.2 per cent were found to have a blood alcohol level of over 100 mg/dL; workers in the transport industry were the most commonly affected. Diazepam was detected in 15.6 per cent of cases, although the extent of its use in the local population of working age was not available for comparison. An autopsy study of fatal occupational injuries in Maryland found that 11 per cent of cases had a blood alcohol concentration of at least 80 mg/dL. Since alcohol continues to be metabolized after death, these rates might underestimate the true prevalence.

Laboratory studies of ‘hangover’ have examined cognitive function the next day after a ‘normal’ evening’s drinking by university students, when the blood alcohol level has returned to zero. They find that performance is impaired on tests of vigilance and reaction time, and possibly memory.

Although heavy drinkers are most at risk of accidents at work, it is moderate drinkers who, because they are more numerous, account for most of the cases; hence ‘the preventive paradox’. Harm at work will be reduced if all employees reduce their alcohol consumption, not only the heaviest drinkers. When a port authority reduced availability of alcohol at lunchtime, it removed a peak of accidents in dock employees in the afternoon and reduced the overall rate of accidents.

Chronic use of alcohol and performance

Light drinking of up to 4 units/day in middle age and above is associated with better cognitive functioning than abstinence, even after adjusting for basic educational attainment, social and health confounders. It is suspected that there are inefficiencies of cognition in those drinking between 8 and 16 units/day, while above 16 units/day impairments of the degree seen in alcohol treatment clinics will sometimes occur, the early signs being impaired problem-solving, rigidity of thought, impaired recent memory and difficulty with spatial tasks.

Epilepsy

‘Rum fits’ were well known in the British Navy, usually occurring two to three days after the ship left port. An analogous situation occurs now in oil rig workers. Oil rigs are alcohol-free zones to which workers return after two weeks on shore. In drinkers who develop chemical dependence, an epileptic seizure can occur when alcohol consumption is reduced or ceases. Although this may be an immediate indication for a change of job if machinery is involved, clinical experience shows that affected individuals do not have recurrence of fits if they maintain long-term abstinence from alcohol (or if, after some months of abstinence, they eventually resume drinking but keep consumption below, say, 10 units per week).

This may be the first presentation of alcohol dependence. Investigations might be necessary to exclude other causes of late onset of fits. The electroencephalogram in alcohol dependence does not show epileptic foci.

Absenteeism

General practitioners are sometimes asked by drug or alcohol users for medical certificates to cover absence from work actually spent seeking drugs or drinking, or recovering from the effects thereof. Clinicians should be aware of the typical pattern. Where weekend drinking is the culture, Monday morning is the most common day for alcohol-related absenteeism, usually because of hangover or gastrointestinal upset. If pay day is on Thursday rather than Friday for the weekly paid staff, some drinkers will not appear for work on Friday. Such absenteeism is common even among those whose alcohol-related problems are not severe.
The study of Scottish company executives/alcohol production workers, mentioned above, found that 4 per cent of the executives and 23 per cent of the workers admitted to being off work because of alcohol in the two-year period before the survey interview. A higher than average medical consultation rate was noted in the ten years that preceded a diagnosis of alcoholism in a sample of US Navy personnel. Drinkers whose problems are sufficient to lead to attendance at an alcohol problem clinic have twice the sickness absenteeism rate of the general population. Sickness absence certificates covering alcohol-related absenteeism span a wide range of diagnoses, including gastritis, anxiety state, nervous disability and injuries. In the New South Wales police force, heavy drinkers were found to have more sickness absenteeism.

Mortality

The famous J-shaped curve of alcohol consumption versus mortality is only seen above age 35. This is presumably because deaths from accidents begin to occur in young people whose average consumption is low, and when they drink heavily they lack tolerance, as well as being inexperienced drivers. The contribution of alcohol has been discussed above. Among new conscripts to the Swedish army (aged 18), those who admitted to drinking over 250 g of alcohol per week (30 units) had a mortality rate over the subsequent 15 years five times greater than the remainder.

The risks of several cancers are increased in drinkers: cancer of the mouth, pharynx, larynx and oesophagus, colorectum and breast cancer in women. Rates of death among heavy drinkers are increased for haemorrhagic stroke, liver disease, suicide and violence. This increased mortality commences with consumption as low as 4 units per day. However, after middle age, abstainers have a higher mortality than light drinkers. Thus, the mortality risk curve for alcohol consumption is J-shaped. Care has to be taken in interpreting these data because the group of 'abstainers' may include ex-drinkers (and often ex-smokers) who have commenced abstaining because of diagnosed illnesses such as heart disease, rather than being life-long abstainers. Moderate drinkers (1–3 units/day) may be people with better social adjustment and a healthier lifestyle than either abstainers or heavy drinkers, but even taking this into account the evidence is increasingly persuasive that moderate ethanol consumption in those over four years of age protects against coronary artery disease and possibly ischaemic stroke.

WORK FACTORS CONTRIBUTING TO ALCOHOL-RELATED PROBLEMS

Mortality rates from hepatic cirrhosis vary with occupational group and are highest in the alcohol manufacturing and retailing industries. Brewery workers were found to have a higher average intake of alcohol at recruitment than biscuit factory workers, but the brewery workers also increased their consumption to a greater extent during the next two years. Thus, both selective recruitment and exposure contribute to the alcohol-related risks in the brewing industry. Both may also be important in seamen (officers and crew) and fishermen, who have mortality rates for hepatic cirrhosis three or four times the average. Absence from home and family, and lack of a normal social and sexual life, are clear risk factors; they may also contribute to the higher rates of cirrhosis in the armed services and the construction industry. In the latter occupation in England, recruitment of labourers from Ireland and Scotland is also relevant, because among them there is a higher proportion of heavy drinkers than among indigenous labourers.

Professions with higher risks include insurance, finance, law and journalism. In the most recent decennial report, UK doctors were for the first time in 40 years no longer showing an increased mortality from alcohol-related causes. Freedom from supervision at work, high incomes and the emotionally demanding nature of their work have been proposed as reasons why these professions have increased rates of alcoholism. The culture at work presumably explains some of the journalists’ problems, just as the business lunch routine and the after-business wine bar have contributed to alcoholism among executives.

Other contributing factors

Clinicians assessing individual patients with alcohol and drug problems must consider the following factors outside the occupational sphere: other psychiatric disorder to which substance misuse is secondary, such as anxiety, phobic or panic disorder, and depressive illness; family history of alcohol or drug misuse (alcohol problems are highly heritable); living alone; or death of a spouse. Divorce or legal separation from a spouse can, of course, be a cause or consequence of substance misuse.

IDENTIFICATION OF THE PROBLEM DRINKER/DRUG ADDICT

The workplace is often where an alcohol or drug problem is first identified. Accidents, illnesses or a drink/drive conviction may make the diagnosis clear. Unreliable time-keeping, coming to work smelling of alcohol and (or) arguments with colleagues are earlier signs, but are often missed. ‘Denial’ of the contribution of alcohol or drugs to such difficulties is common and such overt signs as shaky hands in the morning might wrongly be attributed to ‘stress of the morning business meeting’. The individual may evade any discussion that could implicate alcohol as the cause of his difficulties. The drinker or drug user is likely to perceive any discussion of his habit as one of
moral disapproval: any comment about his behaviour is seen as an insult. He/she may be practised at evasion and colleagues at work may be misled or afraid of upsetting the cantankerous employee, and minimize the problem or cover up. Yet it is the manager at work who is well placed to intervene when an alcohol- or drug-related problem occurs.

Because alcohol has a legitimate and accepted role in Western society, the manager who confronts an employee about smelling of alcohol at work may be made to feel a ‘killjoy’ or ‘wet blanket’. Managers may become more motivated to involve the personnel staff or occupational physician as soon as work performance is affected if they can be persuaded that early intervention for substance misuse can prevent later, more difficult and perhaps costly problems which might arise when the employee is involved in an incident – or long-suffering workmates finally lose their tolerance.

The manager must, however, take a delicate and confidential approach. The manager’s role is not the diagnosis of alcohol or drug problems, but the assessment of work performance. He or she should firmly encourage the individual to consult the occupational physician or general practitioner, who should then deal with the patient with the usual care about confidentiality.

Any clinician assessing a patient with a drink or drug problem should ask about comments or complaints from colleagues and managers at work as well as from those at home, and if disciplinary action has commenced, know what stage has been reached.

When a health screening opportunity arises, a useful questionnaire for alcohol screening is FAST (Figure 67.3).\(^{21}\) The test identifies problems with alcohol at an early stage, as well as later cases of alcohol dependence.

### Assessment

Within the confidential interview (Figure 67.4), the clinician discusses with the employee information from management about performance and attendance. A full history, including a non-judgemental, objective enquiry into drinking patterns and drug use, should eventually be elicited:

- What is your current main concern?
- Help me understand how this came about.
- What are the various factors in your view?
- Where does your use of alcohol fit in? Have you used alcohol to help with stress/insomnia?
- What would your partner say if he/she were here?

The clinician might specifically enquire into the past seven days, work and leisure time, to determine what and where drinking (or drug use) took place. Ask about injuries at home, at work, on the road or at leisure, and enquire about any relation to alcohol. Specifically, ask about police involvement or convictions. Ideally also, information from the family is obtained, because in this situation it is common for individuals to minimize their alcohol or drug intake and the problems caused.

### Clinical features

Intoxication with alcohol or sedatives may manifest as slurred speech or disinhibited behaviour. Inappropriate giggling or elation might indicate cannabis intoxication (Figure 67.5). At physical examination, the heavy drinker may show excessive capillarization of the conjunctivae and skin of the cheeks and nose. Close examination of the tongue may reveal the smell of alcohol on the breath. In the dependent drinker, tremor of the tongue and mouth can be seen before it is visible in the outstretched fingers. Intoxication with sedatives may cause nystagmus. Opiates cause constriction of the pupils; there may be venuценupure marks. The drinker may have an enlarged liver, signs of parenchymal liver disease, cerebellar ataxia particularly affecting the gait, weakness of the proximal shoulder and pelvic girdle muscles, or evidence of peripheral neuropathy.
Concern about performance/absenteeism

HR: ‘There could be a health problem?’

Occupational health

Alcohol problem admitted
BOX A recommend to HR ‘alcohol policy’
Consider safety implications
Consider blood tests for future monitoring
Link with treatment agency
In case of lapse:
Is treatment being followed?

Alcohol problem denied
Physical examination
Blood tests (Figure 26.5)
Positive for alcohol problem
Offer alcohol policy
If accepted, BOX A
Negative for alcohol problem
Negative for other health problem
Disciplinary route

Employee with a suspected alcohol problem

Employee admits problem
Request permission for information from family doctor (GP) records
GP records confirm
Take medical history, note any current medication, examine
Hepatomegaly
signs of neuropathy
Alcohol problem likely if other causes excluded
Smell of alcohol; positive breath or blood alcohol
Alcohol problem likely
LFTs (specify GGT and AST)
(laboratory to keep serum sample for later CDT) Full blood count
GGT, AST, MCV: any one positive and no other reason Alcohol problem likely
Negative/Doubt about a positive
Repeat blood tests in 3 months

Employee denies problem

GP records do not confirm

Objective markers

DRUGS

Workplace urine screening

The UK Transport and Works Act 1992 has led to most operators of passenger transport systems in the United Kingdom introducing urine drug screening for operational staff. Police are empowered to test for alcohol and drugs in railway staff associated with a train accident. Similar legislation was passed in the United States in the 1980s and later federal employees became subject to screening.

That safety is thereby improved has, however, proved difficult to demonstrate. For example, to assess the potential preventive impact of recruitment drug screening, the US Postal Service in Boston monitored industrial accidents, occupational injuries, disciplinary actions and turnover in 2537 new employees. Positive testing for cocaine in the urine at recruitment predicted a raised incident rate in the first and the second year of employment, but testing positive for cannabis was no longer predictive of incidents after the first year. Perhaps cannabis users gradually change their lifestyle as they develop job responsibility. Interpretation of a positive result requires experience and sometimes further analysis.

Reliability of testing

Cannabis metabolites can be detected in urine several weeks after the last dose, but only in very heavy regular users. Traces can be found for three or four hours after passive smoking. Eating biscuits containing poppy seeds can cause a trace of morphine to be found in urine. The concordance between urine analysis and self-reports of drug use in workplace samples tends to be low, suggesting that these detection methods should be regarded as complementary and not alternatives.

Hair grows about 1 cm per month. Drugs and their metabolites are absorbed into hair and can be extracted and measured, for example, by radioimmunoassay. There is doubt about how accurately, if at all, hair analysis can distinguish between frequent and occasional use, and about whether the timing of use can be specified since drug metabolites might ‘move along’ the hair shaft. Evasion or manipulation of the results is easy with urine tests, but not possible with saliva or hair analysis. Both are available through several commercial laboratories.

Legal and ethical pitfalls

An employee’s job could be threatened if a test is positive. Occupational physicians and physicians functioning as ‘medical review officers’ should be familiar with the recommendations given by the Faculty of Occupational Medicine (UK) in its Guidelines for Testing for Drugs of Abuse in the Workplace or those of an experienced forensic toxicologist which are:

1. If, at a recruitment examination or an examination at the request of the employer, blood or urine is to be tested for alcohol or drugs, informed consent must be obtained to collect and analyse the specimen, and to report the results to the employer.
2. Employees should list all medications currently taken.
3. The specimen is collected under supervision, to avoid adulteration or substitution, placed in a tamper-evident container and the steps to testing and recording of the result are audited (the ‘chain of custody’ must be observed).
4. It is good practice to divide the sample into two parts, for analysis at the employee’s laboratory of choice if desired (the specimen cannot be deemed owned by the employer).
5. The employee will have the right to see the result.
6. The medical reviewer or occupational physician, in the view of Forrest, ‘cannot be exempt from the requirement to act in good faith in the best interests of the patients, even though paid by the employer’.

Establishing a drug-testing programme

Before a drug-testing programme of any kind is announced in a company, the employer should be clear about its objectives. These may be public safety, employee safety, financial or information security, or improved performance and quality. The Faculty of Occupational Medicine recommends that companies take legal advice before embarking on a programme. Testing may be in various circumstances, which also need specifying in advance, for example, pre-employment, in-house promotion or transfer, ‘for cause’ (i.e. if there has been unsatisfactory behaviour or performance, post-incident, ‘periodic’, during or after rehabilitation, or as part of a clinical assessment by the company physician).

Monitoring drug abuse treatment

Drug testing should not be an end in itself. It has a use in clinical decision-making, for feedback to patients on progress, and for programme evaluation. However, for patients who are ‘doing well’ (e.g. complying with therapy, employed) a strong or punitive response by the clinician who had detected merely a brief ’slip’ could be harmful overall.

Alcohol

The mean erythrocyte cell volume (MCV) is greater than 98 fL in 30 per cent of men drinking over 50 units per week; serum gamma-glutamyl transferase (GGT) is raised above 45 IU/L in 70 per cent, and in these drinkers rises and falls with changes in consumption. If serum aspartate aminotransferase (AST) is also raised, the clinician can attach
greater confidence to the diagnosis of alcohol abuse. Clearly there are other medical conditions, and medication effects which can cause false positives, obesity is associated with slight elevations of GGT. Two abnormal findings are a stronger indication of heavy drinking than any single abnormality.

Serum carbohydrate-deficient transferrin (CDT) is a marker used by some specialists. A standard 5 mL venous blood sample is required. Only selected clinical chemistry laboratories run the test routinely. The percentage of transferrin which is deficient in its carbohydrate moiety is calculated. This is raised in some 60 per cent of those recently drinking above 60 g per day. It may be elevated in primary biliary cirrhosis, but is only rarely raised in other non-alcoholic liver disease and is not affected by common medications.\textsuperscript{22} Although sensitivity for detecting excessive drinking is only slightly greater for CDT than for GGT, specificity is greater (i.e. fewer false positives). It is useful when the cause of a raised GGT is being explored.

An indirect method of screening for people in whom it might be clinically relevant to ask about drinking, is to ask about fractures or dislocations, head injuries, assaults or road traffic accidents since the age of 18. When sports injuries are excluded, it is found that people who answer ‘yes’ to two or more of the above, and then answer positively to the question ‘Have you been injured after drinking alcoholic beverages’, are likely to have an alcohol problem.\textsuperscript{27}

MANAGEMENT OF SUBSTANCE ABUSE IN THE WORKPLACE

Intervention should occur early, before harm accumulates and dismissal or medical retirement needs to be contemplated. Substance misuse policies and treatment referral procedures have evolved in most organizations. This is partly humanitarian, partly for legal reasons and partly because employers realize it may be cheaper for the company to encourage the employee to have treatment than to put up with his behaviour or to dismiss him.

Workplace policies

The main statements in such policies are:

1. An alcohol or drug problem can be regarded as a health matter, with the corollary that the employee is expected to pursue and comply with treatment.
2. If disciplinary action was indicated, it can be postponed if the employee seeks treatment.
3. If sick leave is required for treatment, the firm will grant it.
4. Information about compliance and success of treatment may be communicated from treatment agency to employer. Evidence of relapse visible at work should be passed to the treatment agency if the employee is still being dealt with under the policy.
5. If there is poor cooperation with treatment, or if treatment fails, the employer may return to the disciplinary route if this were justified (i.e. the ultimate sanctions of disciplinary action or termination of employment on health grounds remain when all efforts at help have failed).

Some large companies in North America employ staff to run the alcohol and drug policy, and to make assessments of drug and alcohol problems. Elsewhere, the responsibility for the policy is with the human resources department, the health and safety team or the occupational health team, and assessments are made by outside agencies including, in the United Kingdom, by the National Health Service. Guidance in the United Kingdom has been provided by the Health and Safety Executive.\textsuperscript{28} It is important that clinicians clarify at the first interview whether such workplace policies exist, and especially whether point 4 (above) applies.

Coercion? – ethics

If there are clear grounds to dismiss an employee, but management postpones this to allow assessment and treatment of an alcohol- or drug-related problem, this may be regarded as ‘constructive coercion’. It is not regarded as ethical for the employer to nudge an employee into medical assessment or treatment with the threat of dismissal if there are as yet no clear grounds for dismissal.

Coercion? – efficacy

‘Motivation to change’ is one predictor of outcome of treatment for substance abuse. An ultimatum from the spouse or the threat of a serious physical illness will often influence motivation, as will an unequivocal statement from an employer.\textsuperscript{29} It is important that such statements are clear – that the obligations and intentions of the firm are delineated and that what is expected of the employee is spelt out. It is possible to do this in a way that is not felt by the employee as punitive.

Several North American studies have shown that the outcome of patients mandated into treatment from the courts or the workplace is no worse than the outcome of ‘voluntary’ patients. In the United States, physicians on probation because of drug or alcohol abuse have, in general, a better outcome than most populations of substance abusers. In part, this may be due to their greater social resources, but may also be because a licensing board has
had a role in their coming for treatment (see under Helping a fellow physician, p. 867).

When treating an employed substance misuser, if his or her problem is already known to the employer, it can sometimes improve the outcome of therapy to recommend such supervision by the employer or his nominee.

When substance abuse has led to doubt about fitness to work in very critical posts, for example in the airline industry (pilots, traffic controllers) and medicine, continued supervision of compliance with abstinence, including random monitoring of breath, sputum, urine or blood tests, contributes to good outcome.

INGREDIENTS OF SUCCESSFUL TREATMENT

Perhaps the most important element of treatment is for the individual to enter a non-judgemental, objective relationship in which he can weigh up the advantages and disadvantages of continuing the alcohol or drug habit. Only then is it possible for him to make a firm decision to alter his habit and obtain support to stick to that decision.

It was common practice in North America, to offer the employee residential treatment with an emphasis on group therapy lasting between four and six weeks. Controlled studies demonstrating the advantage of such relatively expensive treatment over outpatient care are lacking. However, specific psychological treatments such as marital counselling, anxiety management and social skills training have shown to be effective.

Alcoholics Anonymous has helped thousands of alcoholics, in many countries, and a stable fellow employee who is an AA member may be a great help in introducing a colleague. Narcotics Anonymous (NA), for drug abusers, can be found in some cities.

Psychotropic medication to reduce relapse may occasionally have a place if other psychiatric disorders are found to persist after the drug use has ceased.

Two compounds (naltrexone and acamprosate) are now licensed in many countries to help prevent relapse in newly abstaining alcoholics. Their neuropharmacological actions, while different from each other, are consistent with current knowledge of the neurotransmitter basis of dependence and relapse. The characteristics of patients most likely to respond are still to be specified. However, when patients are willing to take disulfiram, in a supervised arrangement to improve compliance (see under Deterrent medication), and are randomly allocated to either that treatment or to supervised acamprosate or naltrexone, disulfiram has been shown to be more effective than either naltrexone or acamprosate.

Medically assisted withdrawal

Withdrawal from alcohol can often be successfully and safely achieved at a specialist outpatient clinic, or at home guided by the general practitioner or nurse. Ideally, the patient is seen daily to monitor the dosage of the medication (usually benzodiazepine) and to ensure that drinking is not continuing. Admission to hospital is appropriate if this fails, or if the individual is liable to severe withdrawal symptoms and lives alone. (A patient drinking 25 or more units per day may require 50 mg of diazepam or equivalent in the first 24 hours, reducing to zero over 5 days.)

Subjects can also withdraw from benzodiazepines, opiates and stimulant drugs as outpatients. The socially unstable young abuser often takes a very wide variety of substances, including alcohol, and discussion during a drug-withdrawal regimen should include strategies of developing a different lifestyle.

Medical aid for the opiate abuser who requests detoxification is necessary only if chemical dependence exists – often such abusers are only intermittent users and hope to obtain more drugs (sometimes to sell) by requesting detoxification. Treatment will consist of either substituting a reducing dose of oral liquid methadone or sublingual buprenorphine, with controls to check other continuing drug use, or attempting to reduce withdrawal symptoms with clonidine or lofexidine, perhaps with a benzodiazepine to aid sleep. A specialist clinic should advise about appropriate doses. Ultra-rapid withdrawal by giving an opiate antagonist while the patient is unconscious under anaesthetic is possible, but is rarely practised because of the risk of respiratory or circulatory failure. It requires full intensive care facilities, an experienced addiction specialist and an experienced anaesthetist. In such hands, the patient’s discharge and return home after being prescribed naltrexone can be achieved in a few days.

Deterrent medication

When an employee has been given his final warning, the treatment agency may suggest that he takes disulfiram supervised at work or at a clinic. The occupational physician or employer’s representative can request assurance that the employee is complying in swallowing the medication as required, which might be daily, or in double doses if administered three days per week. The deterrent effect of this drug is its highly unpleasant alcohol interaction and depends on taking it regularly in sufficient dosage. Counselling on changing lifestyle during the disulfiram-induced abstinence is important if relapse is not to occur when the disciplinary period ends. Naltrexone can be used in the same way with an opiate abuser. Naltrexone blocks the rewarding mental effects of opiates, rather than causing an aversive reaction, and, if taken regularly (perhaps three times per week), greatly reduces the risk of relapse.

Abstinence?

Early, not severely dependent, problem drinkers can sometimes resume problem-free drinking. Those with social
supports (family and job) and without impulsive personalities and many social problems are those who might succeed to control their drinking. Abstinence is the appropriate goal for most other alcohol and drug abusers. Services for opiate addicts, because of the imperative of reducing the spread by needles of AIDS, have emphasized ‘harm reduction’ and offered substitution therapy to many injecting opiate users. Although many opiate users state to research interviewers that they would like to become abstinent, the relapse rate among those who are helped to withdraw is high. Therefore, oral methadone or buprenorphine is offered, to satiate the opioid neuroreceptors and thus to reduce injecting, and stabilize the user’s pattern of life. Patients taking regular doses of substitute opiates may be able to perform satisfactorily at work, unless they are also using additional ad hoc street drugs, which treatment clinics try to prevent but cannot rule out. Maintenance prescribing of benzodiazepine to benzodiazepine addicts is common, and some users continue functioning effectively at work, but should not drive vocationally or operate machinery because reaction time and cognitive function may be impaired.

**Prognosis**

In individuals who have reached criteria for dependence and/or have come for treatment, a period of abstinence from drugs or alcohol of less than a year has no prognostic value. Abstinence for one year begins to indicate a good outcome. Individuals do best when they still have a job and a close relationship. In the emerging life story of males who at some stage in their life abused alcohol, it can be seen that an abstinence period of five years is only very rarely followed by a relapse, but nevertheless can still occur. It is clearly very difficult to decide when it will be safe for a recovering alcohol or drug misuser to resume work, especially if when the job is responsible for public safety, for example as a driver, pilot, ship’s captain or a doctor. Monitoring is essential and might reasonably continue for up to five years, although some US medical boards recommend 15 years.

**Vocational driving licences**

In the European Union and in many other countries, employees with an alcohol or drug problem are not permitted to drive large goods- or passenger-carrying vehicles. A minimum of several years (three years in the United Kingdom) since cessation of treatment, and evidence of recovery, is required before renewal of the licence.

The driver who develops a drug or alcohol problem should declare this to the licensing authorities. Opiate addicts maintained on oral methadone and patients receiving regular benzodiazepines may not hold vocational licences in the UK and the European Community. It is a debated point whether such individuals may hold ordinary driving licences, although studies of psychomotor performance in patients on a stable dose of methadone have not shown impairment.

**Ordinary licence – The high risk offender scheme**

On reapplication for an ordinary UK driving licence following disqualification for drink/driving, a driver must satisfy the Secretary of State for Transport’s medical advisers that he or she is not, or never was, alcohol dependent, if (1) the blood alcohol at the time of the offence was 200 mg/L or more, or (2) he or she refused the tests, or (3) he or she has been disqualified more than once in ten years.

**SUBSTANCE MISUSE AND THE MEDICAL PROFESSION**

The annual reports of the UK regulatory authority, the General Medical Council (GMC), show that alcohol and drug misuse, with or without other psychiatric disorders, is a common cause of unfitness to practise.

‘Stress’ in the medical profession was widely researched and discussed in the 1990s and it appears that personality features may contribute both to an attraction to a medical career and to a vulnerability to stress. Stress can be a factor in substance misuse in doctors, but should not be too readily assumed to be the central issue. For some, addiction has simply begun as a great liking for a drug’s euphoric effects. Medical student life in Western countries can involve heavy drinking. Later on, doctors not only have sufficient income to subsidize heavy drinking, but they also have relatively easy access to other addictive substances. Anaesthetists are at particular risk of opiate misuse (oral or injected) or misuse of anaesthetics (sniffing), and may experiment to the point of dependence. Pharmacists and veterinarians share the high risk of drug dependence due to the availability of addictive drugs.

**Helping a fellow physician**

Work colleagues may have maintained a blanket of secrecy, so that the addiction is well advanced when help is eventually sought. Your support and understanding may be needed, but you may also need to take a firm stance (easier if disciplinary action is pending) to shift the misusing doctor to the point of acceptance that there is a problem to be addressed. This requires courage and compassion, not covering up. If he or she is a work colleague, leave the treatment to a specialist. If the doctor makes no attempt to seek advice, then others who can bring some coercion to bear may need to be involved, for example, the hospital managers, the appropriate section of the local health authority or, when none of these are relevant and fitness to practise is in question, the GMC or appropriate licensing board.
In helping a substance-misusing doctor, the dialogue should be as with an intelligent layman, without assuming he or she has special knowledge. Commence with his or her main concerns, using a non-judgemental style. Avoid secrecy. Be ready to set limits and prevent too early discontinuation of treatment. Beware too ready an acceptance of the view that ‘stress’ or ‘depression’ are the main issues: the main issue may be the substance dependence itself, but this is not yet identified/accepted by the individual. It is easy to collude in a way that only postpones dealing with the dependence on the drug, that is, to making a commitment to abstinence and following methods to achieve that. Monitor progress using objective markers such as breath, blood and urine tests. If matters have reached a point where the professional licensing board is involved, evidence will be required that treatment is being followed and abstinence achieved before limitations on practice are rescinded. The UK General Medical Council appoints supervisors, separate from the treating specialist.

Doctors who resume work tend to have a better outcome than other substance misusers; supervision, with testing, may be a helpful ingredient. Professional mutual support networks should be accessed. In the United Kingdom, there is the Doctors’ and Dentists’ Group, c/o Medical Council on Alcoholism, Tel: 0207 487 4445. In addition, in the United Kingdom, there is the National Counselling Service for Sick Doctors, Tel: 0207 935 5982.

PREVENTION

Limiting the availability of alcohol in the workplace is important and can reduce accidents; similarly, regulations about the taking of psychotropic drugs or alcohol at work or before coming to work can be helpful. One strategy is to provide free hot lunches inside the plant to discourage lunch hour and ‘parking lot’ drinking by blue-collar workers.

Hazardous drinkers, detected opportunistically at family practices, have been shown to respond favourably to fairly minimal medical intervention (such as feedback about their level of drinking or their serum GGT). In one four-year follow-up study, a reduction of sickness absenteeism was demonstrated. Transferring this model to the workplace has been disappointing. In the New South Wales police force, 251 hazardous drinkers attended a brief appointment with a health worker, but this appeared to have no impact on their drinking when compared with a sample of heavy drinkers from police districts where no intervention was being offered. A similar negative result was obtained among Australian male postal workers, although some female staff appeared to have reduced their consumption slightly, related to the intervention. Employee assistance programmes may aim to recruit problem drinkers early, but except in the United States where seeking help for personal problems is perhaps more accepted, self-referrals to these programmes are rare and managers still tend to refer only when impaired work performance is severe or chronic.

Employee committees, when consulted about health promotion they would see as relevant, tend not to mention drugs or alcohol. They perceive organizational stressors as the most important: deadlines, unrealistic expectations, excessive supervision, inadequate supervision, poor feedback and harassment. Health promotion in the workplace should be broad and look at links between personal health practices (eating, smoking, exercise, weight control, stress management) and factors at the workplace. Programmes should help participants to develop or regain a sense of control, efficacy and competence in their health practices, and to use support from family, friends and fellow workers if trying to change these. Such projects are most likely to be successful when the workforce is involved in their development. Health promotion programmes applied in group sessions to workers have not had a striking impact. Didactic teaching that comes down from personnel departments or management is unlikely to succeed in individualistic Western society. It is not known whether more success would be obtained by education projects initiated by the workforce.

Key points

- Alcohol misuse and drug misuse are a cause of absenteeism, inefficiency and work accidents.
- Early identification can be helped by blood tests.
- Abstinence must usually be the goal.
- Workplace policies agreed by employer and employee representatives are helpful.
- Success of an intervention can be helped by sanctions and monitoring which may involve the employer or professional regulator.
- Workplace health education around substances seems to have little effect.

Imaging in occupational lung disease

PAUL M TAYLOR

INTRODUCTION

The developments in imaging technology that have occurred over the last two decades have provided valuable insights into the body’s structure and function. Despite this, the chest radiograph remains the primary and, in many cases, the only radiological investigation performed. The use of more complex imaging techniques often carries a financial and radiation penalty and these must be balanced against the expected benefits.

CHEST RADIOGRAPHY

Conventional radiography

Within a year of Roentgen’s discovery of x-rays chest radiography had been used as a diagnostic tool. The initial images of the chest were crude, but progress was rapid and by the early part of the twentieth century the chest radiograph was a recognized part of clinical investigation. Its validity in occupational lung disease was established as a result of correlative radiological and pathological studies.

The principles of chest radiography are well known. The patient is positioned with the anterior chest placed against a cassette containing the film and the x-ray tube approximately 2 metres from the film, behind the patient. The film is exposed during maximum inspiration. Exposure factors can radically alter the appearance of the resultant radiograph. The radiographer can alter the kilo voltage (kV) of the x-rays produced by the tube. Higher kV x-rays possess more energy and pass more easily through all tissues, producing a ‘flatter’ image with less intrinsic contrast. A high kV exposure may be preferred since it produces clearer images of the mediastinum and the overlying lung. However, this is at the expense of clarity of the ribs and intrathoracic calcifications. The converse occurs with a lower kV exposure.

Radiographic film varies in quality. In order to reduce radiation dose to the patient, manufacturers have developed more sensitive films which produce a similar level of radiographic density at a lower exposure to x-rays. This development, although desirable, is not without its drawbacks and these films may produce a coarser image. This is of particular relevance in occupational disease where subtle alterations in the parenchymal pattern may be significant. The practical impact of these considerations is that in longitudinal studies of workers, no effort should be spared in ensuring that exposure factors and film quality vary as little as possible.

Of equal importance to technical factors are patient variables involved in the radiograph and before any attempt is made at interpretation, the observer should consider the following:

- Is the patient rotated? Rotation produces asymmetry in the size and density of the lungs. Rotation is assessed by noting the position of the medial ends of the clavicles with respect to the spinous processes of the upper thoracic spine.
- Has the patient achieved a satisfactory inspiration? A poor inspiration causes crowding of the basal lung...
Digital imaging

Conventional radiography using radiographic film remains the most frequent method of imaging. However, in the developed world, radiography, including chest radiography, is now increasingly undertaken using digital methods of image acquisition. These include computed radiography (CR) and direct radiography (DR).

In CR, an imaging plate replaces the radiographic film. After exposure, the image produced on the plate is scanned and read by a computer system. The image is then wiped from the plate which is subsequently reused. Direct radiography systems are analogous to digital cameras in that the image is captured directly by the imaging system and transmitted to a computer system without the need for an intermediate plate reading process. The advantages of digital imaging are well described and include a potential reduction in radiation dose, greater reproducibility of the image and the ability to manipulate, process and store the image using one of a variety of storage media. Digital systems may stand alone, with the digital image being printed on to a film to be handled in a similar way to a conventional radiograph, or they may form part of a picture archiving and communication system (PACS) where digital images from several sources, e.g. CR, DR, ultrasound and angiography, are stored, manipulated and distributed within the radiology department and beyond. Digital techniques and digital imaging are well described and include a potential reduction in exposure latitude. It is also possible to manipulate the image to be optimized by changing parameters, such as the exposure latitude. For these reasons, computed radiography systems offer more consistent and reliable images.

is non-linear. In a digital system, there is a linear relationship which ensures a more consistent density to the image, a greater reproducibility between exposures and a wider exposure latitude. It is also possible to manipulate the image using system software. Image manipulation is often referred to as post-processing. Post-processing allows the image to be optimized by changing parameters, such as the image contrast, or adding features, such as edge enhancement, which increases the conspicuity of small structures. In the context of occupational lung disease where early detection of subtle abnormalities is important, the software in the system should be optimized to permit this.

COMPUTED TOMOGRAPHY

The introduction of computed tomography (CT) into clinical practice was a milestone in radiological development. First, it introduced computing into radiology, thus laying the foundations for the development of digital imaging. Second, it established the utility of cross-sectional imaging as a method of displaying anatomy.

The initial CT scanners were suitable only for brain imaging with the system aperture large enough to accommodate only the head. Moreover, the long image acquisition times made them suitable only for immobile structures. By the late 1970s, general purpose CT systems were available and the first reports of their use in the chest were published.

CT has assumed an increasing role in thoracic imaging; however, the principles remain unchanged despite continuing technological development.
During the acquisition of a CT image, the patient lies on the examination table and the area of the body to be examined is positioned within the CT gantry. The CT gantry contains the x-ray tube and an array of x-ray detectors. These are mounted on opposite sides of a ring which surrounds the patient. During the exposure, the x-ray tube rotates around the patient emitting a tightly collimated beam of x-rays. The x-rays emerging from the patient strike the detectors and the data from these are fed to a computer. The computer calculates the attenuation of the beam by the patient's body to produce a matrix (typically 512 × 512) in which the attenuation value of each cell in the matrix is determined. Attenuation values are measured in Hounsfield units (HU). Air has a value of −1000 HU and water 0 HU. Soft tissues in the body range in value between 40 and 80 HU, their attenuation varies depending on factors such as the subject's haemoglobin level, the amount of fat in the tissue and the presence of any calcification. The matrix is displayed as an image by correlating the calculated attenuation values with a grey scale, in which the higher the attenuation value the brighter the shade of grey. Thus, the image consists of many thousands of picture elements (pixels) each one of which represents the attenuation value of a small volume of tissue (voxel). Because of the wide range of calculated attenuation values and the limited number of shades of grey detectable by the human eye, it is not practicable to display each attenuation value as a separate level of grey and the range of attenuation values to be displayed must be selected. The range selected can be altered by changing the window width and level. The window width describes the range of attenuation values that are allocated to the available levels of grey. A narrow window width ensures that tissues of slightly different attenuation are displayed as different levels of grey; this is suitable for demonstrating the mediastinal structures. A wider window is selected to demonstrate the lungs to accommodate the large range of attenuation present. Attenuation values above and below the chosen range appear white and black, respectively. The window level is defined as the attenuation value at the midpoint of the window width. A low level is selected for predominantly low attenuation regions, such as the lung, and a high level for higher attenuation tissues, such as bone.

In common with other digital imaging systems, CT images can be post-processed. Post-processing procedures include changing algorithms to smooth or filter the image, reformatting the data in different planes and statistical analysis of the attenuation data.

**HIGH-RESOLUTION COMPUTED TOMOGRAPHY**

Introduced in the mid-1980s, high-resolution computed tomography (HRCT) of the lungs is now the preferred CT technique in the investigation of diffuse lung disease.8–10 HRCT differs from conventional CT in two key respects:11,12

1. **Section thickness.** In conventional CT, the sections are approximately 10 mm in thickness. In HRCT, the sections are typically no more than 1 mm thick. The beneficial effect of this is that partial volume averaging is reduced. Partial volume averaging occurs when a structure only partially fills a voxel. When the attenuation value for the voxel is calculated an average value is obtained lying between the true attenuation value of the structure and its background. As a result, small structures, such as peripheral pulmonary vessels or small nodules, can be 'lost' because they occupy only a small fraction of a voxel. By reducing slice thickness, the voxels are made smaller and the percentage occupied by these small structures increases, thus decreasing partial volume averaging. The disadvantages of thinner sections are two-fold. First, if the section thickness is reduced from 10 to 1 mm, ten times as many sections would be required to image the same volume of the body. In practice, this is not a problem since the images although 1 mm thick are usually acquired at 10-mm increments rather than contiguously. In effect only 10 per cent of the lung is imaged and this therefore is a second sampling technique problem, inherent in all CT systems, that reducing the section thickness decreases the signal to noise ratio. This makes the images appear rather ‘noisy’ with variations in pixel density even in homogenous body tissue. The problem can be overcome to some extent by increasing the output of the x-ray tube, although this results in a higher radiation dose to the patient.

2. **Reconstruction algorithm.** In calculating the attenuation values of the voxels the computer has to deal with biological heterogeneity of body tissue, variation in x-ray output and other factors which produce variations in the calculated attenuation of ostensibly homogenous structures. To overcome this software used in conventional CT smoothes these variations, reducing the differences between adjacent voxels. However, in heterogeneous tissues, such as the lung, smoothing results in loss of clarity of the margins of small structures making them appear blurred. In HRCT, however, a high spatial frequency processing algorithm is used which has a much reduced smoothing function.

The majority of HRCT images are obtained with the patient supine during maximum inspiration. However, in some circumstances, it may be preferable to perform prone or expiratory images.

Due to the greater hydrostatic pressure in the supine position, the vessels in the posterior lung become distended and there is an increase in the extravascular fluid. This produces an increase in the attenuation of the posterior lung which can obscure underlying structural change.
 Imaging in occupational lung disease

(Figure 68.2a,b). This is of particular importance in asbestosis since the posterior lung bases are the most frequently involved portions of the lung.

By turning the patient prone and repeating the sections, the hypostatic changes are repositioned anteriorly. A period of 5–10 minutes is required for full reversal of these changes. Failure to undertake this manoeuvre can result in fibrosis being obscured by the hydrostatic changes or normal lung being misinterpreted as abnormal.

Air trapping in the gas exchange spaces of the lungs occurs in several conditions including extrinsic allergic alveolitis. It is difficult to detect air trapping on inspiratory scans, but expiratory sections are helpful. On expiration, the normal lung decreases in cross-section and increases in attenuation. In regions of air trapping, these changes fail to occur and they become highlighted against the normal lung.

In recent years, multislice CT has become established in clinical practice. Multislice CT systems subdivide each acquired axial section into multiple (typically 32 or 64) subsections. This produces images of similar resolution in the sagittal and coronal planes, as in the axial planes. The potential benefits of this technique in respect of pulmonary anatomy are under evaluation.

Enhancement of the mediastinal structures by intravenous contrast plays a key role in differentiating normal from abnormal structures, particularly lymphadenopathy. This is not usually required in patients with occupational lung disease, but is invaluable in staging patients with occupationally induced bronchial carcinoma.

ULTRASOUND

Outside the cardiovascular system, the applications of ultrasound in the thorax are limited by its inability to pass through the gas-filled lung. However, ultrasound is helpful in imaging the pleura. It is often difficult to differentiate pleural fluid from solid pleural masses on chest radiography; moreover, the two can coexist. Real-time ultrasound allows detection and quantification of pleural fluid and is a highly sensitive method of detecting small effusions. It can identify pleural masses and permits accurate percutaneous biopsy of lesions including mesothelioma. Pleural plaques can be identified by ultrasound, but CT is the preferred technique.

MAGNETIC RESONANCE

The ability of magnetic resonance (MR) to image in multiple planes with high intrinsic soft tissue contrast without using ionizing radiation has made it an essential imaging tool in many areas of the body, in particular the brain, spine and skeleton. Within the thorax, it has established a role in cardiovascular and mediastinal imaging. Its use in the lung is restricted for several reasons.

1. Magnetic resonance primarily images protons. Within the lung, the large amount of air produces a very low proton density.
2. The combination of air-containing spaces and interlacing vessels produces heterogeneity in the magnetic field which significantly degrades the image.
3. There are physiological movements, in particular cardiac and respiratory motion, which produce artefacts.

Despite these problems, several studies have demonstrated the ability of MR to image patients with diffuse lung disease. It is likely that further developments in MR will be
directed at improving our knowledge of pathophysiological events rather than replicating CT and providing structural data. In this context, the high intrinsic soft tissue contrast of MR may enable the differentiation of active pulmonary infiltrates from more indolent fibrotic processes.

**RADIONUCLIDE STUDIES**

The most frequently performed radionuclide studies of the lung are ventilation/perfusion lung scans in patients with suspected pulmonary embolic disease. In occupational lung disease, two other less frequently used techniques should be considered.

1. Gallium-67 ($^{67}$Ga) is produced by cyclotron. When injected intravenously, it is accumulated, by a variety of mechanisms, into inflammatory tissue including pulmonary inflammation. The process is slow and scans are obtained one to three days after the injection. Several inflammatory processes, including drug-induced lung disease, sarcoidosis, fibrosing alveolitis and asbestosis, have been shown to take up $^{67}$Ga. The resulting scans are sensitive, but not specific.23–25

2. Technetium-99m diethylenetriamine penta acetic acid (Tc$^{99}$m DTPA) aerosols can be used to assess alveolar integrity. The patient inhales the aerosol and the lungs are imaged by the gamma camera. From the resultant images, the rate of clearance of the radionuclide from the lungs is calculated. This is normally less than 4 per cent per minute. Increased rates are seen in patients with a variety of conditions, including extrinsic allergic alveolitis.26 Higher rates of clearance are also seen in smokers and in patients with respiratory infections.27

Although these techniques provide elegant demonstrations of pathophysiology, their role in clinical investigation is limited. Structural changes are more clearly demonstrated by HRCT and conventional pulmonary function tests provide a more practical alternative to assess functional impairment.

**COALWORKER’S PNEUMOCONIOSIS**

**Simple coalworker’s pneumoconiosis**

In addition to coal dust, miners frequently inhale quantities of silica dust from adjacent rock strata. The composition of the coal dust and the proportion of silica affect the radiological appearances of coalworker’s pneumoconiosis (CWP).

The prime radiological feature of simple CWP is the development of well-defined, relatively discrete pulmonary nodules. The nodules tend to spare the extreme lung bases and do not calcify (Figure 68.3).28 Unlike in pure silicosis, mediastinal and hilar lymph node enlargement does not occur as part of simple CWP. The size and clarity of the nodules is related to the composition of the dust. Nodules tend to be larger in those miners exposed to dust with a high silica content. It is now recognized that irregular small opacities can also occur in simple CWP and are associated with dust exposure, the presence of emphysema and impairment of lung function.29,30 The profusion of nodules is related to the degree of exposure. HRCT is more sensitive than chest radiography in the detection of the nodules.31 The extent of CWP demonstrated by HRCT is also related to the severity of pulmonary functional impairment.32,33 At least one study has demonstrated an increased incidence of bronchiectasis in workers with CWP, the severity of which is related to the degree of exposure.34

**Caplan’s syndrome**

Caplan’s syndrome is a rare condition occurring in dust-exposed workers with rheumatoid diathesis (with or without clinical arthritis). Although first described in coal-workers, it has also been observed in workers exposed to silica and silicates. It is characterized by the development of single or multiple well-defined nodules within the lungs, which may be calcified. These are typically 0.5–2 cm in diameter and occur in crops or clusters (Figure 68.4). The nodules may cavitate, enlarge and coalesce, although they often remain static over several years.
Complicated coalworker’s pneumoconiosis

The defining process in the development of complicated CWP is the formation of areas of progressive massive fibrosis (PMF). Characteristically, the lesions occur in the mid and upper zones of the lung and are frequently bilateral. They are ovoid or ‘sausage’-shaped and enlarge over many years to reach several centimetres in diameter. In advanced cases of PMF, there is often distortion and marked emphysema in the surrounding lung. PMF usually occurs on a background of nodules of simple CWP of at least category 2 profusion (see Table 68.1), but the background nodules may become less apparent as the emphysema becomes more advanced. The lesions of PMF rarely cavitate and there may be hilar lymph node enlargement. In clinical practice, the prime differential diagnosis is bronchial carcinoma which has an occurrence, even in miners, many times that of PMF.

Silicosis

The appearances of silicosis are not dissimilar to CWP. However, the degree of fibrosis present in the lung is greater and as a result the nodules are larger, more discrete, and tend to become confluent. Hilar and mediastinal node enlargement occurs and the periphery of the nodes calcifies producing an ‘eggshell’ appearance. Silicosis is now an uncommon condition in developed countries and sarcoidosis is a more common cause of these appearances. However, silicosis remains a problem in less developed countries. PMF occurs infrequently in silicosis (Figure 68.5).

People with silicosis are at increased risk of tuberculosis; this may lead to new upper lobe shadowing on serial radiographs and cavitation of confluent silicotic nodules. HRCT demonstrates changes not appreciable on chest radiography. These include emphysema, bronchial dilatation and, on expiratory sections, air trapping.

Asbestos exposure

With the decline in coal mining in the United Kingdom, asbestosis is now the most frequently encountered pneumoconiosis. The radiological features can be considered under three headings: pleural disease, pulmonary diseases and extrathoracic manifestations.

PLEURAL DISEASE

Pleural plaques are the most frequent radiological feature of asbestos exposure. They form well-defined, rather angular densities. These are most easily seen on the chest radiograph when they lie along the lateral chest wall or over the diaphragm, since in these positions they lie tangential to the x-ray beam rather than en face. The plaques may calcify...
producing a ‘holly leaf’ appearance (Figure 68.6). The full extent of plaque deposition is most reliably assessed by CT (Figure 68.7). On chest radiographs, the appearance of plaques can be mimicked by subpleural fat deposits and prominent intercostal muscles; however, CT can differentiate these appearances. Pleural plaques are almost specific to asbestos exposure, although they are occasionally seen in workers exposed to other silicates.

Diffuse pleural thickening is less common than pleural plaques, but unlike pleural plaques it may lead to a restrictive functional abnormality if it encases the lung. The thickening varies in thickness and has tapered, ill-defined margins. Asbestos-induced pleural thickening uncommonly calcifies and this helps to differentiate it from thickening secondary to empyemas and haemothoraces (Figure 68.8). As with pleural plaques, the extent of pleural thickening is best assessed by CT.

Malignant mesothelioma is accompanied by a pleural effusion in approximately two-thirds of cases and this is often the main radiographic feature, obscuring the underlying tumour. The tumour itself forms a well-defined lobular mass with tongues of tissue extending over the pleural surface producing encasement of the lung in the affected hemithorax. The ribs appear crowded due to the shrinkage of the underlying lung, but rib destruction is an uncommon feature (Figure 68.9). The tumour can spread through the diaphragm. The features are most easily appreciated on CT (Figure 68.10). Although biopsy can be obtained by CT or ultrasound guidance, this is one of the few tumours which can seed along the biopsy track and prophylactic radiotherapy should be administered to the biopsy site.

The main radiological differential diagnosis is of metastatic pleural tumour, particularly adenocarcinomas. Pleural thickening and thymic tumours, which have a predilection to extend into the pleura, can produce similar appearances.
Asbestosis is characterized, on the chest radiograph, by the presence of fine reticular basal shadowing producing loss of clarity of the cardiac silhouette. Increased public awareness in North America and Europe has meant that patients are often investigated when the extent of pulmonary fibrosis is mild, frequently before the radiographic features are visible on a standard chest radiograph and the radiological changes are detectable only on HRCT.
The main HRCT features are ill-defined areas of subpleural high attenuation, linear parenchymal band opacities due to fibrotic strands, peripheral reticulation and curvilinear subpleural densities.\textsuperscript{46,47} These features are most commonly encountered at the posterior lung base and for this reason prone HRCT sections should be performed to prevent them being obscured by hypostatic change (Figure 68.11a,b). Although typical of asbestosis, the features described are not specific and are seen in other fibrotic lung conditions, particularly usual interstitial pneumonia (UIP) and differentiation can be problematic.\textsuperscript{48}

Pulmonary pseudotumour, also referred to as round atelectasis or folded lung, is caused by a severe local inflammatory reaction occurring in the lung periphery adjacent to an area of pleural thickening. It produces a well-defined rounded opacity, usually in the lower lobes and more commonly on the right.\textsuperscript{49} HRCT shows the adjacent pulmonary vessels dragged into the mass producing a whorled appearance described as the ‘comet tail’ or ‘vacuum cleaner’ sign (Figure 68.12).\textsuperscript{50}

Bronchial carcinoma, occurring in patients with asbestosis, has no distinguishing radiological features from bronchial carcinoma occurring in other patients, although there is an increased incidence of synchronous and metachronous tumours.

**EXTRATHORACIC MANIFESTATIONS**

Peritoneal mesothelioma occurs almost exclusively after asbestos exposure. The tumour forms a dense cicatrizing mass that encases loops of small bowel and mesenteric vessels. Barium studies show areas of strictured bowel with fixity and loss of peristaltic activity. The tumour mass and any associated ascites are well seen on CT.\textsuperscript{51,52}

**Siderosis and stannosis**

Iron and tin are both inert dusts and do not excite an inflammatory reaction when they are inhaled. However, they produce striking radiological features. Due to their relatively high atomic number (iron = 26, tin = 50) compared to the majority of elements in the soft tissues (carbon = 6, nitrogen = 7 and oxygen = 8), they are radiographically dense and produce a myriad of small, high-density nodules. The nodules of stannosis tend to be smaller but denser than those of siderosis (Figure 68.13). The appearances can appear similar to other causes of miliary mottling, such as miliary tuberculosis or miliary metastatic deposits. However, the density of the nodules should allow differentiation.

**Berylliosis**

The main adverse effects of beryllium are observed in the lung. Acute exposure to high concentrations of beryllium can cause an acute pneumonitis. The chest radiograph shows patchy airspace opacities which resolve rapidly on removal from exposure. More frequently occurring is chronic beryllium lung disease. Prolonged low-dose exposure produces, in a minority of individuals, a chronic granulomatous reaction affecting the lungs and thoracic structures.
lymph nodes. The radiological features are similar to those seen in sarcoidosis with bilateral nodular pulmonary infiltrates predominantly affecting the mid and upper zones of the lungs often with associated hilar and mediastinal lymphadenopathy.53

Extrinsic allergic alveolitis

In its acute form, extrinsic allergic alveolitis (EAA) produces widespread, ill-defined, small opacities. These are almost invariably bilateral, although the extreme lung bases and apices are often spared.54 The opacities are not particularly dense and produce a hazy veiled appearance to the lungs, described as ‘ground-glass’ opacification (Figure 68.14). The opacities are fleeting and in a substantial proportion of patients, the chest radiograph is normal at the time of presentation. HRCT shows abnormalities more frequently than the chest radiograph and is particularly effective in demonstrating the ‘ground-glass’ appearances (Figure 68.15).55
International Labour Organization classification

Pleural effusions and nodal enlargement are uncommon and this helps differentiate the condition from infective pneumonias.

In the chronic form of EAA, fibrosis occurs, typically in the upper lobes. The radiological differentiation from other causes of upper zone fibrosis, including sarcoidosis and tuberculosis, may be difficult, but pleural thickening, pulmonary and nodal calcification do not occur in EAA.

Pulmonary infections

A wide variety of animal workers are at potential risk of contracting animal-borne infections. The most common are brucellosis, psittacosis and Q fever.

Brucella infection produces an acute pneumonic illness with areas of consolidation visible on the chest radiograph. Hilar and mediastinal lymph node enlargement occurs. In chronic brucellosis, multiple bilateral nodular opacities are present and the appearances can resemble sarcoidosis.

Psittacosis and Q fever both produce pneumonic changes. The radiographic features are indistinguishable from other forms of pneumonia, although Q fever can pursue a chronic course.

Some workers are at increased risk of infection from human sources. Examples include an increased incidence of tuberculous infection in mortuary attendants and influenza in healthcare workers. The radiographic appearances in these workers are identical to those observed in non-occupational cases of infection.

INTERNATIONAL LABOUR ORGANIZATION CLASSIFICATION

In 1930 the International Labour Organization (ILO) published a system for the classification of radiographs of the pneumoconioses. This has been revised on several occasions, most recently in 2002. The system combines qualitative descriptions with qualitative assessments. In order to standardize the classification, the ILO publishes a series of reference radiographs. In addition, the ILO recommends the technical parameters which must be met to allow the radiograph to be classified. These parameters include the type of film used and the exposure of the film. In the United States, radiologists and physicians wishing to apply the classification must attend a training programme to become accredited readers. The widespread use of digital imaging will have an impact on the use of the ILO classification as the conspicuity and appearances of lesions are modified by these techniques. At the time of writing, the National Institute of Occupational Safety and Health in the United States recommends the continued use of conventional radiographs, although it is likely that in the near future a revised ILO classification based on digital radiographs will be introduced.

The aim of the classification is to standardize radiographic classification of the pneumoconioses. It is intended for use in research, epidemiological or statutory investigations; it is not a tool for routine clinical practice.

There are several components which are considered and coded in the classification:

1. Film quality. The quality of the radiograph, which is recorded on a three-point scale. Grade 1 is optimal and abnormalities in exposure, position or processing artefacts, which affect the film quality, are recorded.
2. Small opacities. These are divided into regular and irregular opacities. The regular opacities are graded by size, the irregular opacities by width. The profusion of these opacities is then assessed. Using the short form of the classification, a four-point profusion scale is used, a 12-point scale is used in the extended form.
3. Large opacities. These are graded by size. They are usually few in number and profusion is not considered.
4. Pleural plaques. These are assessed for size, calcification, extent and width.
5. Pleural thickening. In the short form, this is assessed as present or absent. In the extended form, the position, thickness and extent of thickening are recorded for each hemithorax.
6. Additional features. There is a list of additional features which are also recorded. These include the presence of cancer, bullae, effusions and cavities.
The ILO classification (Table 68.2) was designed to be applied to chest radiographs. However, it has been applied to HRCT images. The results, although correlated, are not transposable since HRCT demonstrates higher sensitivity for most of the components.

### Key points

- Chest radiography in occupational lung disease requires meticulous attention to detail to ensure standardization and reproducibility of the images.
- Digital radiography has largely replaced conventional radiography in developed countries.
- High resolution computed tomography is more sensitive than chest radiography in the assessment of the majority of patients with occupational lung disease.
- The radiographic appearances of many occupational lung diseases are similar to other, more common, non-occupational diseases.
- The International Labour Organization classification is a tool for epidemiological, research and statutory compliance, rather than clinical evaluation.

INTRODUCTION

Chronic air flow limitation results from a persistent diffuse reduction in airway calibre relative to the degree of lung inflation (i.e. airway obstruction), which cannot be reversed by treatment. The fixed nature of this obstruction is the cardinal feature, but this is shared by several pathogenically distinct disorders. They are recognized collectively to produce chronic obstructive pulmonary disease (COPD). The importance of COPD lies with its tendency to progress and to cause a disabling, even life-threatening, loss of lung function. It seems likely that 10–20 per cent of current cases can be attributed to occupational causes, but the evidence to confirm this has proved to be illusive. The investigatory difficulties that have arisen will consequently be reviewed in some detail, as will persisting uncertainties and controversies.

It has been conventional to apply the term COPD to fixed airway obstruction which develops insidiously over many years – long before any symptoms are recognized. Recent experience demands an adjustment to accommodate a few novel subacute causes which produce fixed airway obstruction over a matter of weeks or months at bronchiolar level (bronchiolitis obliterans). Bronchiolitis obliterans may also arise acutely as a rare complication of toxic lung injury (e.g. from gassing accidents or warfare), but this has been recognized for many decades and is beyond the scope of this chapter.

DEFINITIONS AND EPIDEMIOLOGY

Airway obstruction which responds partially, but not fully, to treatment implies there may be an asthmatic or acute bronchitic component to the disorder, of which the fixed component alone should be identified as COPD. The fixed component may itself be a consequence of long-standing asthma, but more commonly it is a consequence of emphysema or obstructive bronchiolitis. Bronchiectasis too often leads to COPD, but is an uncommon cause of COPD overall. Whether chronic bronchitis should be considered a cause depends on whether it is defined solely by a persistent, otherwise unexplained, productive cough – as it usually is. Many subjects with mucus hypersecretion (and hence chronic productive cough) have no airway obstruction, implying that when both chronic bronchitis and COPD do occur together, they are usually independent effects of the same inducing cause – for example, cigarette smoking.

It is estimated that about 10 per cent of adults are affected by COPD globally, depending on the diagnostic criteria used. The prevalence is higher (about 14 per cent) in industrially developed countries, with 1–2 per cent affected severely. Although most are smokers, as many as 3 per cent of never-smokers have COPD to some degree. COPD is currently the sixth leading cause of death globally and is projected to become fourth by 2020. It is already ranked fourth in individuals aged over 45 years in Europe.
and the United States, and is responsible for 200–300 deaths per 100,000 per year in industrially developed countries.

Data from the third National Health and Nutrition Examination Survey (NHANES 3) suggest that 19 per cent of COPD in the United States overall can be attributed to work, while among never-smokers the percentage climbs to 31 per cent. The American Thoracic Society estimates independently that about 15 per cent of COPD in the United States is occupationally induced.

The recent Global Initiative on Obstructive Lung Disease (GOLD) adopted the commonly used value of 70 per cent for the ratio of forced expired volume in 1 second (FEV₁) to forced vital capacity (FVC) as the defining point for airway obstruction – that is, the lower limit of normality. It is recognized that the ratio tends to fall as a normal consequence of ageing and so this definition may lead to the prevalence of COPD being underestimated in young adults, but overestimated in the elderly.

**HISTORICAL BACKGROUND**

That COPD might arise as a consequence of the occupational environment is a matter of evolving interest and importance, and not a little controversy. The possibility of COPD of occupational origin, unassociated with complicated pneumoconiosis, first gained widespread acceptance as recently as the 1960s as a result of a series of investigations in cotton workers by Schilling and Bouhuys and colleagues. They suggested that cotton dust-induced airway disease (byssinosis) could be usefully classified into three distinct clinical grades. Workers who developed chest tightness and breathing difficulty only on the first working day of each week were said to have byssinosis grade 1; those who had similar symptoms on additional working days of the week, but who recovered fully away from the workplace, were said to have byssinosis grade 2; and those who had symptoms of persisting respiratory disability were said to have byssinosis grade 3. Physiological studies indicated that byssinosis grades 1 and 2 were associated with reversible airways obstruction, while byssinosis grade 3 was associated with fixed airways obstruction. It was assumed that affected workers followed an orderly progression through these escalating grades. Cotton dust was consequently a potential cause of COPD, and byssinosis grade 3 was the first documented example of occupational COPD.

The specific effects of cotton dust are discussed in detail in Chapter 73, Byssinosis and other cotton-related diseases, and so cotton dust and byssinosis will be mentioned here only to provide a convenient historical focus for reviewing the claims and controversies which have arisen subsequently from many occupational environments concerning COPD.

Many (perhaps most) authorities would now regard byssinosis grades 1 and 2 as occupational asthma attributable to cotton dust. The physiological correlates (acute, but reversible episodes of airway obstruction) are diagnostic of asthma, and the curious work-related periodicity of the symptoms (which had been considered particularly characteristic of byssinosis) has since been observed with other types of occupational asthma. As with active asthma of any aetiology, airway hyper-responsiveness can be demonstrated to a variety of bronchoconstrictor agents at times when byssinosis grade 1 or grade 2 is active. If, then, byssinosis grades 1 and 2 are examples of occupational asthma, is occupational COPD (i.e. byssinosis grade 3) simply a consequence of occupational asthma? This is certainly plausible, since long-standing asthma of non-occupational origin often results in fixed airway obstruction.

The relation of byssinosis grade 3 to byssinosis grades 1 and 2 may, however, be looked at from a different viewpoint to that adopted by Schilling and Bouhuys. The investigations which led to their grading classification were cross-sectional not longitudinal in structure. Grade 1 byssinosis was not, in fact, observed to progress to grade 3 byssinosis, and so it is conceivable that byssinosis grade 3 is a fundamentally different disorder from byssinosis grades 1 and 2, albeit one which is also induced by occupational exposure to cotton dust. If this is so, byssinosis grade 3 could be regarded as the prototype for occupational COPD, and the question arises whether it is likely that cotton dust alone among occupational agents would have this effect on the airways?

Most of the cotton workers of the 1960s had been heavy cigarette smokers for many years, and doubts were expressed subsequently whether the confounding effect of this on the development of COPD (which was barely recognized in the 1960s) was adequately taken into account. Although recent investigations have confirmed that COPD does arise as a consequence of occupational exposure to cotton dust independently of smoking, this relationship remained uncertain for many years, and the confounding role of cigarette smoking came to lie at the centre of current controversies.

**UNCERTAINTIES AND CONTROVERSIES**

The experience with the cotton industry provides invaluable lessons for the assessment of occupational COPD, and for evaluating today’s inevitable controversies. In essence, they centre on whether an excess prevalence of COPD in a given working population has arisen from some other cause (such as smoking or asthma), rather than the working environment, and whether, if the workplace is responsible, COPD arises independently of occupational asthma or as a direct consequence of it – or both (Figure 69.1). There is a further source of confusion – regular exposure to respirable dusts and irritant gases/vapours commonly leads to mucus hypersecretion and to chronic productive cough (i.e. chronic bronchitis). In an occupational setting, this is often termed ‘industrial bronchitis’. When chronic bronchitis develops coincidentally alongside asthma (whether occupational or not), the emergence of obstructive
symptoms (wheeze, chest tightness, undue shortness of breath) is often attributed, not unreasonably, to COPD and to the cause of the productive cough.

The possible presence of coincidental asthma (now a common disease at all ages in the population at large) may consequently simulate occupational COPD. This is particularly likely if industrial bronchitis or smoker’s bronchitis coexists. Asthma of non-occupational origin may also simulate occupational asthma because it is likely to worsen transiently in the workplace if there are respirable irritants, and in some occupational settings (e.g. cotton mills) the development of occupational asthma is as plausible as the development of occupational COPD. If it is true that there are substantial differences in the prevalence of asthma from region to region, from population to population and from birth cohort to birth cohort, as is now suggested, formidable difficulties must be expected in allowing for this if a given working population appears to show an excess of COPD.

The difficulty in distinguishing between asthma and COPD is compounded by the common occurrence of both disorders in the same individual. When this does occur, however, the clinical features tend to resemble those of COPD alone much more closely than asthma alone – as pointed out in the recent American Thoracic Society statement, ‘Occupational contribution to the burden of airway disease’.6

### CIGARETTE SMOKING – CONFOUNDING AND INTERACTIONS

The relative effects of smoking and occupation on COPD can only be assessed from epidemiological investigations where study populations include smokers and non-smokers, and workers with different levels of the relevant occupational exposure (some, ideally, with none). There may be difficulty in finding such a balanced population, and there may be difficulty in avoiding bias in the exposure histories which are obtained. The investigation of possible occupationally induced disease often leads to anxiety, anger and claims for compensation in at least some of the study population. Once these arise, memory for the noxious nature of former workplace environments may prove to be better preserved than that of former tobacco consumption.

An important additional tendency is for those who are best able to tolerate the heaviest levels of tobacco consumption to take on jobs with the most noxious occupational exposures (and vice versa), or for cultural or family influences to link smoking with recruitment to particular types of work. This inevitably confounds any potential effect of the work environment with that of smoking, and is illustrated in Table 69.1.4 Here, the smoking habits of 15- to 16-year-old school leavers applying for a range of apprenticeships associated with three levels of exposure to noxious working environments (low, medium, high concentrations of welding fume) are compared with established workers aged 19–26 years in the same trade groups. The clear differences in current smoking prevalence seen between the occupational exposure groups of the workers can also be observed in the school leavers before any occupational exposure occurred, though age exerted an additional effect and increased the prevalences in the older workers in all work-exposure categories.

Smoking is thus likely to be associated with the very occupational environments which are themselves suspected of causing COPD. This may lead not only to confounding, but to an exaggerated survival bias. The most susceptible workers are likely to leave the particular working environment prematurely if they develop COPD (whether from smoking, occupational exposure or both), thereby producing a surviving population which is less severely affected. Investigation of the surviving workers will underestimate the occupational hazard involved. Furthermore, those workers who are initially less able (or less willing) to tolerate noxious exposures will avoid the relevant working environments and this will exert an additional bias (healthy-worker effect) on the selection of populations who work with the risk of developing occupational lung disease. Investigators, regulating bodies, employers and employees may be hard-pressed to recognize when longitudinal loss of ventilatory function in a working population is truly excessive once the idiosyncratic effect of cigarette smoking is taken into account. Full smoking histories are consequently essential in research, and should include a quantitative measure of cumulative consumption.
The issue is unduly complicated because only a minority of smokers (15–20 per cent) appear to develop COPD (hence the idiosyncrasy) and because doubts over the accuracy of past smoking histories may invalidate, or at least weaken, the statistical analyses involved. There may be strong justification for such doubts. In a UK study of the population at large, it was concluded that up to 7 per cent of smokers and former smokers had described themselves incorrectly as never-smokers,15 while in an American study of coal miners seeking compensation, as many as 15 per cent claimed to be never-smokers despite recording in earlier assessments that they were regular smokers.16

**PATHOPHYSIOLOGY**

Fixed airway obstruction, when not due to chronic asthma, may be a consequence of either destructive disease of the lung parenchyma and interstitium (emphysema), or of intrinsic inflammatory/fibrotic disease of the small intrathoracic airways (obstructive bronchiolitis). It is questionable whether mucus hypersecretion alone (chronic bronchitis) has this effect. With emphysema, airway obstruction and air trapping are associated additionally with impairment of gas transfer and loss of elastic recoil. It is this loss of elastic support to the smaller airways, whose walls are not supported by cartilage, which leads to airway collapse and obstruction (Figure 69.2), particularly during expiration. Most surveys attributing COPD to occupation have not included measurements of parenchymal function (gas transfer) and so it is unclear whether emphysema was the chief underlying mechanism.

Extensive work with COPD attributable to smoking has shown that emphysema is not always present. Even in the absence of emphysema, the smaller unsupported airways provide the most probable primary site for the obstruction to airflow, there being a mixed pathological picture of inflammation and fibrosis chiefly in and around the bronchioles. The disorder is more accurately described as obstructive bronchiolitis or bronchiolitis obliterans, than as chronic obstructive bronchitis (Figure 69.3). However, bronchial inflammation is often seen, especially when there is chronic productive cough. This is best regarded as an independent phenomenon and is often unassociated with airflow limitation. COPD is also associated with bronchiectasis, but the underlying mechanism is at present uncertain.

The potential importance of obstructive bronchiolitis has taken a new twist over the last few years with the recognition of subacute causes among workers inhaling certain food-flavouring materials, synthetic fibre flock and garment printing dyes. Disablement occurs within a matter of weeks or months of exposure onset, rather than years.

**RECOGNITION OF EXCESSIVE DECLINE IN VENTILATORY FUNCTION**

An epidemiological approach to estimating the rate of decline in ventilatory function offers the only practical means of identifying insidious occupational causes of COPD in living populations, though the evidence obtained has been tested experimentally in a number of animal models. If the occupational contribution to COPD in a given workforce is relatively small and if COPD itself is uncommon (often the case in populations subjected to healthy worker and survivor biases), the investigation of large numbers of subjects will be necessary if an occupational effect is to be shown convincingly. Such investigations are necessarily time-consuming and expensive. They must also be complex if multiple regression techniques are to take adequate account of all the various factors which may independently influence the measured end point (i.e. the level of ventilatory function) or interact with environmental exposures of relevance. Otherwise, there is the risk that these factors (e.g. age, height, race, gender, social grouping, changing body mass, smoking, passive smoking, air pollution, viral infections, atopy, airway responsiveness) might be distributed unevenly between subgroups of the study population which differ also in the levels of exposure to the agent suspected of inducing COPD. If such unevenness occurs it
might explain or exaggerate significant differences which appear otherwise to be a consequence of the occupational agent. Conversely, it might mask a true occupational effect in investigations which appear to give negative results.

**Chronic obstructive pulmonary disease and cigarette smoking**

From a series of pioneering epidemiological investigations of COPD attributable to cigarette smoking, Fletcher and colleagues\(^1\) showed during the 1960s that the majority of smokers appeared to experience no adverse effect on ventilatory function. In the minority who were seen to be adversely affected, an excess annual decline in FEV\(_1\) could be deduced from cross-sectional data (i.e. FEV\(_1\) appeared to be excessively diminished in older subjects who had smoked). The magnitude of the apparent decline in FEV\(_1\) with age (FEV\(_1\) slope) was related to the level of smoking consumption. The mean annual decline among symptomatic smokers appeared to be approximately twice that of the non-smokers. The excess rate of decline could be detected after as little as five years of regular smoking and its cumulative dose-related effect was readily quantified by the degree of fixed airway obstruction evident already at the time of the initial measurement of ventilatory function.

A cohort of the men investigated cross-sectionally by Fletcher and colleagues (male transport and postal workers in London) was followed longitudinally, so that the actual annual changes in FEV\(_1\) could be measured. The mean decline in FEV\(_1\) (when standardized for height) was about 30 mL/year. The actual rates of decline were related to height, smoking and symptoms, and they appeared to increase a little with increasing age. The excess rate of decline in smokers ceased when they gave up the habit, but the damage already sustained was permanent (Figure 69.4).

A similar natural history is to be expected from any cause of COPD, though there will be much variability from individual to individual, and in some of those affected many exposure years will pass before the disease becomes evident.

**Discrepancy between cross-sectional and longitudinal data**

When data from the London workers were analysed from the initial cross-sectional study, regression of FEV\(_1\) on age suggested a rather greater mean annual decline of 46 mL/year. That is to say, the differences in FEV\(_1\) between the youngest and oldest participants in the initial study suggested that the mean annual decline in FEV\(_1\), after allowing for differences in height, was about 1.5 times the rate actually measured during the subsequent longitudinal phase of the investigation. The discrepancy was not readily explained at the time. It is a discrepancy which has since
The investigation involved a 'normal' population of 52 adult caucasian males, aged 30–58 years, of whom nine were current smokers, 16 former smokers and 27 never-smokers. There were no relevant occupational exposures. Three subjects reported chronic cough and seven undue breathlessness. The initial 1974 measurements were slightly less than those of 1975, possibly reflecting inexperience with spirometric manoeuvres and so the period 1975–79 may provide a more accurate estimate of longitudinal change than 1974–79.

Thus cross-sectional data cannot be extrapolated to predict longitudinal change with any precision and should not be compared directly with longitudinal data from other investigations. Much of the discrepancy arises because subjects at the younger end of an age spectrum of, say, 20–60 years from a current cross-sectional investigation do not necessarily have the same mean FEV₁ as did those at the older end of the spectrum some 40 years earlier when they were of a similar young age. In fact, the currently young subjects are likely to have greater values of FEV₁ at a standardized young age, partly because they have larger lungs and partly because they are less likely to have sustained respiratory diseases (e.g. tuberculosis, bronchiectasis) which impair ventilatory function. The difference in FEV₁ between younger and older subjects at the time of a cross-sectional study therefore exaggerates the true declines which were experienced by the older subjects during the preceding years. Furthermore, the currently young subjects are likely to encounter less lung damaging insults as they age to 60 years, compared with subjects who had already attained 60 years. Thus, mean longitudinal decline in lung function in populations is not wholly a consequence of increasing age and of cumulative exposure to cigarette smoke or occupational agents.

It depends also on the cumulative burden of all damaging pulmonary insults throughout the ageing period (Figure 69.5).

By using study subjects as their own controls and avoiding the problems which arise from mismatching in cross-sectional studies (i.e. by eliminating between-worker variability), longitudinal studies are inherently more satisfactory. They are less 'sensitive', however, because they detect change over the period of longitudinal surveillance only. By contrast, cross-sectional studies quantify the changes which have occurred throughout the lifetimes of the participants. Longitudinal studies may also be more vulnerable to diminishing participation rates, and this may introduce new risks of bias. They are also lengthy and very expensive.

**Other non-occupational factors of possible relevance**

The study of London transport and postal workers usefully suggested that although intercurrent episodes of respiratory tract viral infection (i.e. episodes of acute bronchitis, exacerbations of COPD) caused significant reductions in ventilatory function, the effect was only temporary. Full recoveries to former levels of ventilatory function were noted within a few weeks, after which the rate of longitudinal decline returned to its usual level. Repeated viral infections do not therefore influence the assessment of occupational COPD from either cross-sectional or longitudinal studies, provided there are no acute infections at the time of study. Whether intercurrent episodes of acute bronchitis following brief exposure to toxic chemicals at work (e.g. gassing accidents) will prove to be equally
benign is currently a matter of much speculation, concern and ongoing investigation. Major accidents which produce life-threatening pulmonary toxicity are recognized to cause bronchiolitis obliterans in a small proportion of survivors, although the majority of survivors appear to recover fully. A few develop asthma, which may persist indefinitely and so pose a further pathway for the emergence of COPD.

This asthmatic complication of acute pulmonary toxicity (it may also follow a series of less toxic exposures, one alone having insufficient potency) has been termed the reactive airways dysfunction syndrome (RADS).19,20 The term is unhelpful in one sense because it suggests, incorrectly, that RADS is a disorder distinct from asthma. However, it is helpful in another sense because it neatly categorises a major subgroup of occupational asthma cases (some 5–10 per cent overall) for which the mechanism is reasonably clear. For the remaining cases, the mechanism(s) is generally assumed to involve hypersensitivity pathways, but confirmatory evidence has been illusive for many causal agents (particularly low molecular weight chemicals) and with certain organic dusts (e.g. from cotton, grain, animal confinement buildings) endotoxin from contaminating Gram-negative microorganisms may play a critical role in inducing asthmatic responsiveness.6

Age, height, race, gender, smoking and increasing body mass all exert important influences on the measurement of ventilatory function, and it may be that passive smoking and air pollution during the course of longitudinal investigation will also exert potentially important (adverse) effects. The wide range of apparent individual susceptibility to COPD suggests a dependence on genetic factors and there is supportive evidence for this especially from twin studies.21,22 Genetically determined atopy has not generally been found to influence COPD, but this depends on how COPD is defined and how vigorously an asthmatic contribution is excluded.

Analysis of data from the American Multicentre Lung Health Study suggests that airway responsiveness (to methacholine) may prove to be almost as important as cigarette smoking in exerting an adverse influence on the rate of decline in ventilatory function.23 If it is confirmed that a measure of asthmatic activity is relevant to predicting the development of COPD (a relationship enshrined in what became known as the Dutch hypothesis of the 1970s and 1980s, but disputed thereafter), then factors of aetiological relevance to asthma may also need to be taken into account when studying COPD.24,25 It may be useful, therefore, to consider the occupational agents (or environments) that have been associated with COPD in two categories – those which are also believed to cause asthma through ‘non-RADS’ pathways and those which are not. It may also be useful to classify them according to whether current evidence identifies them as ‘definite or probable’ causes of occupational COPD (Table 69.3) or merely ‘possible’ causes (Table 69.4).

### CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND AGENTS KNOWN TO INDUCE ASTHMA

**Naturally occurring inducers of occupational asthma**

Respiratory disease in grain workers has been widely recorded since the eighteenth century and the time of Ramazzini. Grain dust has become a particularly well-recognized cause of occupational asthma, although the precise causative agent (or agents) remains unclear. Storage mites, microbial contaminants, pesticides and fungicides, and even rodent urinary proteins have all been incriminated together with allergenic material derived from the grain itself. A number of investigators have produced impressive evidence that occupational exposure to grain dust may also lead to COPD, though none has suggested that this is a direct consequence of occupational
asthma and most have found some inconsistencies among their data. The uncertainty as to the precise causal agent extends to many other settings associated with occupational COPD (and asthma), and thus Tables 69.3 and 69.4 refer either to a particular agent or to a particular setting.

The experience of Chan-Yeung and colleagues in the port of Vancouver provides a useful illustrative example. They followed port grain workers and control subjects working in civic centre posts between 1978 and 1990. After six years, the annual rates for the decline in FEV1 were significantly greater among the grain workers (−31 mL/year) than the controls (+4 mL/year), but when the smokers alone were studied little difference was noted between grain workers and controls (−36 mL/year versus −31 mL/year). In this particular investigation, therefore, the grain–COPD effect was seen largely in the non-smokers (in whom asthma was not satisfactorily excluded though atopy proved to be irrelevant) and it appeared to be of similar magnitude to the smoking–COPD effect in the control workers. Furthermore, its demonstration depended on there being an unusually small annual decline in FEV1 among the controls (in fact, there was a trivial increase). After 12 years, significant differences between grain workers and controls were no longer evident, but this may have been a consequence of survivor bias or of the greatly diminishing levels of grain dust exposure during the course of the investigation. Not all investigators have found this COPD effect. When it was observed, it was generally clearer among the smokers than non-smokers, contrary to the Vancouver experience.

Grain dust is also encountered by farm workers, who additionally encounter other types of occupational dust from harvesting and storing crops, hay and straw, and from handling and feeding livestock. Several asthmagenic agents may contribute to their risk of COPD, which has been demonstrated from a number of studies. The refined product of grain, flour, is encountered by many workers beyond the farming community, and has proved to be a potent cause of allergic asthma and rhinitis. It too appears to cause COPD, not necessarily in association with asthma.

With wood dust, a further common cause of occupational asthma, evidence for a COPD effect is less strong. Again there is evidence that smokers may be unduly susceptible to it. This is noteworthy in view of the curious ‘protective’ effect of smoking observed with occupational asthma attributable to western red cedar. A similar protective effect in smokers, for which there are plausible immunological explanations, has been observed with extrinsic allergic alveolitis and sarcoidosis, and so should not be dismissed too hastily.

Chemical inducers of occupational asthma

In the United Kingdom in recent years, di-isocyanates have been a common cause of occupational asthma and di-isocyanate asthma continues to provide a typical example of asthma attributable to occupational chemicals. Not unnaturally, di-isocyanate workers have provided a focus for investigations, of which there have been many, of possible occupational COPD. The results have been conflicting. A major multicentre surveillance programme in the United Kingdom revealed no hint of a COPD effect, while study of a single di-isocyanate-producing plant in the United States suggested a crippling occupationally induced mean decline in FEV1 exceeding 100 mL/year. Both investigations may have been flawed: the one because there was an implausibly low prevalence of occupational asthma (and possibly a major survivor bias), the other because the levels of ventilatory function observed initially were too well preserved for an excessive decline of such a degree to have been occurring before the investigation commenced.

The five-year investigation of Diem and colleagues of workers in a new toluene di-isocyanate-manufacturing plant included an extensive series of exposure measurements, from which the workforce was usefully separated into categories of low–average cumulative exposure (<68.2 ppb-months) and high cumulative exposure (>68.2 ppb-months). The high exposure group showed a significantly greater annual decline in FEV1 (−37 mL/year) than the non-smokers of the low exposure group (+1 mL/year), but it was not influenced by smoking. Smoking did, however, lead to a similar excessive decline in those with low levels of di-isocyanate exposure. Thus, similar excessive declines in FEV1 of modest degree appeared to result from either di-isocyanate exposure or smoking, without there being any additive or multiplicative effects (Figure 69.6). These conclusions differ from the general consensus, which does favour an interaction between smoking and the occupational environment, but they mirror those derived from the grain workers in the port of Vancouver. Interestingly, Diem and colleagues attempted to identify asthmatics from their study population, and showed no weakening of the COPD effect when these workers were excluded from the analysis.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND AGENTS NOT KNOWN TO INDUCE ASTHMA

Cadmium

Cadmium-induced emphysema was first described in 1952. For some years, doubts persisted as to whether the apparently excess prevalences of COPD noted among some, but not all, cadmium-exposed working populations might instead be a consequence of smoking. More recent investigations involving long-term surveillance have provided more convincing evidence that cadmium does indeed cause emphysema. Thus, in a case–control study, Davison and colleagues found radiographic and spirometric evidence of emphysema in twice as many men manufacturing copper–cadmium alloy for at least one year than in
unexposed controls with similar smoking habits, and they identified a significant dose–response relationship linking cumulative measures of exposure to decline in gas transfer.

Although cadmium is a trace component of cigarette smoke, cumulative exposures from smoking alone are not likely to approach those sustained occupationally. It seems improbable that smoking-induced emphysema could be attributed to cadmium.\(^{39}\)

### Mineral dusts

Although airway obstruction was quickly recognized to be a feature of complicated pneumoconiosis and of its accompanying emphysema, COPD in the absence of complicated pneumoconiosis was until recently attributed to other, coincidental, disorders. High mortality rates from respiratory disease in some groups of miners led to early and intensive investigations of large numbers in many countries.\(^{40–43}\) Although complicated pneumoconiosis and occupational tuberculosis were associated with excess respiratory mortality and morbidity, the pattern of respiratory disease in miners seemed otherwise similar to that in their families and in suitably matched control populations.\(^{44–47}\) It appeared to be related more to social circumstances (and particularly to smoking) than to the working environment.

The largest investigations involved coal miners, principally because of the enormous populations employed over the years in the coal mining industry and partly because of political influence. Particularly detailed cross-sectional studies from British and American coal mines both showed excess declines in FEV\(_1\) related to estimated cumulative levels of exposure to coal mine dust, after appropriate adjustments for the effects of smoking and other potential confounders.\(^{48–51}\) Similar associations between lung function impairment and exposure were subsequently reported from other countries. In the most heavily exposed miners, the severity of the dust effect approached that of smoking. The conclusion that coal mine dust causes COPD was partly but not fully supported by subsequent longitudinal studies – FEV\(_1\) decline during the surveillance period being related to the cumulative (lifetime) levels of exposure, but not exposure sustained during the actual periods of surveillance.\(^{52,53}\) The cumulative level of exposure from employment onset was calculated from measured levels during the studies together with estimates of earlier levels using extrapolations and so could include inaccuracies. The relation might also have been confounded by factors exerting an accumulated effect over the years of exposure (for example, air pollution, passive smoking and weight gain), for which adjustments were not made. For some, uncertainty persists. It may prove to be irrefutable because exposure levels (hence risk) and the numbers of active coal miners (hence epidemiological power) have diminished too profoundly. The optimal opportunity to demonstrate a COPD effect from coal dust may already have passed.

The evidence does, nevertheless, point to a COPD effect from coal dust.\(^{54}\) This led to it becoming a prescribed industrial disease in the United Kingdom in 1992 (Prescribed Disease D12: ‘Chronic bronchitis or emphysema’ in underground coal miners, see www.opsi.gov.uk/si/si1993/Uksi_19931985_en_1.htm, for more information), providing the claimant has worked underground for at least 20 years and severity is sufficient to reduce the FEV\(_1\) by 1 litre from its predicted value. An amendment of 1996 catered for miners of short stature and benefit became payable as soon as the FEV\(_1\) fell to or below 1 litre. The UK’s prescribed diseases legislation requires that the relevant occupational exposure doubles, at least, the risk which already exists within the population at large (thereby making it more likely than not in an affected individual that the disease in question would not otherwise have arisen). At present, only occupational exposure to coal mine dust is considered to meet these requirements, although COPD from occupational exposure to cotton dust or cadmium is already covered by separate state legislation. A possible need for wider ‘prescription’ was considered by the UK’s Industrial Injuries Advisory Council in 2007. It recommended that surface work with coal dust should also qualify for state compensation, provided the worker has exposure for a minimum of 40 years. This implies that two years of surface work has roughly the same adverse effect as one year underground, and so surface and underground work can now be aggregated to satisfy the minimum requirement for cumulative exposure.

![Figure 69.6 Longitudinal loss of FEV\(_1\) versus toluene di-isocyanate (TDI) exposure. Compiled from data in Ref. 35.](image)
Similar events were experienced in South Africa in relation to exposure to respirable silica in gold mines. Although state compensation became available there from 1952, later investigations did not provide uniformly supportive evidence of a silica-related loss of ventilatory function. More recently, cross-sectional and longitudinal studies have shown an excess of COPD in silica-exposed workers which could not be attributed to smoking, but there was no clear relationship with intensity of exposure. In one investigation, silica and smoking appeared to exert effects of similar magnitude, while in another, the influence of smoking on FEV₁ decline was approximately twice that of silica exposure. In the severe cases which led to death, an interaction between the two environmental factors seemed likely.

Both siliceous and non-siliceous ore is encountered in the refining and smelting of metals generally, and exposure to a number of airborne mineral dusts is inevitable during the processing of iron and steel. The dusts involved are considered 'mixed', and in some circumstances have posed excess risks for pneumoconiosis, lung cancer and COPD. Investigation of some groups of asbestos-exposed populations has suggested asbestos-induced impairment of ventilatory function at the small airway level, thought not of sufficient degree for asbestos to be considered a cause of COPD.

So far there is not convincing evidence to suggest that man-made (ceramic) mineral fibre poses a risk for COPD. The issue could change, however, as fibres of increasingly smaller diameter are produced. Some exposed populations have shown an excess prevalence of pleural plaques, but this was possibly a consequence of earlier, coincidental exposure to asbestos.

Welding fume

Welding fume is conveniently considered separately from other minerals, partly because the circumstances of exposure are rather different, partly because a possible COPD effect in welders is a matter of considerable topical interest and partly because evidence of an additional asthmagenic effect is now emerging. The latter is convincing for stainless steel welding fume (where hypersensitivity to chromium is presumed), but most welders work with mild steel or other metals, not stainless steel, and the evidence for asthma here is less convincing.

Consistent with the investigation of numerous workforces exposed regularly to respirable irritant or noxious dusts, vapours or fumes, many investigations of welders have demonstrated a clear excess prevalence of chronic productive cough (industrial bronchitis). Until recently, none has found convincing evidence of an excess of airway obstruction implying, perhaps, that if there is a COPD effect it must be of relatively small degree.

A small but significant COPD effect was the conclusion of a cross-sectional study of 607 shipyard workers carried out by Cotes and colleagues. The workforce spanned an age range of 17–69 years. After allowing for age and height, the trades associated with welding fume exposure showed a mean and significant overall loss in FEV₁ of 250 mL compared with the unexposed trades. This effect was noted only among the smokers. From the original study population, 487 were re-examined seven years later. Multiple regression analyses suggested that FEV₁ was declining at an annual rate of 16.2 mL for a 50-year-old non-smoking worker without occupational exposure to welding fume. The additional losses attributable to smoking and welding fume exposure were 17.7 and 16.4 mL/year, respectively. Interactions were noted between welding fume and smoking, and between welding fume and atopy. There was no effect from welding fume on gas transfer. The longitudinal study consequently suggested that a mild COPD effect attributable to welding fume might also occur in non-smokers, but it confirmed that this effect was greater in smokers. The further enhancement of the effect in atopic subjects provides a hint of an asthmatic component, and the lack of any effect on gas transfer suggests that COPD was not occurring as a consequence of emphysema. In the absence of smoking and atopy, the risk of COPD was not clearly doubled by welding fume.

Non–tobacco smoke

Although welding fume usually contains smoke (particulate products of combustion) from surface coatings or contaminants, its probable adverse respiratory effects are chiefly consequences of metal fume itself. Smoke (and oxides of nitrogen and sulphur) from sources other than welding and tobacco may nevertheless contribute to COPD, whether encountered in industrial settings, during firefighting, in polluted air generally or in poorly ventilated domestic environments where biomass (e.g. wood, crop residue, charcoal, dung) is used as a cooking fuel. Biomass smoke, in particular, was thought to explain the higher prevalence of COPD in a rural compared with an urban area of China, both in the study populations as a whole (12.0 versus 7.4 per cent) and in the non-smoking women who did most of the cooking (7.2 versus 2.5 per cent). A further Chinese study demonstrated a significantly diminished relative risk of COPD in both men (0.58) and women (0.75) when efficient chimneys were installed for cooking stoves that were previously unvented.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE OF SUBACUTE ONSET

The unusual experience of observing COPD develop over a matter of weeks or months only, has made it much easier to identify a number of interesting and recently emerged causes of subacute bronchiolitis obliterans. Because of moderate or severe (even life-threatening) disablement, the identities of the causal agents were quickly established. Evidence
that bronchiolitis obliterans could result from inhaled popcorn-flavouring ingredients was first published in 2002. Its recognition in eight former workers from a single American factory packaging popcorn for microwave use led to the term ‘popcorn worker’s lung’. It was sufficiently severe in four that lung transplantation was considered. Investigations by the National Institute for Occupational Safety and Health (NIOSH) showed that the prevalence of fixed airway obstruction among continuing employees was 3.3-fold that expected, that bronchiolitis obliterans could be detected in workers from four of five subsequently studied microwave popcorn plants and that a prominent ingredient providing a butter taste (the oily organic chemical 2,3-butanedione [diacetyl]) could cause airway necrosis when inhaled by laboratory animals. Subsequent publications have shown that occupational exposure to diacetyl, as a food-flavouring ingredient, has caused obstructive bronchiolitis in settings other than popcorn manufacture and in countries other than the United States. \[\text{NIOSH}\] showed that the prevalence of fixed airway obstruction was 3.3-fold that expected, that bronchiolitis obliterans could be detected in workers from four of five subsequently studied microwave popcorn plants and that a prominent ingredient providing a butter taste (the oily organic chemical 2,3-butanedione [diacetyl]) could cause airway necrosis when inhaled by laboratory animals. Subsequent publications have shown that occupational exposure to diacetyl, as a food-flavouring ingredient, has caused obstructive bronchiolitis in settings other than popcorn manufacture and in countries other than the United States. The Industrial Injuries Advisory Council in the United Kingdom has recommended prescription of bronchiolitis obliterans in association with exposure to diacetyl.

No evidence at present suggests that diacetyl is hazardous when ingested, but the possibility is not lightly dismissed. Inhaled diacetyl causes a relatively pure form of obliterative (or constrictive) bronchiolitis as does the ingestion, as an appetite suppressant, of leaf extracts from the Asian shrub, Saururus androgynus, in the population at large. Occupational exposures to the sprayed garment print dye, acramin (Ardystil syndrome) and dust-containing fragmented synthetic polymer fibres (flock worker’s lung), carry the potential for more widespread parenchymal lung disease. Some affected subjects show a lymphocytic pneumonia or bronchiolitis obliterans organizing pneumonia (BOOP), while in others the subacute inflammatory response is largely confined to the bronchioles. Acramin is no longer used as a transport chemical for the dyes used for garment printing, and flock worker’s lung appears to occur only when rotary cutters (rather than guillotine cutters) are used to produce flock. In consequence, both diseases should be readily controllable. It remains to be seen whether a suitable substitute will be found for diacetyl within the food-flavouring industry (perhaps butter itself) and whether the sporadic cases of obstructive bronchiolitis identified so far may prove in an epidemiological sense to be tips of icebergs. In any event, physicians need to be aware that COPD is not always an insidious disease which progresses slowly over many years. Some cases, and perhaps many, are subacute in nature and they may arise in unexpected settings.

**PERSPECTIVE IN THE POPULATION AT LARGE**

The relative risk posed to the general population by common allergens, outdoor air pollution, air pollution within the home and respirable agents at work is a matter of increasing public concern, particularly with regard to the aetiology and progression of COPD and asthma. Both disorders are clearly dependent on changing patterns of life within industrially developed countries and so environmental factors must be of great relevance. It may be that many different respirable agents are capable of exerting an influence and that in different individuals the measured COPD effects are due to different combinations of these agents (the ‘multiple hit’ hypothesis) together with inherent susceptibility.

Recent investigations in the former east and west regions of Germany provide interesting comparisons within the developed world between, respectively, an area of high smoking prevalence and relatively high outdoor air pollution from industrial emissions, and one of high domestic affluence. It appears that COPD dominated in the former and asthma in the latter, although in the more affluent societies there is greater not lesser outdoor pollution from vehicle exhausts. This is thought to be of relevance to asthma in Los Angeles where such pollution is persistently high and intermittently dramatically so, but a recent comparative study using measurements of airway responsiveness between an urban area with more modest exposure to vehicle exhaust (Newcastle upon Tyne, UK) and a rural area with low exposure (Cumbria and the English Lake District) showed no difference. Vehicle exhausts are changing qualitatively as well as quantitatively, however, and it remains to be seen whether the products of catalytic converters will pose new hazards despite eliminating those associated with lead.

Further perspectives regarding the possible role of occupational exposures in the aetiology of COPD in the population at large can be seen from the results of an epidemiological investigation of urban (Bergen) and rural (Hordaland) communities in western Norway. A postal survey first sampled 5000 individuals from a total population of 250,000, and from the respondents an age-stratified sample of 1500 was invited to undertake a more detailed investigation that included respiratory symptoms, smoking history, work history and spirometry. In all, 1275 individuals participated. When COPD was defined from strict spirometric parameters alone (FEV1/FVC < 70 per cent and FEV1 < 80 per cent of predicted), smoking proved to be the only explanatory variable of clear relevance from multiple regression analyses.

When COPD was defined less stringently but more clinically from objective spirometry (FEV1/FVC < 70 per cent) or subjective symptoms (chronic productive cough together with undue breathlessness or wheeze), the odds ratios for participants reporting specific occupational exposure to aluminium, welding/metal fume, quartz or asbestos all increased to significant levels; so too did the odds ratio for heavy exposure to any source of occupational dust. An increased prevalence of COPD was also noted in the urban compared with rural communities, but this was attributable to the greater number of elderly individuals (who were affected disproportionately) living in the city of Bergen.
The study population was consequently sufficiently large for subjective evidence of occupational productive cough to be demonstrated. However, the excess prevalences of strictly defined airway obstruction, which were noted among certain groups of workers, did not reach conventional levels of statistical significance.

In its 2007 review, the UK’s Industrial Injuries Advisory Council did not identify any further occupational causes, other than coal mine dust, cotton dust and cadmium fume, which it considered should qualify for state compensation. This should not be interpreted to mean that the council does recognize additional causes of occupational COPD. Its tasks are to recognize causes of COPD which are likely to cause significant disability (i.e. a loss of FEV₁ of at least 1 litre or a loss in short subjects so that the FEV₁ is no more than 1 litre) and to identify which circumstances of cumulative exposure increase this risk of COPD at least two-fold. This implies, in the individual satisfying these criteria, that it is more likely than not that he/she has become significantly disabled by COPD because of occupational exposure. As the council acknowledged, there is evidence that many other occupational exposures may well cause COPD, and it may be that evidence will emerge in due course to show that some do indeed pose a risk of such a magnitude as to justify state compensation within the United Kingdom.

CONCLUSIONS

Evidence relating occupational environments to COPD is extensive but often conflicting, and this inevitably stimulates controversy. Any summary is necessarily influenced by personal, biased and possibly preconceived views and so it should be emphasized that the following key points reflect a changing scene and a personal interpretation of it.

Some occupational environments are likely to exert a COPD effect and it may be that 10–20 per cent of all cases of COPD in industrially developed countries are occupational in origin.

Key points

- Differences in individual susceptibility play an important role.
- The impact of occupational exposures on COPD is likely to be less than that of smoking (perhaps much less), but will vary from industry to industry depending on potency and exposure level of the agent involved.
- Complex adverse interactions probably exist with smoking and (presumably) with other environmental agents.
- It is plausible that both asthmatic and non-asthmatic pathways play a role.
- Occupational COPD will be found uncommonly in the absence of both smoking and asthma.
- Some cases of fixed airway obstruction are subacute rather than chronic in their development, and have surprising and unexpected causes.

Health effects of ultrafine/nanoparticles

KEN DONALDSON, ROBERT J AITKEN, JON G AYRES, BRIAN G MILLER AND C LANG TRAN

INTRODUCTION

Nanoparticles (NP) and ultrafine particles are interchangeable terms used to describe particles less than 100 nm in size. It has been suggested that the term 'ultrafine' be constrained to accidental or naturally occurring particles of this size and that the term 'nanoparticles' be used for manufactured particles of this size, but there is no general agreement on this, and the terms are used interchangeably in this chapter.

Occupational lung disease has long been associated with exposures to low aspect ratio (roughly spherical or globular) particles such as silica, coalmine dust, or high aspect ratio particles (fibres) like asbestos. Chronic diseases such as pneumoconiosis, chronic obstructive pulmonary disease (COPD) and cancer are the typical end points. Such 'conventional' (in the sense of long-recognized) particles tend to be in the size range 0.1–10 μm. Since the last edition of Hunter's Diseases of Occupations, particle toxicology has undergone a shift in thinking to focus on the finer fractions where the most inflammatory potential seems to lie, according to the recent findings of epidemiological studies into the health effects of urban air pollution and experimental studies in laboratory animals. Thus, recent experience with combustion-derived nanoparticles (CDNP), such as diesel soot, suggests that additional acute end points, such as acute coronary syndrome and exacerbations of airways disease, may need to be considered in addition to the long-term end points of lung disease, such as pneumoconiosis. Such different end points imply that nanoparticles act by different mechanisms from conventional particles. Additionally, research into the potential hazard of nuisance dust (dust of low toxicity and low solubility) has demonstrated that surface area, rather than mass, is a better dose metric for explaining the inflammatory reaction in the lung. This finding is directly relevant to nanoparticles which have a very large surface area to volume ratio. Recent concerns regarding risks from nanoparticles stem from the rise of nanotechnologies and the potential for new types of nanoparticles to be developed. However, experiences with ambient particles (particles found in the general environment) and nuisance dust have also contributed to the present state of concern over nanoparticles. Nanoparticles are a challenge for occupational medicine because of the rise of nanotechnologies and the increasing use of nanoparticles in manufacturing and research, as well as the realization that exposure to nanoparticles has been a feature of some conventional occupations, such as welding and driving. Trying to define the risk in occupations with exposure to nanoparticles is difficult at present, and not only because the technology is relatively new. This chapter includes a section on exposure measurement to explain how uncertain current measurement techniques are, and hence the limitations of trying to apply occupational exposure limits to protect workers. As well as being difficult to measure and markedly heterogeneous, nanoparticles have a propensity to translocate in the body and could therefore have effects distal to their portal of entry through the lungs, nose, gut or skin.

The main occupational exposures to nanoparticles occur in the situations shown in Table 70.1.

There is a small but increasing toxicology database on the new types of manufactured (or engineered) nanoparticles, but the predominance of human studies, chamber exposure and epidemiology, have focused on other types of 'traditional' nanoparticles, such as bulk-manufactured nanoparticles like carbon black or TiO₂ and diesel particles and welding fumes. The measurement of nanoparticles in
the air poses a difficult problem that is being addressed in ongoing research (Figure 70.1).

**TOXICOLOGY**

**Origins of concern over ultrafine/nanoparticle exposure in the workplace**

**PARTICULATE MATTER**

Concern regarding the potential adverse effects of nanoparticles came to the fore in the 1990s when the environmental air pollution literature highlighted the importance of particulate matter (PM) ($\text{PM}_{10}$ particles in ambient air collected using a sampling convention that has 50 per cent efficiency for particles with an aerodynamic diameter of 10 $\mu\text{m}$) as the most potent component of the air pollution cocktail. Adverse effects of $\text{PM}_{10}$ were seen in some susceptible populations with increases of as little as 10 $\mu\text{g}/\text{m}^3$, suggesting that this was a potently toxic exposure. This sparked off substantial research into which component(s) of $\text{PM}_{10}$ might be most important. This research highlighted the ultrafine fraction as a likely major arbiter of adverse effects, although not the only potentially harmful component of particulate matter in air pollution. The ultrafine component of PM in urban air is dominated by combustion-derived nanoparticles (CDNP) like diesel soot. CDNP have a number of components and properties that enable them to be potent producers of free radicals and oxidative stress in the environment of the lungs, leading to inflammation (Figure 70.2) (reviewed in Ref. 3). Although adverse effects are seen in asthmatics and patients with COPD, the lead adverse effects of $\text{PM}_{10}$ are seen in patients with cardiovascular disease, where increases in $\text{PM}_{10}$ and $\text{PM}_{2.5}$ ($\text{PM}_{2.5}$, particles in ambient air collected using a sampling convention that has 50 per cent efficiency for particles with an aerodynamic diameter of 5 $\mu\text{m}$) were found to exacerbate atherothrombosis leading to deaths and hospitalizations.

A potential mechanistic link was made between ultrafine particles and cardiovascular effects that has developed into more generic hypotheses regarding the impact of nanoparticles on atherothrombosis and heart rate variability (see under Effects of nanoparticles on extrapulmonary sites, p. 908).

COPD, chronic obstructive pulmonary disease.

**Table 70.1** Different nanoparticle types, potentially exposed populations and their potential effects.
Figure 70.2  Mechanism of the effects of combustion-derived nanoparticles in causing inflammation and how this leads to adverse respiratory and cardiovascular disease. Dotted lines represent alternative pathways for the effects of inhaled combustion-derived nanoparticles (CDNP) on the cardiovascular system, i.e. effects emanating from the pulmonary response via inflammatory mediators and oxidative stress versus direct transfer of particles to the blood.

**NUISANCE DUSTS**

In the 1980s, concern arose regarding ‘nuisance dusts’. These low toxicity low solubility materials, such as carbon black, titanium dioxide and zinc oxide are regulated in workplaces at a few milligrams/m$^3$, in recognition of their low intrinsic harmfulness. However, rat studies showed that after lifetime exposure to clouds of particles at these concentrations, rats developed pulmonary fibrosis and lung cancer. A considerable research effort was put into the relation this had to human risk and the conclusions were as follows:

- Rats suffer from an unusually florid inflammatory response to nuisance particles – so-called rat lung overload.\(^5\)
- Surface area is the metric driving the onset of the inflammatory response, indicating rat lung overload, not mass or volume or particle number.\(^6\)

This latter finding immediately raises concern regarding nanoparticles, because of their high surface area per unit volume. Indeed, nanoparticles caused a more rapid onset of rat lung overload, at lower mass burden, than seen with larger particles of the same material.\(^7\) Although ‘overload’ has not been demonstrated in humans, the general principle of particle surface being a driver of inflammation is generalizable.

**THE RISE OF NANOTECHNOLOGIES**

There has been a great deal of specialist and public interest in the ‘nanotechnology revolution’. Nanotechnology can be defined as the manipulation, precision placement, measurement, modelling or manufacture of sub-100 nm scale matter. Manipulation of matter at the nanoscale will greatly influence most areas of our life, such as manufacturing, engineering, health, pharmaceuticals and information technology.\(^8\) While much of the nanotechnology endeavour is applied to surfaces and matrices, it has also led to development and accelerated production of a wide range of nanoparticles of different types and different properties. These include a range of metal oxides, metals such as silver, carbon-based nanoparticles, such as carbon black and fullerens, and complex nanoparticles, such as quantum dots. One of the principal reasons why nanoparticles are such a focus for research and development is the propensity for particle properties to change as particle size decreases. As metal particles become progressively smaller, for example, a higher percentage of the atoms in the particle are found on the surface of the particle instead of being locked away inside the metal where they cannot interact with other chemicals. Fine palladium has less than 4 per cent of the palladium atoms on the surface of the particle, but pure palladium nanoparticles have 24 per cent of the metal atoms available on the surface. Thus, below 100 nm and particularly below about 10 nm, properties such as the dynamics of dispersion, rate of dissolution and/or aggregation, particle number, surface area and potential to adsorb and react with other substances can all change and these different properties can all be exploited industrially.

For this reason, discovery and development of new nanoparticles for various applications is likely to increase. However, the changing properties alluded to above may also have toxicological implications if the particles enter the body. A rapid expansion in new and different types of nanoparticles that are being developed and the potential for their large-scale production brings with it potential risk to human health and to the environment.\(^9\) In the initial phase, this will occur predominantly in the workplace as these nanoparticles are handled during integration into products. Eventually, however, the particles can be released during wear and destruction throughout the product life where there will be more widespread environmental exposure. Diverse use and numerous potential exposure scenarios mean that manufactured nanoparticles (MNP) are likely to make contact with the body via the lungs, gut and skin. In the UK, the Royal Society/Royal Academy of Engineering report on nanotechnology and its risks\(^8\) was the starting point for concern regarding the potential harmful effects of nanoparticles and the term ‘nanotoxicology’ was quickly coined to embrace this aspect of particle toxicology which might represent a unique class of particulate toxins that differed from conventional pathogenic
Health effects of ultrafine/nanoparticles

More recently, ‘grand challenges’ for safe nanotechnologies have been published.11

Nanotubes and high aspect ratio nanoparticles

Asbestos and fibre toxicology, in general, has considerable resonance in the public and scientific mind. There is thus added concern regarding the toxicology of fibre-shaped or high aspect ratio nanoparticles (HARN).8 Carbon nanotubes (CNT) are HARN whose production is increasing dramatically, because of their potentially useful properties and the fact that they can be made as very long fibrils (Figure 70.3).12 Research to date has shown CNT to be highly fibrogenic after instillation into rodent lungs,13–16 but these were not individual ‘fibre-shaped’ nanotube particles, but rather bundled, particulate aggregates. The question regarding whether nanotubes can be present in the air as long thin particles has not been addressed at the time of writing. However, one study17 has addressed the likely impact of such long nanotube fibres in relation to the ‘fibre pathogenicity paradigm’ which includes asbestos. The current paradigm for fibre pathogenicity is that fibres are pathogenic if they are thin, biopersistent and longer than around 20 μm.18 As regards thinness and biopersistence, there is good evidence that nanotubes satisfy these components of the paradigm as a result of their intrinsic structure (thinness) and being composed of highly durable graphene (biopersistence). The study17 examined the third component of the paradigm, i.e. the length-dependence of pathogenicity. A direct mesothelial model was chosen that measured the inflammation and granulomatous response to long and short nanotubes and relevant controls. Essentially, the results showed that carbon nanotubes conformed to the length-dependent paradigm in that long (greater than 15–20 μm) nanotubes were highly pathogenic but that short (<5 μm) had no pathogenicity. The end points were inflammation and granuloma formation following direct exposure of the peritoneal mesothelium in mice. Long and short asbestos showed exactly the same length-dependent behaviour with ‘frustrated’ or incomplete phagocytosis of the long fibres of either asbestos or nanotubes being an important underlying stimulus to inflammation (Figure 70.4).

There are a number of caveats in interpreting this work to mean that exposure to long nanotubes in workplaces might lead to mesothelioma: it is not known whether nanotubes are present in the air in workplaces in appreciable numbers; it is not known whether nanotubes that deposit in the air spaces of the lung can find their way to the pleural mesothelium in the way that asbestos does, nor whether, even if they did, they would cause mesothelioma.17 However, these data do sound a warning bell that HARN may behave like asbestos in some ways.

Other types of high aspect ratio nanoparticles need to be considered for their conformity with the fibre paradigm.

Deliberate exposure to nanoparticles: nanomedicine, cosmetics and food technology

There are a number of scenarios where there is use of nanoparticles with a high or certain likelihood of penetration into the body. They are mentioned here for completeness. The use of nanoparticles in medicine is developing and holds out promise for therapeutics, imaging and tissue engineering. The types of particles used in nanomedicine generally differ from the types of ‘hard’ nanoparticles discussed so far. They include liposomes, dendrimers and polymers, but carbon-based nanoparticles such as C60 and carbon nanotubes have been advanced as potentially useful medical nanoparticles. Nanoparticles are also present in some cosmetics, such as sunscreen (TiO2 and ZnO) and anti-ageing face cream (C60). There is a possibility that such particles could cross the skin and enter the body, or be toxic to the skin, but this has not been convincingly

Figure 70.3 Scanning electron microscope view of multi-walled carbon nanotubes showing the extreme thinness of the fibres and their length compared to the scale bar; the similarity with asbestos is obvious. Image courtesy of Craig Poland, The Queen’s Medical Research Institute, Edinburgh, UK.

Figure 70.4 Macrophages that are undergoing frustrated or incomplete phagocytosis of long amosite asbestos (a) or long multi-walled carbon nanotubes (b). E, erythrocytes.
demonstrated so far. Nanoparticles are also present in food but risks, if any, associated with this are not well characterized. The direct introduction of such nanoparticles into or on to the human body means that their toxicokinetics, toxicity and fate are potentially quite different from those of nanoparticles encountered accidentally in the workplace or the general environment.

**TOXICOLOGY OF NANOPARTICLES**

The toxicology of MNP is at a very early stage and relies at present on (1) analogy with CDNP and (2) experience gained with a limited number of nanoparticle types that have been bulk-produced for decades, e.g. carbon black, titanium dioxide, and (3) limited *in vitro* and *in vivo* studies with new MNP. It remains to be seen whether general rules will emerge that will allow us to generalize on the extent or mechanism of toxicity for any untested nanoparticle sample. Currently, the hazard of nanoparticles is defined on a case-by-case basis, but the concept of a structure/activity relationship for nanoparticles that would allow prediction of toxicity from physicochemical analysis is attractive. This goal, however, lies some time in the future.

**ANIMAL AND CELLULAR STUDIES**

Exposure, dose and response together with ADME (absorption, distribution, metabolism and excretion) produce toxicokinetic data that allow us to describe the detailed history of a toxin in the body of a rodent species and extrapolate to humans. Mass balance toxicokinetic analysis is not available for any pathogenic particle, including nanoparticles. Most pathogenic particles have not been considered to be metabolized and excreted in any conventional way. However, because of their small size, nanoparticles may undergo transformation and excretion by such routes. Mechanistic toxicologists are especially focused on ‘dose’ as a key to understanding molecular and cellular toxicity, as well as contributing to understanding the best metric. For nanoparticles, the optimal dose-metric is not yet elucidated, but mass is probably not the best metric and surface area is often assumed to be a better index. However, surface reactivity is also important and is likely to vary with different particle types since they can be composed of a range of materials and can be different sizes and shapes. Our understanding of the responses to nanoparticles in humans is based entirely on CDNP as the most-studied exposed population. The PM10/CDNP literature suggests that atherothrombosis and airways diseases and cancer are the most likely responses. The proclivity of MNP to translocate to different sites in the cell and within the body could mean that exposure to nanotechnology-derived NP might produce extra risks to other target organs (brain, liver, etc.). For example, if nuclear translocation is seen with some NP, then neoplastic outcomes might be anticipated, and if HARN behave like asbestos fibres then the pleura could be a target, with mesothelioma production.

**EXPOSURE AT PORTAL OF ENTRY**

In the past, particle toxicology concerned exclusively the lungs, but with the advent of nanoparticle toxicology there has been a seismic shift in perception of what qualifies as ‘target tissue’ and, following inhalation of nanoparticles, the blood and brain are seen as secondary targets for particle effects. Aerodynamic diameter is the key particle parameter that predicts whether any particle gains access to the lungs and it also determines the site of particle deposition in the lungs. Nanoparticles deposit with moderate efficiency throughout the lower respiratory tract and with high efficiency in the nose and upper respiratory tract. Nanoparticles may be formed as inseparable aggregates and group together in agglomerates with time and so their aerodynamic diameter may change. The fate of agglomerates in terms of de-agglomeration or further agglomeration in the lining fluid of the lungs following deposition is unknown, but is likely to depend on particle type.

**TRANSLOCATION FROM THE PORTAL OF ENTRY**

Animal studies show small but definite translocation of radioactive nanoparticles from the lungs to the blood following instillation exposure, and to the brain following inhalation exposure. There is no evidence for this type of translocation following inhalation of any nanoparticle type in man at the time of writing and a previous report that this does occur has been disputed. A flow diagram of the hypothetical fate and effects of nanoparticles is shown in Figure 70.5, based on limited animal studies with a few selected nanoparticle types.

**Nanoparticles in the lungs**

**INFLAMMATION AND OXIDATIVE STRESS**

The dominant hypothesis for the mechanism of lung injury caused by CDNP is that oxidative stress produced at the particle surface leads to intracellular oxidative stress, cell injury and lung inflammation. The oxidative stress is produced as a consequence of the properties of the combustion-derived NP, principally the large surface-area metals and organic molecules (reviewed in Ref. 31). Oxidative stress–responsive transcription factors, such as NF-κB and AP-1, then translate this oxidative stress into pro-inflammatory proteins, a sequence of events described for a number of pathogenic particle types. Inflammation can then set in train a number of pathological processes, such as airways disease, cardiovascular disease, fibrosis or cancer. This is also the dominant paradigm for MNP and we recently reviewed the data on MNP in terms of this paradigm. The literature on carbon nanotubes, metal oxides, fullerenes, quantum dots and other NP types was reviewed and despite the very different particle samples used and different models, such as cell-free, cellular and animal, there was evidence of oxidative stress, cell injury and
inflammation with all the different nanoparticle types. Additionally, NP have been seen to inhibit phagocytosis, which could allow enhanced interaction of NP with epithelial cells with pro-inflammatory consequences.

**FIBROGENICITY**

Carbon nanotubes have been found to be especially efficient at causing pulmonary fibrosis after instillation. These fibrogenic effects have been seen after instillation into rat lungs and could be a consequence of high doses and dose rates. Inhalation studies would be very illuminating, but none has been published at the time of writing.

**GENOTOXICITY AND CARCINOGENICITY**

Earlier carcinogenesis studies with ultrafine carbon black and TiO₂ in rats did show lung cancer with high exposures, but these were complicated by rat lung overload, a non-specific response of the rat lung to high levels of even low toxicity particles that probably does not operate in humans. However, the findings that some types of nanoparticle can cross the nuclear membrane and gain close proximity to the genetic material, pose the question as to whether such nanoparticles might have an increased genotoxicity hazard.

**Effects of nanoparticles on extrapulmonary sites**

**CARDIOVASCULAR SYSTEM**

Inflammation in the lungs may also affect cardiovascular risk and so explain the increased risk of cardiovascular death and hospitalization with increased PM₁₀ (reviewed in Refs 39–42). Atherosclerosis is widely recognized to be an inflammatory process. There are two possible patterns of association: a link between chronic low-grade inflammation and the slow process of atherogenesis, and an association between an acute systemic inflammatory response and a transiently increased risk of an acute atheromatous plaque rupture. Toxicology studies have shown that ambient particles that are concentrated to cause high exposure (concentrated ambient particles, CAPs) can influence atherogenesis in the AopE mouse model. The mechanism is unknown, but could include lung inflammation or systemic inflammation and oxidative stress, translocation of NP to the blood and direct interaction with endothelium or the processes within plaques could also play a role. A recent study showed that three intratracheal injections of nanotubes into mouse lungs could cause oxidative stress in the aorta. Further research on this is warranted. Microvascular/endothelial dysfunction in rodents exposed to ultrafine/nanoparticles has been demonstrated. Nemmar and colleagues have demonstrated that nanoparticles delivered into both the blood and the lungs enhanced the size of an experimentally produced thrombus. Radomski et al. showed that MNP of various sorts could increase platelet aggregation in vitro and so could enhance thrombosis. Some of these effects could be mediated by inflammation in the lungs since systemic inflammation is a risk factor for ischaemic heart disease, and predicts long-term cardiovascular risk in both patients and healthy populations.

In addition to frank inflammatory effects in the lungs and particle translocation, there is another mechanism whereby pulmonary deposition of nanoparticles might affect the cardiovascular response. Deposited nanoparticles may cause activation of pulmonary neural reflexes via interaction with receptors present in the lungs, and may
initiate changes in the autonomic function and cause a change in heart rate variability (HRV). These changes in parasympathetic input may contribute to increases in arrhythmias and subsequently to cardiovascular morbidity and mortality associated with particle exposure. Many studies have demonstrated an association between environmental particle exposure and changes in heart rate variability, and this is a potential mechanism for adverse effects of MNP in workplaces.

**BRAIN**

Limited studies indicate that nanoparticles can gain access to the brain following deposition in the nose, via the nerves that run from the olfactory epithelium into the olfactory lobes of the brain. Nothing is known of the dosimetry in relation to exposure nor whether this is a generic property of nanoparticles. However, if this is a general property of NP, then given the ubiquitousness of combustion-derived nanoparticles in our environment, it is likely that most urban dwellers have a burden of nanoparticles in their brains. Indirect evidence that this is indeed true and that there might be adverse effects on the brain comes from studies in Mexico City, an area with very high particle pollution, describing unusual brain pathology in the young. It is not known if nanoparticles can generally cross the blood–brain barrier, but medical nanoparticles have been designed to translocate efficiently to the brain from the blood.

**OTHER EFFECTS**

Very small particles and structures could have a range of other effects that are not seen with conventional particles. For instance, they may not be detected by the normal phagocytic defences allowing them to gain access to the blood or the nervous system. Very small particles are smaller than some molecules and could act like haptens to modify protein structures: either altering their function or rendering them antigenic, raising the potential for autoimmune effects.

**Nanoparticles at the cellular level**

The various compartments of the cell, evolved to isolate various functions and structures in order to control and effect efficient cell function, normally operate also to contain particles in a few compartments and exclude them from others. Depending on the particle size phagosomes, phagolysosomes, pinocytic vesicles and clathrin-coated vesicles all may contain particles, while particles are normally excluded from the nuclei and mitochondria. However, recent work has suggested that NP may penetrate membranes that act as a barrier to bigger particles and can relocate within cells, finding potential new targets for toxicity. Li and colleagues have demonstrated that the ultrafine fraction of air pollution can enter mitochondria and cause respiration and oxidative stress effects. Geiser and colleagues have shown that, unlike larger particles, nanoparticles can enter macrophages by non-microfilament-mediated processes and that they can freely diffuse within the lungs, as if there were no membrane barriers. They have also demonstrated that nanoparticles can enter erythrocytes, which have no normal particle uptake mechanisms. Li et al. showed that nanoparticles of silica, but not larger particles of the same material, were able to enter the nucleus and form aggregates with nucleoproteins.

Once inside cells, MNP can have a range of effects that depend on the surface dose and surface reactivity. The ability of the particles to produce oxidative stress and pro-inflammatory gene expression are typical responses. However, cell-specific functional impairment is to be expected, e.g. inhibition of the ability of phagocytes to phagocytose.

Oxidative stress from other particles can stimulate proliferation and cause genotoxicity. As well as having unusual toxicokinetics at the whole body level, NP may therefore show unusual ‘microtoxicokinetics’ and so may affect cellular structures not targeted by larger particles; particle-derived oxidative stress may thus result in toxicity, inflammation, proliferation and genotoxicity.

**CHAMBER STUDIES WITH NANOPARTICLES IN HUMANS**

Toxicity of ultrafine particles/nanoparticles can be studied using controlled exposures in the laboratory. These are complex and expensive studies which raise some ethical concerns, so the literature is small.

**Diesel exhaust challenge**

Laboratory exposures to diesel exhaust replicates real-life exposure, but it is difficult to separate out the effect of the particle from the gaseous components so attribution of specific outcomes to specific components needs to be undertaken with caution. There have been two broad types of study – those involving nasal challenge and those involving inhalational challenge. There are two main caveats when considering this approach to toxicity:

1. While diesel exhaust contains a substantial fraction of ultrafine particles, absolute attribution of toxicity to the ultrafine fraction using this approach cannot be made with complete confidence.
2. Studies are usually limited to healthy volunteers rather than putative at-risk groups of subjects (such as the elderly, or those with existing cardiovascular disease).

**NASAL STUDIES**

Studies of diesel exhaust particle instillation into the nose have shown induction of mucosal inflammatory changes and nasal hyper-reactivity and allergen potentiation by
induction of specific IgE formation and by steering cytokine production towards a Th2 profile. These responses are likely to be mediated by the production of reactive oxidant species as the phase II enzymes, GSTM1 and GSTP1, modify these effects. It is difficult to be sure about the relevance of the local lining fluid concentrations of these particles produced in these studies compared with those achieved in real life, but this mechanism does cohere with animal work and findings from studies involving larger particles in ambient air pollution.

**INHALATIONAL CHALLENGE**

Exposures of healthy volunteers to doses ranging between 100 and 300 μg/m$^3$ of PM$_{10}$ from diesel exhaust for an hour, usually without exercise, is associated with airway neutrophilia. In some studies, there has also been an increase in lymphocyte numbers in bronchoalveolar lavage and, in one study, evidence of increased migration of macrophages into the airways and potentiation of their phagocytic capacity. There is also some evidence to suggest that these neutrophils are activated with elevations of myeloperoxidase.

Ozone may enhance this response. In one study in healthy volunteers, one hour of 300 μg/m$^3$ diesel exhaust particles followed five hours later by two hours of ozone at 200 ppb showed, apart from an increase in neutrophils and myeloperoxidase (MPO) in induced sputum, a clear association between neutrophil counts and levels of MPO and matrix metalloproteinase 9 (MMP9) suggesting neutrophil activation. Increased levels of interleukin 8 with enhancement study. Intriguingly, in asthmatic subjects, no neutrophilia. In some studies, there has also been an increase in IL-10 levels in bronchial mucosa. There is also evidence suggesting that exacerbations of asthma can be caused by exposure to diesel exhaust particles.

Thus, diesel exhaust appears to cause an inflammatory response at relatively low levels of exposure for short periods of time. However, this is seen only in normal individuals not in asthmatics, perhaps reflecting either a different time course for asthmatics or a different mechanism of inflammation, bearing in mind that the epidemiological evidence suggests that exacerbations of asthma can be caused by exposure to diesel exhaust particles.

Studies of the effects on the cardiovascular system have been variable. There are inconsistent reports of changes in heart rate variability, but perhaps a more consistent effect on endothelial responsiveness as judged by modulation of tests of forearm vasodilatation. In 30 healthy volunteers exposed to 300 μg/m$^3$ of diesel exhaust with intermittent exercise for an hour, endothelial responsiveness was attenuated after diesel exhaust exposure with a suggestion of an initial and delayed increase in plasminogen activator activity. At 24 hours, there appeared to be an increase in the circulating levels of TNFα and IL-6 and a reduction in acetylcholine-induced vasodilatation.

This suggests that there is a dynamic component to the effects of diesel exposure, although it should be noted that not all studies are consistent, with one other study showing no effects of 100 or 200 μg/m$^3$ diesel on 13 healthy volunteers on a wide range of clotting factors.

Chamber studies are helpful in understanding the response to diesel exhaust, but do not necessarily point to the active component being in the ultrafine fraction. Extraction of the ultrafine component from a diesel engine for subsequent challenge has not been undertaken and this would be the logical next study, although this is difficult to achieve.

**ULTRAFINE CARBON CHALLENGE**

Studies have also been undertaken of ultrafine carbon exposure in healthy volunteers or subjects with mild asthma, at higher doses than ambient when considered in mass terms. These have shown inconsistent influences on heart rate variability, with evidence of increased adhesion molecule expression in peripheral blood monocytes, but no acute phase response which would be compatible with retention of white cells within the lung following exposure. A study of 20 patients with severe coronary artery disease (i.e. those who are likely to be more at risk) exposed to carbon particles with a median diameter of 60 nm and a range of up to 300 nm for an hour at concentrations equivalent to those achieved on a day when ambient PM$_{10}$ levels would be 100 μg/m$^3$ showed no change in any cardiac parameter with carbon alone in diseased patients, but in healthy controls showed an increase in the high frequency power component of heart rate variability. This suggests that the diseased patients on treatment may show a loss of the protective effect of a vagal response to a stimulus.

**EPIDEMIOLOGICAL STUDIES**

Epidemiological studies of ultrafine particle/nanoparticle exposure are limited to welding fume and diesel exhaust exposures.

**Welding fume**

Welding fume constitutes an aerosol which includes combustion products from the base metals, electrode coatings, shielding gases, fluxes and paint or surface coatings. Heat produces metal oxides, but these will be of differing valency and information on the relative proportion of these different valencies is not available. Very small particle (tens of nanometres in size) are produced in the primary process and these tend to aggregate into chains of primary particles.
EXPOSURE ASSESSMENT

A number of different approaches to quantification of exposure to welding fume have been employed. Personal exposures to mass of particles have been used, but as ultrafine particles are of very low mass this may not be the best approach. Personal inhaled exposures to metals (particularly nickel and aluminium) may be more relevant than urinary levels of metals, but both are logistically troublesome. Finally, magnetopneumography, the amount of metal in lungs is assessed using magnetic resonance and is assumed to be an indicator of overall exposure, has been used. However, how this truly relates to relevant exposures is not known.

In general terms, welding in confined spaces (such as by shipyard workers and tunnel workers) is associated with higher exposures, and lack of local exhaust ventilation system is associated with much higher exposures.

METAL FUME FEVER

This condition is one of the most common reactions reported by welders and may be of relevance to the specific exposure to ultrafine particles, potentially by generation of acute phase reactants.

RESPIRATORY SYMPTOMS

There is consistent evidence that exposure to welding fume is associated with an increased prevalence of cough, productive of sputum. In countries where control of occupational exposures is poor, the prevalence is higher, often even into the 90 per cent range, but in general the prevalence of productive cough ranges between 20 and 40 per cent, being usually around three times higher than controls. The risk of chronic productive bronchitis is also reported to be higher in welders than non-welders, usually by a factor of about two.

LUNG FUNCTION

Reducions in lung function are more variably reported. Some studies show a reduction in FEV₁ and the presence of an obstructive defect (using the criteria of a reduced FEV₁ and a reduced forced expiratory ratio), but in most studies there are no measurable changes in basic spirometric variables. However, reductions in maximum mid-expiratory flows, usually to the order of 10–15 per cent below controls, are fairly consistently reported. In absolute terms, around two-thirds of this decrement is due to smoking with one-third due to welding fumes.

OCCUPATIONAL ASTHMA

Welding fumes are recognized as a cause of occupational asthma, but the evidence to support this is mixed. The evidence is strongest in stainless steel welders where workers are likely to be exposed to known respiratory sensitizers, notably chrome, nickel and vanadium. It is reasonable to suggest that where welders are exposed to metal fumes containing these elements, there is a significantly increased risk of occupational asthma. There is some evidence that exposure to welding fume increases bronchial responsiveness in one study from Newcastle (in the UK) showing a dose–response relationship. Following specific bronchial challenge in stainless steel welders, late responses typical of occupational asthma have been seen.

In some welders, particularly stainless steel welders, cross-shift falls in lung function have been recorded. This has been well characterized by Fishwick and colleagues who specified that a fall in FEV₁ of >5 per cent after 15 minutes welding was significant and found this detriment more frequently in exposed welders than among welders non-exposed over a similar time period. Some welders show persistent cross-shift falls in lung function even after 20 years or more of welding, although others show attenuation of this effect with time.

While it is assumed that the causal agent for welding-induced occupational asthma will be in the base metal, it is also possible that other factors associated with the welding process might be risk factors for the development of asthma. These could include exposures to other agents other than welding fume, such as cleaning agents involved in the welding process, or possibly fume arising from the electrode coatings, the content of which is often unclear. However, asthma is a disease which characteristically affects the medium-sized airways where deposition of ultrafine particles is limited, which might point to factors other than the ultrafine particles being important in its genesis among welders.

INTERSTITIAL LUNG DISEASE

There have been a number of cases reported of restrictive ventilatory defects in welders. This effect, allowing for technical issues, seems to be real, although unusual. Again, this seems to be more frequent in those countries where control of exposure to welding fume is less effective. A study from the 1970s in the United Kingdom showed that 7 per cent of welders had pneumoconiosis on the basis of radiography and lung function. Siderosis from welding fume, although well recognized, has no clinical implications. As deposition of ultrafine particles in the alveoli is high, an alveolar disease is a logical potential outcome of exposures to such particles.

Diesel exhaust

EXPOSURE

The internal combustion engine is an important source of nanoparticles in the general and working environments. The diesel engine produces exhaust containing 20–100 times more particles than that from petrol (gasoline) engines and a proportion of these are sized in the nanoparticle range. The exhaust is a mixture of soot, gases including oxides of sulphur and of nitrogen, vapours and liquid aerosols, and the particles are either soot or condensates of the other phases. The mixture varies with the type,
age, condition and operating temperature of the diesel engine, and with the composition of the fuel itself. Precise characterization of the size distribution is made difficult by the propensity of the particles to form, dissolve, agglomerate and attract other molecules, e.g. polycyclic aromatic hydrocarbons (PAHs) to their surfaces, in a dynamic process. Therefore, the totality of any health risk from diesel exhaust does not necessarily derive from the nano fraction alone, as measured in air.

Occupations with exposure to diesel exhaust include trucking and transportation, and underground mining, where both transport systems and other mechanical equipment may be diesel powered. Of course, traffic exhaust pollution is a major contributor to the ambient particulate concentrations to which whole populations are exposed.

Because the primary route of exposure to diesel exhaust is respiratory and because some of its components are known carcinogens, interest in the past has focused mainly on possible lung cancer risks. Toxicological evidence from exposed rats has convincingly demonstrated carcinogenic activity, but not consistently in mice nor in hamsters. In addition, results from exposing rats to carbon black, as a surrogate for diesel soot without organic compounds, showed similar tumour incidence, suggesting that carcinogenicity was not due to the organic. Evidence with other particles suggests that the carcinogenicity at experimental doses may be a function simply of physically overloading the rat lung with ultrafine particles and not relevant to human risks.

Evidence from human epidemiology suggests that long-term exposure to diesel exhaust in a variety of occupational circumstances is weakly associated with lung cancer (relative risk, 1.2–1.5 compared with unexposed workers) and that the association persists where adjustment for smoking is possible. However, poor exposure assessment in most of these studies severely limits the possibility of using these results for quantitative risk assessment.90 The largest and most informative studies of railroad workers and teamsters (truck drivers) in the United States, reviewed by the Health Effects Institute (HEI)’s Diesel Epidemiology Expert Panel, showed differences in lung cancer risk between job categories in the railroad workers, but no increase in risk with duration of employment. The teamster studies showed an exposure–response association. The gravimetric exposures used differed between the studies, but in both cases would have been dominated by particles larger than the nano range.

Studies of cancer end points are facilitated by the death and cancer incidence registration systems which collect outcome data routinely in many countries. No such systems exist for other respiratory conditions, such as asthma and COPD, so occupational studies of these conditions are difficult and risks are assessed largely by analogy from non-occupational investigations. However, one study of COPD mortality in diesel-exposed railroad workers91 reported increased odds of mortality from this cause with increasing length of employment, with an odds ratio of 1.6 for workers with >16 years’ work.

Concern is often voiced over the possible role of particles in the causation or exacerbation of asthma. The incidence of childhood asthma has increased steadily as traffic volumes have increased, but the increase has been seen even in communities with very low pollution, so the evidence for particulate pollution as a primary cause is weak. However, there are numerous studies showing that episodes of exacerbation of asthma are more frequent on high-pollution days and in subjects living in proximity to higher than average exposure sources, e.g. near main roads. In addition, animal experiments and human volunteer studies in healthy adults have shown clear inflammatory effects on the lungs and other tissues following exposure to diesel fumes.

These inflammatory responses link to current knowledge regarding the effects of particulate air pollution in the general population. The data come from two types of study, i.e. ‘time-series’ and ‘cohort’. In the former, the association between daily totals of events, such as deaths or hospital admissions, is related to current and recent pollution levels measured locally. These studies typically can detect effects over days or possibly a few weeks, and they may have no information on the characteristics of those affected, except possibly age and sex. Cohort studies, on the other hand, usually have good baseline information on each subject, and they typically compare event incidence between subgroups; particularly relevant are studies which compare between locations with different average concentrations of particulate pollution.

Both types of study have demonstrated effects of particles, but the magnitude of effects in the cohort studies is much greater than in time-series studies, presumably reflecting the long-term build up of damage from chronic exposures. Both types of study have identified that the largest and most consistent effects are in mortality from cardiovascular and respiratory causes, with some additional evidence from the cohort studies for increased lung cancer risks in locations with higher average pollution.

Initially, the finding of a cardiovascular mortality effect from inhaled pollution was puzzling, because no mechanism had been identified. The body of recent research reviewed above has now suggested possible mechanisms. However, we know of no studies of these effects in occupational settings.

To summarize, diesel exhaust fumes include a proportion of nanoparticles. Diesel exhaust is an irritant and is classified by a number of authorities in different countries as a probable human carcinogen of the lung. It has inflammatory effects and these increase the risks of asthmatic exacerbations, and may also increase cardiovascular risks, including cardiovascular mortality. In the main, these health effects are not specific to diesel exhaust, which will have the effect of modifying the risks from other causes contributing to these disease processes. It seems likely that the cardiovascular effects are associated primarily with the nanoparticle fraction, but this may not be true of the carcinogenicity, which has been ascribed to the adsorbed PAHs and is less likely to be mediated by particle size.
Given the evidence, action and regulation to minimize human exposure to diesel exhaust is justified, both in the environment and in the workplace. Although there have been many improvements to diesel engines over recent decades, some of these have increased the number of smaller particles produced, and it is not known whether these changes have decreased or increased the risks described above.

RISK ASSESSMENT AND THE CHALLENGE OF MEASURING EXPOSURES TO NANOPARTICLES IN THE WORKPLACE

Nanoparticle types

As indicated under Introduction (p. 903), it is overly simplistic to regard nanoparticles as a single class of material. In practice, nanoparticles include a diverse range of chemical composition, size and structural form. In addition to established ultrafine particles which have been manufactured for several decades, such as TiO₂, many new variants of existing materials and entirely new materials are being developed. These include metals, metal oxides, ceramics, semiconductors and organic particles. They can include composites, having for example a metal core with an oxide coating or alloys in which mixtures of metals are present. Carbon-based particles include fullerenes, the best known of which is C₆₀ (buckminsterfullerene), which has a cage-like structure. Carbon nanotubes, mentioned under Nanotubes and high aspect ratio nanoparticles (p. 906), exist in a variety of forms, but primarily comprise rolled-up sheets of graphene which form high aspect ratio particles. These particles may also be functionalized by addition of molecular groups.

Potentially, exposure may occur to the particles themselves, or to agglomerations of these particles or to particles in the presence of a formulation material, such as a liquid carrier. These nanostructured particles may be much larger than the size limits which are currently used to define nanoparticles. Maynard and Aitken suggested a classification scheme for these nano objects which potentially may be helpful in the development of risk management strategies (Figure 70.6). Production methods include gas phase processes, such as flame pyrolosis and chemical vapour deposition, and liquid phase emulsion reactions. They vary from laboratory scale to full industrial production. Uses and applications of nanomaterials are growing rapidly.

Occupational hygiene practice

As with other particles and chemicals, risks to health may be reduced by understanding and controlling exposures in at-risk populations. In an occupational context, this will include those involved in the development, production and use of these materials. Currently, there is a substantial gap in knowledge about the likely exposure scenarios and the relevant exposure levels, duration or population size. Published guidance to support good occupational hygiene practice is only just beginning to emerge. The British Standards Institute’s Nanotechnologies Guide to Safe Handling document provides a coherent framework by which potential risks may be addressed. It is based on a conventional risk assessment framework and incorporates a hierarchical approach to exposure control (eliminate, substitute, enclosure, engineering control, procedural control and personal protective equipment). Overall, the approach is intended to be conservative, as well as giving

**Measurement of nanoparticles in the workplace**

In most early epidemiology studies, dust (particle) samples were collected on to a filter or other media and subsequently analysed off-line to define estimates of exposure, expressed as a concentration in air. In some of the early studies in the coal industry, the samples were analysed by counting particles on the filter under a light microscope. This resulted in an estimate of exposure in terms of particle number concentration. Epidemiology studies in the coal industry later showed a good correlation between pneumoconiosis and mass concentration. Subsequently, the use of mass concentration measurements to demonstrate compliance with established occupational exposure limits has become the norm in most occupational scenarios.

A range of sampling instruments are available which may be used to collect samples for analysis. Usually these are small devices, comprising a selection stage, a filter (the combination often referred to as the sample head) and a sampling pump mounted on the torso of a wearer. The sampling head is typically positioned in the ‘breathing zone’, normally on the upper chest, of the wearer and the samples collected referred to as ‘personal samples’. The use of personal sampling is widespread, since aerosol concentrations in workplaces can have wide spatial variability and a personal sample represents the closest approximation to actual exposures. This approach has typically been used to assess exposure to ultrafine particles, such as welding fume or carbon black in the workplace. For welding fume, however, the breathing zone is modified by the presence of a welding helmet and the sample is therefore collected inside the helmet.

A further refinement of this approach is collection of a ‘biologically relevant aerosol fraction’. In this context, biological relevance is characterized by where in the respiratory tract a particle can potentially deposit, and determined as a function of particle size, measured in terms of aerodynamic diameter. For this reason, international standards have been developed which define the size of particles capable of penetrating to the various regions of the respiratory tract. The three most commonly used standards relating to occupational exposure are the inhalable fraction (representing that fraction of aerosol which can enter the respiratory tract), the thoracic fraction (particles capable of penetrating to the airways below the larynx typically defined according to a selection curve with a 50 per cent cut off at 10 μm (10 000 nm) and the respirable fraction (particles defined according to a selection curve with a 50 per cent cut off at 4 μm (4000 nm), which can penetrate beyond the ciliated airways to the gas exchange region of the lung.

Sampling aerosols with instruments that match one of the three size fractions is generally accepted as good practice, and occupational exposure limits typically apply to mass concentrations of a specific fraction, in almost all cases either the inhalable or thoracic fraction.

One exception is the class of fibrous particles, such as asbestos or glass fibre. Although some of the toxic mechanisms associated with asbestos exposure remain unclear, it is known that ill health following exposure is associated with physicochemical properties, such as fibre length and surface chemistry, and the persistence of the fibres in the lungs. As a result, exposure is not characterized in terms of averaged mass and composition, but rather by the number (concentration) of fibres in the air with a specific shape and composition.

Currently, measurement of nanoparticles in workplaces is problematic and there are no established guidelines or protocols and very little published experience. A critical issue is the choice of measurement metric (i.e. mass, number or surface area concentration). As in the earlier coal industry example, it is necessary to choose a metric which is correlated with the health effect of concern. However, emerging toxicological evidence suggests that, for at least some nanoparticles, potential health effects are more likely to be correlated with surface area concentration, rather than mass concentration. For some high aspect ratio nano-materials, it is probable that, like larger fibres, number concentration will prove to be the most appropriate metric. Although instruments are available to measure each of these metrics, there are in each case a number of limitations to the utility of these.

**MEASUREMENT OF PARTICLE NUMBER CONCENTRATION**

Optical particle counters in which light scattered from a particle is counted as a pulse, are used routinely for counting larger particles (Figure 70.7). However, these devices do not operate well in the nanoparticle size range, since the...
wavelength of the light used in them is greater that the particle size, and so the light is not scattered. Condensation particle counters (CPCs) overcome this limitation by passing sampled particles through a chamber containing a saturated atmosphere (usually of alcohol or water) which condenses on to the particles, forming larger droplets which can be detected by the optical system and counted.95 This largest particle size detected by the device is set using a size-selecting inlet, and the lower size limit depends on the specific instrument, but is typically in the range of 10 nm. These devices are typically fairly robust, hand-held instruments which can therefore be used to provide real-time information on particle number concentration, but no information on particle size. Although they are hand held, CPCs are not yet at a size which can be incorporated into a personal sampler.

CPCs may also be used as a counter in series with instruments which can select differing size fractions as a function of time. One such device is the differential mobility particle sizer (DMPS).95 This instrument sequentially selects particles according to their electrical mobility by stepping the voltage across a pair of electrodes. By sequentially counting these particles using a CPC, a particle size distribution can be produced.

Measuring particle number concentration in isolation can, however, be misleading. In all particle number concentration measurements, the integration limits over which a particular instrument operates are critical in interpreting the reported results. CPC instruments become increasingly insensitive to particles smaller than 10–20 nm. Concentrations measured with instruments with different sensitivities might therefore differ substantially, particularly if the particle count median diameter is close to or in this range, which is often the case.

A further complication relates to the ambient aerosol. Unless the workplace is operating under clean room conditions other nanoscale aerosols, for example from combustion sources, may be present in the workplace and result in overestimation of the levels of nanoparticles emitted from the process under investigation. In the same way, CPCs do not provide any information about particle shape and so cannot discriminate between HARN and compact nanoparticle forms.

Off-line assessment of nanoparticle number concentrations is feasible by collecting particles on to suitable media and analysis by electron microscopy, although this approach has to date not been validated. Despite the difficulties, this is currently the only practicable approach for assessing HARN number concentration.

MEASUREMENT OF PARTICLE MASS CONCENTRATION

In principle, assessment of the mass of nanoparticles can be achieved using a personal sampler with an appropriate size-selecting cut-off point to collect a sample on to appropriate media for subsequent off-line gravimetric or chemical analysis. Currently, however, there are no commercial devices of this type available. One issue to be resolved in a device of this type is the size at which the cut point would be set. Although nanoparticles are currently defined104 as particles having one dimension less than 100 nm, agglomerates of such nanoparticles are still likely to be biologically relevant but would be excluded by such a device. A second issue relates to the actual masses which would be collected by a device with a 100-nm cut. It is probable that these masses would be substantially below those typically collected in current occupational hygiene practice presenting great challenges in relation to limits of detection.

MEASUREMENT OF SURFACE AREA CONCENTRATIONS

In recent years, emerging methods such as diffusion charging provide a more viable approach to measuring aerosol surface area in situ (Figure 70.8). The instrument works principally by the mechanism of unipolar diffusion charging. Ions are produced in the carrier gas by a corona discharge. The ions attach to the surface of the particles in proportion to the total surface area and are collected in an electrically insulated particle filter. The electric charge is converted to a DC voltage signal in an electrometer amplifier. Good agreement has been shown105 between diffusion chargers from Matter Engineering (LQ1-DC; Matter Engineering, Wohlen, Switzerland) and EcoChem (DC2000CE; EcoChem, Delia, CA, USA), TEM-derived surface area and size distribution-derived surface area for sub-100 nm particles.

Active surface area does not scale directly with geometric surface area above 100 nm. Diffusion chargers are
specific to nanoparticles only if used with an appropriate inlet preseparator.

A recent variant of this approach is the TSI Nanoparticle Surface Area Monitor (NSAM) Model 3550 (TSI Inc, Shoreview, MN, USA). In this device, the instrument response has been tuned by changing the voltage on the ion trap, such that the signal has been shown to relate to the human lung deposited surface area (expressed in cm²/m³) of the tracheobronchial or alveolar regions of the lung. Although this is a promising device, its utility has yet to be fully investigated.

**Recommended sampling strategy for risk assessment**

While all of these devices are capable of providing useful information on mass, number or size concentrations, none provides the utility of taking personal samples and all require careful interpretation of the data obtained to provide useful and comparable information. Maynard and Aitken\(^6\) have suggested the concept of an idealized sampler. Such a device would be capable of measuring all the attributes of interest relating to the physical, chemical properties of engineered nanomaterials-related particles: (1) it would be portable to allow it to be worn by potentially exposed subjects; (2) it would be capable of providing time-differentiated information; and (3) it would be inexpensive, to allow large numbers of such instruments to be purchased for any given study. No such instrument is currently available, nor is it likely that in the short term such an instrument will become available. Until such time then, any attempt to characterize workplace exposure to nanoparticles should preferably involve a multifaceted approach incorporating many of the sampling techniques mentioned above. Brouwer et al.\(^106\) recommend that all relevant characteristics of nanoparticle exposure be measured and a sampling strategy similar to theirs would provide a reasonable approach to characterizing workplace exposure.

The first step would involve identifying the source of nanoparticle emissions using a CPC. It is critical to determine ambient or background particle counts before measuring particle counts during the manufacture or processing of the nanoparticles involved. If a specific nanoparticle is of interest, then area sampling with a filter suitable for analysis by electron microscopy should also be employed. Electron microscopy can be used to identify specific particles and can estimate the size distribution of the particles.

Once the source of emissions is identified, aerosol surface area measurements should be conducted with a portable diffusion charger and aerosol size distributions should be determined with a DMPS or ELPI using static (area) monitoring. The location of these instruments would need to be considered carefully, ideally as close to the work areas of the workers as possible.

Finally, personal sampling using filters or grids suitable for analysis by electron microscopy or chemical identification should be employed, particularly if measuring exposures to specific nanoparticles is of interest. Electron microscopy can be used to identify the particles and can provide an estimate of the size distribution of the particle of interest.

By using a combination of these techniques, an assessment of worker exposure to nanoparticles can be conducted. This approach will allow a determination of the presence and identification of nanoparticles and the characterization of the important aerosol metrics.

**CONCLUSION**

Ultrafine particles/nanoparticles form a diverse group of materials that share a similar small size, but have varied compositional characteristics and so different adverse health outcomes might be expected. They pose a threat to the lungs because of their potential to become airborne where they can be easily inhaled, in view of their small size. There are long-standing exposures to some types of nanoparticles, such as diesel soot and welding fume and epidemiology studies document a range of adverse pulmonary effects in such exposed workers. Exposure in chamber studies confirms a range of inflammatory effects. Less well understood hazards and risks are attached to new and emerging nanoparticles, products of the nanotechnologies industries. These nanotechnological particles, aimed at specific industrial usages, can be complex and can have diverse sizes, composition and coating to support their industrial applications. The impact of such modifications on toxicity is poorly understood in general. In addition, some ‘engineered nanoparticles’, such as carbon nanotubes, have a high aspect ratio and the potential parallels with asbestos are clear. One area of research focus is the cardiovascular system as a target for inhaled nanoparticles, a concern extrapolated from the PM\(_{10}\)/combustion-derived nanoparticles experience, where cardiovascular effects are the main health impact. The potential for nanoparticles to translocate from their portal of entry in the lungs poses new targets and mechanisms for the effects of nanoparticles, such as the blood and the brain, that are ill understood. These new types of hazard from inhaled nanoparticles are currently the focus of considerable research.

Effective exposure assessment is absolutely necessary for the determination of risk. While welding fume and diesel soot are measured in the air by mass, the best metric for relating nanoparticle exposure to health effects remains under debate. Measurement of low mass concentrations of manufactured and engineered nanoparticles in the air, against a changing background of ambient nanoparticles from sources such as fuel combustion, presents a challenge that is currently being addressed at national and international level.

Ultrafine/nanoparticles represent an interesting and ubiquitous category of potentially pathogenic particles whose adverse effects could be substantial. Additions to the
list of candidate particles requiring testing are to be anticipated, in view of the burgeoning nanotechnologies. Viewing ultrafine/nanoparticles as a class of particles with both common and diverse pathogenic mechanisms, reflecting their origin and structure, should provide impetus and direction to research. There is an urgent need for greater understanding of these ubiquitous industrial materials and their hazard, so that there is improved understanding of the risks for those who work with them.

### Key points
- Nanoparticles are a subclass of particles defined on the basis of having one dimension less than 100 nm (0.1 microns). Nanoparticles have received increased attention over the last few years, especially because of the rise of nanotechnologies, which produce novel types of nanoparticle for industrial use and subsequent potential for inhalation exposure.
- Exposures to nanoparticles of diesel soot and other combustion-derived nanoparticles also occur in the general environment. In the occupational environment, nanoparticle exposures also include welding fume, carbon black, amorphous silica, and other bulk-manufactured nanoparticle types.
- The toxicological effects of nanoparticles appear to be related to their large surface area per unit mass, which leads to an ability to cause oxidative stress and inflammation in lung tissue. Some nanoparticle types have a fibrous shape and so there is concern over whether they might pose an asbestos-type hazard. The small dimensions of nanoparticles give them potential for translocation from their site of deposition to the blood and brain and other potential target tissues.
- Human epidemiological studies and chamber studies have predominantly addressed the effects of diesel soot and welding fume. Exposures to both of these nanoparticles is associated with lung cancer in epidemiology studies, while exposure to welding fume is associated with a number of other end points, including systemic effects and lung fibrosis. Chamber studies show pro-inflammatory effects and also systemic effects of both exposures.
- There is a pressing need for portable samplers that allow real-time quantification of nanoparticle mass, number, or surface area in the workplace. A number of different types of instrumentation are undergoing research and development for this purpose.

INTRODUCTION

An increasing proportion of the workforce is working in non-industrial indoor environments, among which the modern office environment is becoming the most common workplace. Other similar environments include schools and other educational institutions, day-care centres and hospitals, as well as care homes. These environments have traditionally been considered as safe, because occupants are usually not exposed to high levels of physical, chemical or biological compounds potentially hazardous to health. This view has been based on simple causal models where an identifiable single agent causes a well-defined occupational disease. In multifactorial causal webs, several component causes create complex environmental conditions, which may increase the risk of developing well-defined diseases or the occurrence of a set of symptoms and signs, which form disease-like entities. The idea of a safe office environment was already being strongly challenged in the early 1980s by reports of a high prevalence of symptoms in employees working in modern office buildings. These health problems were often related to indoor air quality and ventilation. A World Health Organization working group on indoor air and health characterized these in their report on ‘sick’ building syndrome. These observations have stimulated long-term research programmes, which have provided more insight into the type of specific diseases, symptoms, signs and syndromes, which can be caused by modern non-industrial environments. This chapter provides a presentation of these problems. First, the determinants of indoor air quality are presented. Second, the most common occupational exposures in non-industrial environments and their health effects are presented systematically. Third, specific diseases related to non-industrial workplaces are presented. A discussion of their impact on public health and their economic consequences concludes the chapter.

SOURCES OF OCCUPATIONAL HAZARDS IN NON-INDUSTRIAL ENVIRONMENTS

Components of the indoor environment

The determinants of indoor air quality in the non-industrial workplace can be divided into the following: (1) outdoor sources, (2) type of building, (3) occupants and their activities, (4) physical indoor sources and (5) heating, ventilation and air conditioning. In addition, psychological and social factors are important determinants of health.

The main route of exposure to the physical environment is inhalation, but skin exposure may also be relevant. Social environment causes both psychological and physical effects via psychological processes.

OUTDOOR SOURCES

The air, water and soil surrounding the building have the potential to have an impact on the indoor air quality.
Industry, traffic, heating and natural sources contribute to outdoor air pollution and indirectly to indoor air quality, but outdoor–indoor penetration has not been sufficiently studied. The geographic location of the building is therefore an important determinant of many indoor factors. The proximity of busy traffic routes or industrial plants may contribute substantially to total exposure to various environmental pollutants in the non-industrial work environment, but the type of building and ventilation system plays an important role in managing these exposures.

THE TYPE OF BUILDING

The type of building, the structure, openings and the type of ventilation system influence the penetration of outdoor pollutants into buildings, as well as the elimination of air pollutants from indoor sources. In a sealed building, penetration and elimination depend mainly on the function of the ventilation system. The location of an air inlet in a building can be important, because it may influence the penetration of outdoor pollutants from local sources back into the building. For example, an air inlet facing a bus stop may result in high concentrations of diesel exhaust gases and particles indoors.

OCCUPANTS AND THEIR ACTIVITIES

Occupants are an important source of indoor air pollution in non-industrial workplaces. Human metabolism results in carbon dioxide, carbon monoxide, ammonia, acetone, alcohol and various other odorous organic gases, which are released into the indoor air through breathing and perspiration. In addition, occupants release bacteria and viruses, which may cause infections. Clothing textiles may release various types of particles and clothes may carry animal dander from one environment to another. Munir and colleagues measured substantial concentrations of cat and dog allergens in Swedish day-care centres. The levels were related to the number of children and staff with cats or dogs at home. Cleaning method or cleaning frequency had little effect on allergen levels which were higher than in homes with pets.

Office activities, such as paper handling, including carbonless copy paper, photocopying and printing may generate important exposures to gases and particles. Studies in paper industries with high paper dust levels have suggested that paper dust can be highly irritative. Carbonless copy papers contain solvents and colour-forming chemicals and these have been suggested to be potential sensitisers. In many countries, tobacco smoking is still an important source of indoor air pollution, although national smoke-free workplace legislation is shown to be a valuable tool to protect people against the adverse health effects of environmental tobacco smoke exposure. When non-smokers occupy the same indoor space as smokers, they inhale tobacco combustion products that are released into the air, i.e. they undergo passive smoking. The smoke inhaled by these non-smokers is called environmental tobacco smoke (ETS), tobacco-smoke pollution or second-hand smoke, and it is formed mainly of sidestream smoke (SS) and, to a small extent, exhaled mainstream smoke (MS). SS is smoke released into the air from the smouldering end of a cigarette between puffs, whereas MS is smoke inhaled by a smoker during a puff. Both types of smoke contain thousands of chemicals, including approximately 50 carcinogenic and tens of irritative and toxic substances. The concentrations of many harmful substances are higher in undiluted SS than in MS, but the final concentrations of hazardous compounds inhaled by non-smokers are determined by factors such as the number of smokers, the number of cigarettes smoked and the volume of the space.

PHYSICAL INDOOR SOURCES

There is increasing evidence that interior surface materials used in floors, walls and ceilings, as well as furnishing are potential sources of indoor air pollution. In the 1970s, exposure to formaldehyde from building materials emerged as a large-scale health problem. Formaldehyde (HCHO) is present in several building materials (particleboard, fibreglass and plywood), paintings and wall paints, glued wallpapers, coatings, fabrics, draperies, carpets and insulation materials, and is emitted significantly from pressed wood products (particleboard, hardwood plywood paneling, medium density fibreglass) which are made using adhesives that contain urea-formaldehyde and wood products containing phenol-formaldehyde resins, conversion varnishes and latex paints. With available measurement techniques and being a singular chemical compound, regulatory processes have lead to reduction of formaldehyde use in building material and hence to dramatic reduction of indoor air formaldehyde concentrations in non-industrial workplaces and homes.

However, interior surface materials are potential sources of a large number of other volatile organic compounds (VOCs). VOC emissions are categorized into primary and secondary sources. Primary emissions refer to non-bonded or free VOCs within building and surface materials and normally found as additives, or solvents, or monomers of low molecular weight. Secondary emissions are physically or chemically bounded VOCs which are emitted or formed through mechanisms, such as reactions between ozone and aliphatic hydrocarbons (in photocopiers and laser printers), or reactions between ozone and fitted carpets or limonene, or microbiological emissions on damped surfaces (MVOCs), or hydrolysis of wet PVC flooring materials or degradation of building and interior surface materials. The most reported VOCs include ethanol, limonene, carbonyls (aldehydes and ketones), aliphatic, cyclic and aromatic hydrocarbons, methylene chloride, terpenes, glycols, acids and esters and their individual concentrations vary from 5 to 50 µg/m³.

Polyvinyl chloride (PVC) is a polymer and a major building material in which phthalates are used extensively as plasticizers to enhance the flexibility, viscosity, stability
and other desirable physical properties of PVC. Plasticized PVC is used extensively indoors as wall and flooring covering in kitchens, bathrooms and children’s playrooms and bedrooms, because it is inexpensive and is easy to clean. Other uses of plasticized PVC indoors are as roofing materials, shower curtains, electric cables, adhesives and synthetic leather. Because phthalate esters are not covalently bonded to the polymer with which they are mixed, they can migrate from PVC material and adhere to the surfaces of indoor particulate matter (PM), as well as house dust. Phthalate may also migrate to PM surfaces, following wear and tear of PVC materials or use of other PVC products, such as nail polish.

Dampness and moisture from building structures and interior surfaces is an important source of indoor pollution, not only in the home, but also in non-industrial workplaces, including office buildings, schools and day-care centres. Damp or moisture accumulates in building structures and/or interior finishes via leaks in roofs, windows or pipes; or moisture from the ground penetrating into the building structure by capillary movement; or moisture from humans and indoor activities such as cooking, bathing, human expiration and humidifiers; or moisture already present in the building material from the time the building was erected. The usual signs are colour changes in and loosening of the surface materials, wet spots on the surfaces, visible moulds and mould odour. Air humidity influences the materials where the climate is moist and warm throughout the year, but has little influence in a cold climate where outdoor air humidity is relatively low throughout the year.

Indoor environments constitute a complex mixture of viable and non-viable microorganisms, which produce fragments, toxins, allergens, microbial volatile compounds (MVOCs) and other chemicals. Dampness is likely to enhance indoor concentration of some of these organisms, in particular dust mites and fungi. Fungi also produce a number of toxins and irritants with suspected respiratory health effects. Dampness may also enhance chemical emissions from buildings and interior surface materials, sometimes compromising the integrity of the material. Emissions of irritants and odorous substances from microbiological and chemical processes on building structures and interior finishes following dampness have also been noted.

HEATING, VENTILATION AND AIR CONDITIONING

Heating, ventilation and air conditioning influence indoor air quality in different ways. Changing the air dilutes the concentration of pollutants from indoor sources when the outdoor concentrations are lower than indoor concentrations. Ventilation systems may also serve as sources of indoor air pollution. Air humidification equipment, used to alleviate the effects of dry air, may serve as source of microbial pollutants some of which may have adverse health effects.

OCCUPATIONAL EXPOSURES IN NON-INDUSTRIAL WORKPLACE ENVIRONMENTS AND HEALTH

Changing the air

The main purpose of a ventilation system is to maintain good indoor air quality in buildings by changing the air by removal and dilution of pollutants and supply of fresh air. In naturally ventilated buildings, air moves into and out of the building through intentionally provided openings, such as windows or doors, or through non-powered ventilators, or by infiltration.

Air change influences the concentrations of indoor air pollutants according to the following formula:

$$ C = \frac{G}{Q_v \epsilon_v} $$

where $C$ is the concentration of the contaminant, $G$ is the generation of contaminant (volume flow), $Q_v$ is the clean air flow to the room and $\epsilon_v$ is the efficiency of pollutant removal.

Insufficient air change or ventilation may lead to accumulation of contaminants and moisture problems, which may lead to adverse health effects. There is also evidence that excessive ventilation may increase emission rates from some materials, as well as increase the resuspension of sedimented particulate matter into indoor air. Insufficient air change is a common problem in office buildings, schools and day-care centres. Air change rates measured as air flow in volume units per hour have been measured as relatively low, but air flows in particular calculated per person were very low in schools and day-care centres. Carbon dioxide concentrations reflect excessive human burden. Studies in day-care centres in Denmark, Finland, Norway and Canada have reported low air flows per person and high carbon dioxide concentrations. Ventilation rates below 5 litres/s per person are likely to cause indoor air pollution problems in non-industrial facilities with high emission rates. Based on several epidemiologic studies, the minimum ventilation rate for office buildings is recommended to be 10–15 litres/s per person.

Thermal environment

The thermal environment, including temperature, relative humidity and air velocity, may influence human health, well-being and performance both directly and indirectly. Thermal environment may act indirectly by either influencing sources, emissions and indoor concentrations of indoor pollutants or by possibly modifying the adverse effects of exposures. Temperature is probably the most important indoor air quality parameter in non-industrial workplaces. Temperature can be considered suitable if the occupants feel comfortable and do not wish to be warmer or cooler. Satisfaction with temperature depends on several factors,
including indoor air temperature, radiation temperature from the sun and from cold and warm surfaces and equipment, and surface temperature.\textsuperscript{28} Thermal comfort is a function of the total body heat exchange with the environment. Individuals vary substantially in satisfaction with temperature, which means that in a given space it is virtually impossible to achieve conditions where 100 per cent of the occupants are satisfied. In an environment of 22°C with negligible radiant temperature and lower than moderate air movement, approximately 80 per cent of the occupants in sedentary work with light clothing feel comfortable. The remaining 20 per cent would prefer a lower or higher temperature, thus a 100 per cent occupant satisfaction rate can only be achieved by personal control of temperature. The optimal temperature in office work is 22 ± 2°C.\textsuperscript{29,30}

Perceptions of dry air may be caused by low relative humidity, but such sensations may also be related to other indoor air parameters, such as high temperature, particles and organic gases. Humans do not have a special sense to perceive humidity, and perception of dry air is related to irritation of conjunctivae, mucosae and skin.\textsuperscript{31} Perceived temperature is strongly related to relative humidity: the sensation of warmth decreases in lower relative humidity. A controlled crossover trial showed that perceived air dryness is alleviated by steam humidification for relative humidity of 29–39 per cent during winter when the relative humidity in non-humidified periods varied between 12 and 28 per cent.\textsuperscript{32}

The thermal environment directly affects the neural sensors of mucous membranes and skin, and may provoke neuron–sensory responses indirectly by changes in blood circulation.\textsuperscript{33} There is evidence that symptoms affecting the eyes, airways, skin and central nervous system are related to temperature and relative humidity. The concept ‘sick building syndrome’ (SBS) has been used to describe a set of symptoms common among office workers in buildings with indoor air problems.\textsuperscript{1} The occurrence of SBS symptoms is related to temperature\textsuperscript{29,30} and relative humidity,\textsuperscript{34} and the relation between the occurrence of SBS symptoms and temperature is U-shaped, with lowest prevalence in temperature between 21 and 23°C.\textsuperscript{29}

**Dampness and mould problems**

Based on a 2004 literature review including studies from several European countries, the United States and Canada, it was estimated that at least 20 per cent of buildings had one or more signs of dampness problems.\textsuperscript{35} Many non-industrial workplaces including office buildings, schools and day-care centres have dampness problems and the prevalence of dampness problems is likely to vary from 10 to 50 per cent, depending on building type, location and the criteria used.

A large number of epidemiological studies have assessed the relation between dampness and moulds at home and the risk of health effects. In the most recent systematic review and meta-analysis by Fisk et al.,\textsuperscript{36} dampness and moulds increased the risk of upper respiratory tract symptoms (summary odds ratio (OR) of 13 studies: 1.70, 95 per cent CI, 1.44–2.00), cough (summary OR of six studies in adults: 1.52, 95 per cent CI, 1.18–1.96), wheeze (summary OR of five studies in adults: 1.39, 95 per cent CI, 1.04–1.85), current asthma (summary OR of ten studies: 1.56, 95 per cent CI, 1.30–1.86) and development of asthma (summary OR of four studies: 1.34, 95 per cent CI, 0.86–2.10). Few studies have assessed the effects of workplace dampness and mould problems.\textsuperscript{37–41} Moisture and debris in ventilation systems, possibly by supporting microbiologic growth, may increase adverse respiratory effects, particularly among asthmatics. The risk of lower respiratory symptoms, throat irritation and rash/itchy skin have been shown to be related to the fungal and endotoxin levels in floor dust.\textsuperscript{40} Non-specific symptoms were positively associated with unidentified chair fungi.\textsuperscript{41} Upper respiratory symptoms were positively associated with total fungal concentrations recovered from chair dust. There is also evidence that dampness and mould problems in schools increase the risk of respiratory symptoms\textsuperscript{42} and general symptoms, such as headache and concentration problems.\textsuperscript{43} The effects of dampness and moulds on asthma and asthma-related symptoms are discussed under Asthma, p. 925. In summary, dampness and mould problems are common in non-industrial workplaces and have similar health effects as these problems in the home.

**Allergens**

Traditionally, relevant exposures to allergens have been thought to take place in the home where the most important sources include dander from cats, dogs and other hairy and feathered pets, house dust mites and excretions, insects, pollen and dust from clothes and other textiles. Studies in day-care centres have shown that occupants can also be exposed to common domestic allergens probably via transportation on children’s clothes.\textsuperscript{3} Outdoor pollen via openings and ventilation systems is also a likely allergen in non-industrial workplaces. Exposures to indoor allergens usually cause IgE-mediated type I immunological reactions in the airways of individuals who have propensity to specific sensitization. Thus, allergens in the workplace may contribute to an increase in the risk of asthma and allergic rhinitis. The authors did not find any empirical studies focusing on this occupational health problem in non-industrial work environments.

**Volatile organic compounds**

The potential effects of exposure to VOCs in the levels appearing in non-industrial indoor environments range from sensory irritation at low and medium levels of exposure to airway inflammation, to neurotoxic, organotoxic and carcinogenic effects at high exposure levels. Some of the VOCs, including benzene and vinyl chloride, have been identified as human carcinogens in much higher levels than occurring in
non-industrial environments and others, such as chloroform, have been found to be carcinogenic in animals. VOCs may affect the airways and induce inflammation and airway obstruction. Molhave suggested three mechanisms for the effects of exposure to low-level VOCs: sensory perceptions of the environment, weak inflammatory reactions and environmental stress reactions. Humans use several senses to identify VOCs: the sense of smell in the nasal cavity, the sense of taste on the tongue and/or the stimulation of sensory nerves in the skin surface. The perception of air quality is an integration of these sensations. Sensory nerves in the skin mediate irritation, smarting or itching (i.e. symptoms). Eyes may form tears as a protective reflexion (i.e. signs). Chemical mediators usually cause acute reversible inflammatory reactions leading to dilatation of vessels and changes in colour and temperature of the tissue. Environmental stress from complex perceptions may lead to increases in stress hormone levels and blood pressure and consequently to fatigue, irritability, reduced tolerance, as well as psychological processes and symptoms. VOCs from water-based paint was shown to increase the prevalence of asthma by two-fold in a study of healthy Swedish adults. Work-related symptoms of eye irritation, cough with sputum and itchy hands are also common among workers using water-based paints.

Office equipment

An increasing amount of equipment and supplies are used in modern offices. Carbonless copy paper can be a source of various particles and volatile organic compounds, such as solvents and colour-forming chemicals. Exposure can be direct through contaminated air to the eyes, nasal mucosa and or indirect through fingers used for handling the paper. Photocopying is also a potential source of chemicals, including VOCs, ozone, particles and resin. Epidemiological studies conducted in northern Europe and the United States have consistently shown an increased risk of SBS symptoms related to handling of carbonless copy paper. Exposure to carbonless copy paper, paper dust and fumes from photocopiers and printers (FPP) may increase the occurrence of SBS-related symptoms, chronic respiratory symptoms, chronic bronchitis, general symptoms (headache and fatigue) and respiratory infections. There is also evidence that exposure to paper dust and to FPP increases the risk of upper respiratory and skin symptoms, breathlessness, tonsillitis and middle ear infections. Effects on asthma are discussed under Asthma, p. 925.

Environmental tobacco smoke or secondhand tobacco smoke

Sidestream smoke contains the same carcinogenic, irritative and toxic compounds as mainstream smoke and on a biologic basis, it is likely that ETS has similar respiratory effects to active smoking. Exposure to ETS ten years ago was still common in most European and North American countries, as shown in Table 71.1, but is now radically decreasing due to progressive smoke-free workplace legislation. However, ETS remains a major global occupational health problem in both non-industrial and industrial workplaces. Table 71.2 summarizes the evidence of the health effects of occupational exposure to ETS. There is abundant evidence that workplace ETS exposure is causally linked to lung cancer and coronary heart disease, and there is strong evidence that such exposure is related to increased risk of asthma in adults. Strong evidence also links reduced birthweight in newborns to ETS exposure of their mothers during pregnancy. In addition, relatively strong evidence links ETS exposure to chronic obstructive pulmonary disease (COPD) and stroke and one study suggests its association with severe pneumonia.

SPECIFIC DISEASES OR SYNDROMES RELATED TO NON–INDUSTRIAL INDOOR ENVIRONMENTS

Asthma

Many studies have suggested that the prevalence of asthma has increased at least in western countries in the late twentieth century. There are several possible explanations for this, including changes in environmental exposures, changes in lifestyle habits, changes in diagnostic and management practices of asthma, as well as methodological issues. There is a trend towards an increasing proportion of the workforce working in an office-type environment, where they may be exposed to indoor pollutants. Energy-saving measures have sometimes led to reduced ventilation of the indoor spaces, which can increase the levels of indoor pollutants. Both development of adult-onset asthma and exacerbations of underlying asthma have been linked to many exposures in non-industrial indoor environments.

Occupational asthma is asthma where the probable principal cause is a chemical, physical or biological exposure at work. It can be induced by a sensitizer or long-term or intermittent exposure to low levels of irritants. The diagnostic criteria of occupational asthma are presented in Chapter 72, Occupational asthma, p. 941. The diagnostic procedures include a thorough occupational history and inventory of exposures in the workplace, which in some cases may include environmental measurements of exposures at work, serial peak expiratory flow recordings on work days and days off work, spirometry, histamine or methacholine challenge, and for some exposures immunological tests (specific IgE and/or skin prick tests). When hypersensitivity is suspected as the underlying mechanism, specific bronchial challenge tests can be carried out in expert centres. Comparison of lung function during exposure and away from it can also be tested in a workplace challenge. As many of the non-industrial indoor...
environmental exposures are likely to induce irritant, rather than hypersensitivity-induced asthma, specific bronchial challenges may not be the way to proceed in the diagnostics and the role of a good-quality serial peak expiratory flow (PEF) recording is emphasized. The recently studied known or potential causes of occupational asthma in non-industrial indoor environments are reviewed briefly in this section.

Occupational asthma is a medicolegal concept and remediating environmental measures should be taken when appropriate from the disease management point of view even if the legal definition of occupational asthma may not be met. Many countries have compensation systems covering occupational asthma, but the systems vary between different countries, so information to be given to the patient depends on the local system.

Work-aggravated asthma is a concept more recently introduced to the literature. It means that work exposures aggravate the symptoms of pre-existing asthma and lead to less well-controlled asthma, even if they are not the principal cause of the asthma. This is likely to affect the employee's work ability. The control of asthma can be improved by reducing the workplace exposures and ensuring that the asthma medication is adequate.

**SECONDHAND TOBACCO SMOKE EXPOSURE**

Among children, the causal role of secondhand smoke (SHS) exposure at home for both onset of asthma and exacerbation of asthma has been established.\(^{36,57}\) In recent years, an increasing number of studies have also addressed the relationship between SHS and adult asthma.\(^{13,57,58}\) SHS exposure at work and at home was related to adult-onset asthma in a large Finnish population-based case–control study, the OR estimates being 2.16 (95 per cent CI, 1.26–3.72) in relation to workplace exposure and 4.77 (95 per cent CI, 1.29–17.7) in relation to home SHS exposure in the previous 12 months.\(^{59}\) Cumulative SHS exposure over lifetime at work and at home was linked to increased risk of asthma showing an exposure–response relation. The risk estimates, usually OR, from other studies varied between 1.15 and 4.7.\(^{13}\) Several studies found a stronger effect related to workplace SHS exposure than home exposure.

The mechanisms by which SHS induces asthma are not well known. SHS contains many irritant substances that can induce mucus hypersecretion and inflammation in the airways. Long-term exposure could lead to irritant-induced asthma.\(^{59}\) Tobacco smoke also seems to cause epithelial damage and to increase epithelial permeability to environmental allergens and has been shown to enhance allergic reactions to some inhalable allergens. There is also some evidence that SHS exposure may cause bronchoconstriction and increased microvascular leakage, which are typical for asthma.\(^{60}\)

Subjects with asthma have chronic inflammation in their airways and consequently, may be particularly susceptible to the adverse effects of SHS exposure, so SHS may be a cause of work-aggravated asthma. The review by Jaakkola and Jaakkola\(^{61}\) and another by the Californian Environmental Protection Agency\(^{57}\) identified a total of nine studies on the role of SHS exposure for exacerbation of a pre-existing asthma. The studies showed that in adult subjects with asthma, SHS exposure at home and/or at work is related to increased occurrence of respiratory symptoms, increased use of bronchodilator and steroid medications, reduced general health, increased health-care use including emergency department visits and hospitalizations, increased bronchial hyper-responsiveness and reduced spirometric lung function. The Third National Health and Nutrition Examination Survey (NHANES III) found that adult asthmatics with the highest serum creatinine levels had significantly lower lung function levels, especially in women, compared to those with low SHS exposure levels.\(^{62}\)

**INDOOR DAMPNESS AND MOULD PROBLEMS**

In 2007, Fisk and colleagues\(^{36}\) reported a meta-analysis of 33 studies on dampness and mould problems in homes and asthma and respiratory symptoms. In analyses combining studies of children and adults, the estimated OR of lifetime asthma was 1.37 (95 per cent CI, 1.23–1.53) and that of current asthma 1.56 (1.30–1.86). Thus, the results suggested a 30–50 per cent increased risk of asthma in relation to indoor dampness and mould problems. The risks of cough and wheeze were also statistically significantly increased, the effects being usually slightly larger among children.

In 2004, Jaakkola and Jaakkola\(^{63}\) reviewed the literature on indoor moulds and asthma in adults. They concluded that there is strong evidence that indoor moulds at home increase the risk of asthma, as epidemiological studies have consistently found a relation between exposure to dampness and moulds at home and the risk of asthma in adults. The OR of asthma has ranged between 1.3 and 2.2 and there is some evidence of a dose–response relationship with more severe mould problems being related to a higher OR. They also concluded that there is increasing evidence that indoor moulds at work increase the risk of wheezing, with an OR between 1.3 and 2.8. A recent Finnish incident case–control study showed evidence that indoor moulds at work significantly increase the risk of asthma, with an OR of 1.54 (95 per cent CI, 1.01–2.31).\(^{64}\) That study indicated that women, young adults and smokers are particularly susceptible to the adverse effects of workplace indoor moulds.

The mechanisms by which indoor dampness and mould problems could lead to asthma are not yet fully understood, but several potential mechanisms have been suggested. These include IgE-mediated hypersensitivity reactions to fungal allergens or to mite allergens,\(^{65}\) toxic effects of mycotoxins produced by fungi and non-specific inflammatory reactions caused by fungal cell wall components, such as 1,3-β-D-glucan and ergosterol.\(^{66,67}\) It is not known whether these mechanisms are specific for different species of moulds.

In Finland, indoor moulds have been a rather common cause of occupational asthma according to the Finnish Register of Occupational Diseases. However, this is a difficult diagnosis to make, as hypersensitivity reactions seem to be the underlying mechanism only in a minority of mould-induced cases. Thus, specific bronchial challenge tests may not be very useful. Currently, the diagnosis of occupational asthma due to mould problems is based mainly on serial PEF recording, while at work and off work, in conjunction with a history that asthma started in a workplace where there is clear evidence of mould problems.

In addition to the role of indoor moulds for inducing asthma, there is some evidence that indoor moulds also increase the severity of a pre-existing asthma, suggesting that it may cause work-aggravated asthma.

Overall, it can be concluded that there is increasing evidence suggesting that prevention and prompt repair of indoor dampness and mould problems in both the home and work environments prevents asthma. There is some
evidence that correction of indoor and dampness problems leads to alleviation of asthma symptoms in damaged workplaces. The long-term prognosis of occupational asthma from indoor moulds is not well understood, but minimizing mould exposure by repair of the damage or relocation of the affected individual is recommended as management.

OTHER OFFICE ENVIRONMENT EXPOSURES

The recent Finnish Environment and Asthma study on adult-onset asthma also investigated the relationship between some office work exposures and asthma. Regular occupational exposure to self-copying paper that contains inks and solvents was linked to significantly increased risk of asthma, with an OR of 1.66 (1.03–2.66).68 No exposure–response relationship was detected with increasing number of hours working with self-copying paper per week. A significant increase in asthma risk was observed among those with an exposure of between 1 and <15 hours. It was speculated that this could suggest a hypersensitivity reaction, so that even small amounts of exposure might induce the reaction. Exposure to paper dust, in general, was significantly related to the risk of adult-onset asthma, with an OR of 1.97 (95 per cent CI, 1.25–3.10).69 An increasing risk of asthma was observed with increasing hours of exposure to paper dust at work. More studies are needed to investigate the mechanisms behind this observation. A case–control study from Sweden has also reported increased risk of asthma in relation to paper dust exposure.69 In contrast, exposure to fumes from copying machines and printers was not significantly associated with asthma in the Finnish study.

Some individual cases of occupational asthma in relation to acrylate glues used in flooring have been detected. Indoor plants in offices have also been reported as identified causes of occupational asthma, a commonly involved plant being the weeping fig (*Ficus benjamina*).70

The Finnish Environment and Asthma Study also evaluated potential links between interior surface materials and adult-onset asthma.71 It found a significantly increased risk of asthma in office workers who reported that at least half of the wall surface area in their office was plastic (OR 2.43, 95 per cent CI, 1.03–5.75). It was speculated that phthalates contained in PVC materials could be the mechanism explaining this finding. Plasticizers of PVC have been shown to induce inflammation in the airways of humans and in animal models.72 The risk of asthma was also somewhat increased in relation to large areas of textile wall material and wall-to-wall carpet.

CLEANING CHEMICALS

Recent studies have detected increased risk of asthma among cleaners. The OR from the studies ranged between 1.42 and 8.1. The agents that have been identified as important exposures include cleaning chemicals containing ammonium, bleach (containing chlorine) and some disinfecting substances. In addition, long-term exposure to a mixture of irritating chemicals may induce asthma via an irritant-induced mechanism. There are also reports in the literature of occupational asthma of personnel other than the cleaners themselves, where the exposure was attributed to residues of cleaning chemicals after the cleaning had taken place.76

Extrinsic allergic alveolitis

Extrinsic allergic alveolitis, also known as hypersensitivity pneumonitis, is type III and IV hypersensitivity reaction of the alveolar and bronchiolar tissue and interstitium of the lungs, in response to inhaled antigens. Farmer’s lung caused by mouldy forage is the best investigated form of extrinsic allergic alveolitis, but it can be related to a range of environmental allergens in the workplace and at home, including fungi, bacteria, some animal species (e.g. pigeons, rodents), plant proteins and less commonly reactive chemicals.77–79 Microbiological contamination of air conditioners or humidifiers in indoor environments has been reported as causes of extrinsic allergic alveolitis in office environments and printing works. Contaminated water, for example in washers, has also been reported as a source of outbreaks of extrinsic allergic alveolitis in some factories, such as car manufacturing.80 Spraying or vaporization of recycled or stored water has often been involved. The causative microbes identified include fungi, such as *Micropolyspora faeni*, *Aspergillus* and *Penicillium* species, and bacteria, such as *Thermoactinomyces vulgaris* or *Klebsiella* species. In addition, bacterial endotoxins and in some cases amoebae have been detected as significant contaminants. Extrinsic allergic alveolitis caused by contaminated humidifiers is often called ‘Humidifier lung’.

Extrinsic allergic alveolitis presents as an acute, subacute and chronic form. The acute form is easiest to recognize, as the patient typically experiences cough, chest tightness, febrile chills, malaise and flu-like symptoms three to eight hours after exposure. The symptoms wane spontaneously over a few hours, but recur on subsequent exposure. This is the form most commonly described in outbreaks of humidifier lung. The subacute form develops without obvious episodes of flu-like illness and presents as progressive shortness of breath, dry cough and weight loss. The chronic form is the least well described, presenting as slow development of interstitial fibrosis. The subacute and chronic forms of this disease may well go undetected.

The diagnosis of extrinsic allergic alveolitis from indoor contaminants includes the same diagnostic tests as other forms of extrinsic allergic alveolitis. The diagnostic criteria are presented in Chapter 74, Extrinsic allergic alveolitis, p. 970. The key point is to find the source of exposure and,
to investigate this, it is important to take a thorough exposure history and if needed, to conduct a worksite visit, including environmental measurements. Immunoglobulin G (IgG) antibodies (i.e. precipitins) can often be measured to the causal antigen, for example to many moulds and birds. However, IgG antibodies have also been measured in asymptomatic exposed workers, so they may simply be indicators of exposure and not necessarily of disease.

In physical examination, a typical finding is crackles in the lower fields of the lungs. Standard chest x-ray is abnormal in about 80 per cent of cases of extrinsic allergic alveolitis, so a normal finding does not rule out the disease. In acute and subacute forms, the typical findings are fine interstitial infiltrates, while in the chronic form of the disease the radiological appearance is irregular scarring, related to diffuse pulmonary fibrosis or even diffuse emphysema. High-resolution chest computed tomography (CT) shows patchy ground glass opacities, decreased attenuation due to air trapping and a mosaic pattern. In lung function tests, a typical finding is restrictive ventilatory function impairment (with both forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV1) reduced with normal FEV1/FVC, as well as reduced total lung capacity), although sometimes a combined restrictive and obstructive pattern may be observed. As extrinsic allergic alveolitis is a diffuse parenchymal disease, the diffusion capacity of the lungs is typically reduced (both DLco and Kco). With a mild form of the disease, arterial blood gases show hypoxia only in relation to exercise, while in more advanced disease the patient may be hypoxic at rest. Carbon dioxide tension may be lowered due to hyperventilation stimulated by low oxygen tension. The lung function findings reflect the interstitial nature of the disease and are not specific for extrinsic allergic alveolitis. It should be borne in mind that all the physiological findings may have subsided if the patient has not been exposed for some time before the investigations.

It is usually recommended that bronchoscopy with bronchoalveolar lavage (BAL) and sometimes transbronchial biopsy be carried out when investigating a patient with suspected extrinsic allergic alveolitis. Surgical lung biopsy is rarely needed for the diagnosis of this disease. BAL typically shows increased total cell count, with an increased proportion of lymphocytes (>40 per cent). T-helper to T-suppressor ratio is usually reduced to less than 1. After acute exposure, neutrophils are transiently increased in BAL. The characteristic histopathologic findings of EAA include diffuse interstitial infiltrate, scattered non-caseating granulomas and cellular inflammation of the bronchioles. A specific inhalation provocation test with the relevant specific antigen can be performed to confirm the diagnosis, but this is rarely needed to establish the diagnosis. Such challenge tests should only be conducted in centres with considerable experience with them. A more common approach to this is to carry out a worksite challenge test with lung function testing before and after workplace exposure.

The most important in the management of extrinsic allergic alveolitis is to remove the source of exposure from the work environment or, if this is not possible, to remove the patient to another, uncontaminated work environment. If the source of exposure is a contaminated humidifier or air conditioning system, cleaning of this is essential. It is important to remember that those performing this cleaning should wear respiratory protection equipment. Oral corticosteroids may be given at the acute episodes, as they have been shown to shorten the recovery time and reduce the probability and severity of recurrence, but currently there is no evidence that they would affect the long-term outcome of extrinsic allergic alveolitis. In the case of farmer’s lung, reduction of exposure by using motorized respirators is an option for treatment, but this is not a solution for extrinsic allergic alveolitis related to indoor sources. Prevention of extrinsic allergic alveolitis focuses on prevention of exposure. In the case of indoor microbiological contaminants, preventive actions include adequate building techniques and maintenance of the buildings, and ventilation and humidification systems. Any dampness or mould problems detected should be repaired promptly.

**Humidifier fever**

Humidifier fever is a disease with similar symptoms to those experienced in extrinsic allergic alveolitis. The patient typically experiences fever, nausea, sweating and myalgia, sometimes with breathlessness, four to eight hours after exposure. However, the subject typically develops tolerance on continued exposure, so the symptoms diminish towards the end of the working week. After a break from work, for example over the weekend, the attack is usually worse again (i.e. Monday morning fever). Outbreaks have been reported in relation to bioaerosol exposure from contaminated humidifier water in offices and printing houses, but this disease differs from extrinsic allergic alveolitis (i.e. humidifier lung) in that the disease mechanism seems to be a toxic alveolitis, usually due to bacterial endotoxins. The patients may have specific IgG antibodies to the microorganisms growing in water reservoirs as a sign of exposure. The patient may present with fine crackles from the lungs in physical inspection and show reduced diffusing capacity of the lungs and/or mild restriction. The chest x-ray is often normal. The patient should monitor their body temperature twice a day (in the morning and after work) and work days should be compared to days off work.

Cessation of exposure leads to improvement of symptoms spontaneously. For example, when the humidifier equipment is turned off, airborne levels of bacteria and endotoxin fall. It is important to detect the source of exposure and to clean the contaminated humidifier or air conditioning system (with the cleaners wearing adequate respiratory protection equipment). According to current thinking, humidifier fever does not lead to any long-term health problems. Regular maintenance of humidifiers and air conditioners is the best approach to prevent humidifier fever.
Legionnaires’ disease

*Legionella pneumophila* is a bacterial microorganism that is found widely in nature in wet surroundings and it is capable of colonizing cooling towers and hot water systems. Infection presents in two forms: pneumonia called ‘Legionnaires’ disease’ and acute self-limiting influenza-like illness called ‘Pontiac fever’.

An outbreak of pneumonia occurred at the American Legion Convention in Philadelphia in 1976. *Legionella pneumophila* was identified as the causative organism and its spread was linked to the hotel’s air conditioning system. Of 221 persons affected in this outbreak, as many as 19.5 per cent died. Other outbreaks have subsequently been described related to cooling towers and hot water systems, for example in hospitals and office buildings. Recently, an outbreak of Legionnaires’ disease was related to poorly maintained air conditioning equipment in Cumbria, UK. The outbreak caused several fatalities and resulted in prosecution of the individual who was responsible for deciding how frequently the air conditioning system was serviced. Infections linked to Legionella were also detected among individuals who had passed through the alley where the system vented.

The incubation period for Legionnaires’ disease is between two and ten days. The clinical development of the disease varies from mild cough and fever to widespread pulmonary infiltrates and multiorgan failure. The early symptoms include malaise, myalgia, fever and mild cough, sometimes with blood in the sputum. Neurological symptoms range from headache to severe encephalopathy. Watery diarrhoea occurs in 25–50 per cent of cases. In chest x-ray, a typical initial finding is unilateral lobe infiltrate, although it may present in a wide variety of manifestations. *Legionella* is typically associated with rapidly progressive infiltrations. Complete recovery of the infiltrates may take between one and four months. In chest CT, *Legionella* presents as ground glass appearance in the affected lobes, the patient typically having hyponatraemia and being bradycardic and hypotensive. C-reactive protein increases in the early phases of disease. The definitive diagnosis is based on isolation of the organism by culturing respiratory secretion on buffered charcoal yeast extract agar with four days of incubation. Urinary antigen detection is a good rapid test, but it is less sensitive than culture. Serological detection of antibodies is less useful.

Legionnaires’ disease requires treatment in hospital. Erythromycin used to be the drug of choice, but the second-generation macrolides, such as azithromycin and clarithromycin, quinolones, and telithromycin have replaced its use. In severe cases and in immunocompromised patients, a combination of a second-generation macrolide and quinolone may be used.

Outbreaks of Pontiac fever have also been reported in hospitals and offices. The incubation period is 24–48 hours and the attack rate of the exposed seems to be as high as 90 per cent. The symptoms include malaise, myalgias, fever, chills and headache, non-productive cough and nausea. There is no pneumonia in this milder form of *Legionella pneumophila* infection. The therapy is symptomatic and recovery usually takes place within one week.

Superheating of hot water to >50°C and flushing are the most important methods to disinfect the water distribution systems and prevent *Legionella* infections. In hospitals where organ and bone marrow transplants are performed, it is recommended that routine environmental culturing of *Legionella* be carried out.

Sick building syndrome

The concept of sick building syndrome (SBS) was first applied in the 1980s as a health problem related to indoor air quality. A UK epidemiological study characterized empirically the main components of SBS: nasal, eye and mucous membrane symptoms, dry skin, lethargy and headache. The WHO working group suggested that there was an association between the symptoms and forced (mechanical) ventilation systems, and the British study reported an excess of symptoms related to air handling, especially air conditioning. The concept of SBS has also been used to characterize work-related health problems in non-industrial workplaces, such as day-care centres, schools and hospitals. Research has revealed a complex set of modern occupational health problems underlying the SBS. It has been postulated that there is no single disease entity which could be diagnosed within individuals. The symptoms of SBS are symptoms and signs of a number of different health outcomes with different manifestations and aetiological factors. One, or a set of environmental determinants of different ontological nature, i.e. physical or social, can cause the symptoms and signs. Therefore, the phenomenon SBS consists of several types of relations between environmental determinants and health outcomes, and a singular exposure can cause different health outcomes and a given symptom can be caused by one, several or a combination of different exposures and exposure patterns.

Figure 71.1 presents the worker (inner circle) and the office environment (outer circle–inner circle) and illustrates phenomena in the office environment or non-industrial work environment in general. First, the work environment is divided into physical and social environments, which both include determinants of human health and well-being. Second, man can be viewed to constitute two different domains, the one belonging to the physical phenomena and the other to the psychological phenomena, and the health outcomes related to the environmental determinants are thus either physical or psychological, or both. The purpose of this simplified model is to elaborate the different types of phenomenon. The relationship between these phenomena theoretically describes how the environmental determinants can affect human health and well-being and can cause both physical (objective) and mental (subjective) outcomes. A disease or health state can have physiological and/or psychological underlying mechanisms and manifestations.
The first step to identify relevant relations between possible health problems and their environmental or constitutional determinants is to consider the components of the SBS (Table 71.3). The symptoms and signs of interest can be categorized into two dimensions: anatomical site and hypothesized underlying mechanism. The main anatomical sites are the eyes, the respiratory tract (nose, airways, lung parenchyma), the skin and the central nervous system. Possible underlying mechanisms include mechanical irritation and inflammation, immunological/allergic reactions, toxicity, infection and environmental psychological stress.

The symptoms arising at the different anatomical sites are non-specific as to their causes. Inference about their causes and underlying mechanisms can be made by characterizing the type and intensity of the symptoms and the time and place of their occurrence. Therefore, a number of environmental factors, e.g. artificial mineral fibres, formaldehyde and pollen, can cause similar eye symptoms via mechanical irritation and/or chemical toxicity and/or allergic reactions. Biochemical or immunological investigation of tear fluid or conjunctiva, and/or measurements of indoor air quality may help to identify the underlying mechanisms and environmental causes of the symptoms. Exposure to a given environmental factor may cause different mechanisms and signs in different individuals or environmental conditions. For example, the effect of a complex mixture of office air could cause different types of symptoms and different health outcomes in different individuals depending on personal susceptibility and, in addition, one or several mechanisms could be involved.

Table 71.4 summarizes different physical exposures and social factors, which may cause one or several symptoms and signs of SBS. The role of thermal environment and air change is discussed under Thermal environment, p. 923. Dampness and mould problems have also been linked to increases in the risk of several of the typical symptoms related to SBS, including irritation of eyes, nose and throat. There is increasing epidemiological evidence that the risk of asthma, asthma-like symptoms and allergic rhinitis is related to the presence of PVC materials which are sources of di-ethyl-hexyl-phthalate and its metabolic products.

According to the occupational stress model, stress arises when there is perceived imbalance between external demand and response capabilities, especially under conditions where failure to meet demands has important consequences. The job strain or ‘demand–control model’ developed by Karasek in 1979 suggests that the joint effect of high demand and low control will lead to negative health outcomes. Baker et al. developed the demand–control model by emphasizing the role of social support in moderating the adverse effects of occupational stress. Jaakkola suggested that the demand–control model characterizes both conceptually and empirically the effects of social environment on the SBS-related symptoms. This is supported by results from epidemiological studies conducted among Finnish and British office workers. A Swedish cross-sectional study of 532 office workers showed that the three-dimensional model of demand–control–support can predict symptoms compatible with SBS.44

**Adverse pregnancy outcomes**

An increasing number of women are working outside the home during pregnancy. This increasing trend of women working in pregnancy underlines the need to understand the potential adverse effects of prenatal exposures taking place in workplaces. Workers in non-industrial workplaces are exposed to several factors which are potential causes of reduced fetal growth, preterm delivery, spontaneous abortion and congenital malformations. The concentrations of individual compounds of exposures are typically lower in non-industrial compared to industrial workplaces, but exposures may comprise complex mixtures in which the compounds act synergistically. In this section, known or potential, recently investigated occupational causes of adverse pregnancy outcomes are discussed in brief.
SECONDHAND TOBACCO SMOKE

There is substantial evidence that exposure to secondhand tobacco smoke of the mother during pregnancy increases the risk of low birth weight and preterm delivery. Although individual studies were often inconclusive, a meta-analysis by Windham and colleagues\(^9\) suggested that exposure to SHS during pregnancy has a small, but significant adverse effect on birthweight and increases the risk of low birthweight. The evidence of effect on preterm delivery was weaker,\(^9\) but supported by a Californian\(^5\) and a Finnish study.\(^6\) In the latter, work exposure was a stronger determinant of adverse pregnancy outcomes than home exposure.

ORGANIC SOLVENTS AND VOLATILE ORGANIC COMPOUNDS

There is evidence that work exposure to organic solvents may reduce intrauterine growth and increase the risk of small-for-gestational age infants. Previous epidemiologic studies conducted in laboratory workers,\(^9\) drycleaners,\(^9\) pharmacy assistants,\(^10\) and workers in the petrochemical industry\(^11\) have suggested an association between exposure to organic solvents and fetal growth. These observations are based on studies in industrial work and laboratories, where the exposure levels for singular compounds exceeds those of non-industrial workplace levels. However, workers in non-industrial environments may be exposed to rather high concentrations of a complex mixture of VOC, i.e. total VOC concentrations, but the effects of such exposures on the risk of adverse pregnancy outcomes have not been studied.

STRESS

Based on a recent systematic review, the overall evidence is indicative of an independent association between prenatal maternal stress and adverse pregnancy outcomes.\(^12\) Evidence consistently suggests that exposure to stressful stimuli increases the risk of preterm delivery. The effect on low birthweight and fetal growth was mediated by
the absence of psychosocial resources, such as positive personality characteristics and social support.

Cancer

The International Agency for Research in Cancer (IARC) summarized the available evidence on the effects of exposure to secondhand smoke on cancer in 2004. They found sufficient evidence to conclude that involuntary smoking is a cause of lung cancer in never-smokers. The excess risk was estimated to be of the order of 20 per cent for women and 30 per cent for men. The evidence on the effects on cancers of the nasopharynx, nasal cavity, paranasal sinuses, cervix and gastrointestinal tract was found to be sparse and conflicting.

Several volatile organic compounds, including benzene and vinyl chloride, are shown to be potential human carcinogens at levels taking place in industrial workplaces. There is no evidence that levels of such exposures in non-industrial workplaces increase the risk of cancer.

PUBLIC HEALTH IMPACT AND ECONOMIC CONSEQUENCES

There are no reports of an overall estimate of the impact of non-industrial occupational hazards. The public health impact and economic consequences from the two most common hazards, dampness and mould problems and second-hand tobacco smoke exposure have been assessed recently.

Mudarri and Fisk assessed the public health risk and economic impact of dampness and mould exposures in the United States on current asthma using effect estimates for current asthma from exposure to dampness and mould in homes from Fisk et al. They assessed the proportion of current asthma cases in the United States that are attributable to dampness and mould exposure to be 21 per cent (95 per cent CI, 12–29). Based on the literature covering dampness and mould problems in schools, offices and institutional buildings, the risks from exposure in these buildings are similar to risks from exposures in homes. Of the 21.8 million people reported to have asthma in the United States, approximately 4.6 (2.7–6.3) million cases are estimated to be attributable to dampness and mould exposure in the home. The national annual cost of asthma that is attributable to dampness and mould exposure in the home is estimated to be $3.5 billion ($2.1–4.8 billion).

According to recent estimates from Europe and the United States, significant numbers of workers are exposed to secondhand tobacco smoke in their workplaces: approximately 7.5 million workers in 15 EU countries and 24.6 million workers in the United States. Experience from different parts of the world with national, state-wide or local smoke-free workplace legislations has shown that such legislation is feasible to implement and leads to significant decline in SHS exposure of employees in the short and long term, compared to situations where there are no, or only a few, voluntary smoking restrictions. These reductions in SHS exposure have been accompanied by health benefits, including reduced respiratory symptoms and acute myocardial infarctions, and increased lung function levels. Experience from Finland shows that following implementation of national smoke-free workplace legislation, smokers’ attitudes become more favourable towards smoking restrictions in the workplace. A body of evidence also shows that such legislation leads to reduced active smoking, by increasing the number of smokers who cease and by reducing the tobacco consumption of continuing smokers. The weight of evidence suggests that smoke-free workplace legislation will result in a considerable reduction in the burden from several chronic diseases and substantially reduce health care costs.

MANAGEMENT AND PREVENTION

The location of the building is an important determinant of indoor exposures. Therefore, health issues should be taken into account when deciding on the location of the building and when designing it. The building and its ventilation system can be used to protect its occupants from high levels of ambient air pollution. Use of building materials with low chemical emission is an important aspect of source control to reduce indoor air pollution in non-industrial workplaces. Several macroscale activities are likely to reduce population exposure from material emissions and producers of building materials should develop and produce materials with lower emissions. Testing of new materials entering the market is a critical factor, but can be difficult, because the number of surface materials used can vary in different micro-environments and emission rates depend on air change, temperature, humidity and building structures. Special emphasis should be placed on materials covering large surfaces, such as walls and floors. Consumers should be informed about the emission rates of different materials and they should be educated to demand the least damaging materials, as this is the most efficient way to influence the market. Classification of materials, paints and chemicals would help the consumer to choose products and provide guidance to the builders and producers.

Many typical dampness and mould problems can be prevented in the planning, construction and maintenance of buildings. These problems can lead to serious health effects and therefore should be mitigated at an early phase.

Sufficient air change, at least 10 litres/s per person in sedentary work, is the most important characteristic of a good non-industrial indoor environment. Both emissions from occupants, their activities and other sources, e.g. surface materials, should be taken into account when defining the minimum ventilation rate.

In many developed countries in colder climates, overheating of non-industrial workplaces is common, whereas in warm climates, the cooling during the summer is often excessive. The optimal indoor temperature for sedentary work is 21–23°C. Thus, less winter heating and less summer cooling may reduce acute symptoms and improve
thermal comfort, while providing substantial energy conservation benefits.

Finally, maintenance of buildings and heating, ventilation and air conditioning systems is an important aspect of primary prevention of the harmful effects of indoor environmental problems.

As is the case in industrial workplaces, the same is true for those in non-industrial work environments, if an individual worker or a group of workers become ill from an occupational cause, it is important to assess the potential risk from the exposure to the health of other workers, in order to prevent further cases of occupational disease.

### Key points

- An increasing proportion of the workforce is working in non-industrial indoor environments which have traditionally been considered as safe, because occupants are not exposed to high levels of physical, chemical or biological compounds traditionally thought to be hazardous to health.
- In non-industrial environments, such as offices, day-care facilities, schools, hospitals and nursing homes, several physical, chemical, microbiological and/or social factors create complex environmental conditions which may increase the risk of developing well-defined diseases or occurrence of a set of symptoms and signs often through multifactorial causal webs.
- Occupational exposures in non-industrial workplaces can cause several diseases including asthma, extrinsic allergic alveolitis, humidifier fever, Legionnaires’ disease, as well as reduced fetal growth, and non-specific symptoms and signs of the eyes, airways, skin and central nervous system denoted as ‘sick building syndrome’.
- The most common occupational health problems are related to the physical environment, including the thermal environment, insufficient air change, dampness and mould problems, environmental tobacco smoke and emissions from office equipment and paper handling and from interior surface materials, especially in new buildings or after recent refurbishment, and factors of the social environment including occupational stress and organizational factors.
- Action points for the prevention of indoor-related health problems include maintenance of sufficient air change (>10 litres/s per person) and optimal temperature (21–23°C), use of low emitting surface materials, isolation of unnecessary pollution sources from work space (e.g. photocopying, excessive paper handling, storage of solvents and cleaning agents), prompt mitigation of dampness and mould problems and good management of the workforce.

INTRODUCTION

It is estimated that exposures in the workplace account for around one in ten cases of new or recurrent asthma in adulthood. Many general respiratory physicians may be surprised by the magnitude of this proportion which is derived from meta-analysis of epidemiological studies that have examined, in the main, the distribution of asthma in different occupations. Their scepticism probably reflects not only differences in the way that clinicians and epidemiologists understand ‘attribution’ and the geographical variation in all occupational lung diseases, but also the frequency with which an occupational aetiology for asthma is overlooked. On the other hand, physicians with an interest in occupational disease and especially those concerned directly with the health of employees in high-risk workforces will not be taken aback. Indeed most will agree that work-related asthma is among the most common of occupational respiratory diseases, particularly in the industrialized world.

There are two broad categories of work-related asthma. First, the disease may be induced anew by exposure to an airborne sensitizing or irritant agent encountered at work. This, the focus of this chapter, is generally termed ‘occupational asthma’. Such asthma may develop in an employee who has or does not have a previous history of asthma from another cause. Alternatively, pre-existing asthma may be provoked by workplace exposure(s) to ‘exacerbating’ agents which commonly include irritant fumes or dusts, cold air and physical exercise. This, termed ‘work-exacerbated asthma’, is probably very common and is generally manageable with careful attention to workplace exposures, protective equipment and appropriate pharmacological treatment of the underlying disease.

Occupational asthma almost always develops as an immune response to an airborne sensitizing agent in the workplace. The nature of this ‘hypersensitive’ response is such that there is a latent (‘sensitizing’) period of several months between initial exposure and the development of symptoms and subsequently the provocation of symptoms by very low exposures to the inducing agent. Presumably a reflection of variations in innate susceptibility, not all exposed employees will become sensitized although, depending on the levels of exposure in a workplace, very high proportions may do so. In most cases of occupational asthma caused by airborne proteins, the immunological response is characterized by the production of specific IgE antibodies. In cases arising from exposure to chemical agents, the type of immunological response is far less well understood.

Occupational asthma may also arise – albeit uncommonly – from very high exposures to respiratory irritants. The mechanism of this response, originally termed ‘reactive airways dysfunction syndrome’, but now more commonly referred to as ‘irritant-induced’ asthma, is primarily non-immunological. Most well-characterized cases follow single ‘toxic’ exposures to agents such as chlorine or oxides of nitrogen. It remains unclear whether more frequent, but less intense exposures to irritants in the workplace can give rise to asthma, although domestic exposures – to cleaning sprays, etc. – have been associated with incident ‘asthmatic’ symptoms.

Respiratory sensitization to an occupational agent is one of very few well-established causes of adult asthma. It is thus
potentially preventable and furthermore offers a rare opportunity to cure an asthmatic patient of their disease. Moreover, it seems to be a costly disease. In the UK, the total lifetime costs of cases of occupational asthma reported to a national surveillance scheme each year (a fraction only of the true number of cases) are estimated to be up to £100 million. Only a small proportion of these costs are borne by employers, the rest accruing to the state and the individual. For these reasons, the disease has a high profile in industrial legislation in most of the developed world.

CAUSES OF OCCUPATIONAL ASTHMA

The published literature includes between 300 and 400 workplace agents reported to have caused occupational asthma. In some instances, the number of cases of asthma is very small. Those agents, and the occupational circumstances under which exposure to them occurs, which are widely recognized to cause a substantial burden of disease are listed in Table 72.1. Occupational asthmagens are generally categorized as being of either high or low molecular mass. The former are usually proteins that act as complete allergens; the latter are ‘chemical’ agents, which probably become antigenic only after conjugation with a body protein such as human serum albumen.

Currently, the respiratory allergenicity of all recognized chemical allergens is identified, for example on a safety data sheet, by the risk label ‘R42’ (‘may cause sensitization by inhalation’). This signifies either that there is published evidence in humans that the substance can induce specific respiratory sensitization, or that there have been positive results from appropriate animal tests or that the agent is an isocyanate (unless there is evidence that it does not cause hypersensitivity). In the future, the familiar R42 label is likely to be replaced, under the Globally Harmonized

System of Classification and Labelling of Chemicals, by 'H334' (‘may cause allergy or asthma symptoms or breathing difficulties if inhaled’). Under the new regulations, a respiratory sensitizer is defined as a substance that will induce hypersensitivity of the airways following inhalation on the basis of evidence in humans or positive results from an appropriate animal test.

The list of agents which can cause occupational asthma is, necessarily, ever expanding. Fairly comprehensive information is available in specialist textbooks and websites. It is in any case prudent to assume that any airborne protein (of either animal or vegetable origin) and any highly reactive chemical is capable of inducing respiratory sensitization.

MECHANISMS OF OCCUPATIONAL ASTHMA

Disease that is induced by exposure to a sensitizing agent encountered at work is the most common form of occupational asthma. It has the characteristic features of an acquired, immunological (‘hypersensitive’) reaction. Thus, specific sensitization and asthma develop only in a proportion (usually a minority) of exposed subjects and only after an asymptomatic (latent) period of exposure lasting several weeks or months, but occasionally years. Once asthma has developed, symptoms are provoked by concentrations of the sensitizing agent which are too low to provoke symptoms in non-sensitized workers and which the affected individual would previously have tolerated.

Most, if not all, protein respiratory sensitizing agents have the capacity of stimulating a T\(_{H2}\) lymphocyte, IgE-associated immune response. IgE sensitization is ascertained by skin prick testing with water-soluble extracts of the responsible allergen or a search for specific antibodies in serum. Assuming equivalence of the antigens used in the different methods and with appropriate interpretation of test findings, skin prick and serum IgE tests produce broadly comparable results. On the grounds that occupational asthma from high molecular mass (protein) allergens is an immediate-type hypersensitivity, it should in all cases be accompanied by specific sensitization to the causative allergen which are too low to provoke symptoms in non-sensitized workers and which the affected individual would previously have tolerated.

The same cannot be claimed for low molecular mass chemicals which are ‘incomplete’ allergens. Identifiable immune responses to such agents are usually not to the chemical itself, but to hapten–protein conjugates. For example, serum IgE antibodies to antigen–human serum albumen (HSA) conjugates may be detected in most cases of occupational asthma caused by acid anhydrides and in some cases of asthma attributable to diisocyanates and reactive dyes. An exception is platinum salt hypersensitivity which is almost always accompanied by positive responses to skin prick testing – but not by demonstrable specific IgE production – with dilute solutions of complex platinum–halide salts.

Such examples, however, are rare among the many chemical causes of occupational asthma suggesting that the relevant allergen–protein conjugate has yet to be identified or that alternative mechanisms are responsible. Specific IgE to diisocyanate–protein conjugates is detectable in only around 25 per cent of cases of asthma caused by this important group of chemicals, and a study of patients with a confirmed asthmatic reaction to controlled exposures, but absent IgE responses did not detect upregulation of IgE receptors. Other important causes of occupational asthma in which specific IgE responses are apparently absent include colophony fumes and plicatic acid. In some cases where ‘specific’ IgE antibodies are detected, it is unclear that they have any pathological or diagnostic specificity.

Consequently, alternative immunological mechanisms for occupational chemical sensitization have been postulated. For example, most T-cell clones collected by bronchial biopsy of patients with diisocyanate-induced asthma are of CD8 phenotype producing gamma interferon and IL-5, rather than IL-4. Such T cells may represent a CD3\(^+\)/CD4\(^-\)/CD8\(^+\) population expressing a \(\gamma/\delta\) T-cell receptor specific for the diisocyanate.

Alternatively, non-immunological pathways may (also) be important in some causes of occupational asthma. For example, plicatic acid in western red cedar can directly activate complement and tolune diisocyanate may have direct actions on bronchial smooth muscle acting as a bronchoconstrictor or as a beta-2 adrenergic blocking agent. Neurogenic mechanisms may also be relevant in some instances. Toluene diisocyanate, in addition to its postulated pharmacological effects (above in this section) stimulates, in animal models, neuropeptide release and inhibits neutral endopeptidase.

Such non-immunological mechanisms do not readily explain the typical pattern of hypersensitivity-induced asthma, arising after a period of latency and associated with increasing sensitivity to low exposures, but they may have important secondary roles in explaining the clinical picture. Alternatively, some chemical agents may be capable of inducing more than one asthma phenotype, one immunological (through IgE-associated mechanisms) and one non-immunological. The distinction of these will require more careful clinical and epidemiological study than is currently available.

Irritant-induced asthma

Asthma developing shortly after exposure to high concentrations of inhaled respiratory irritants probably reflects non-immunological mechanisms. A small number of bronchial biopsies have been carried out in patients with irritant-induced asthma and indicate bronchial inflammation with lymphocytes and plasma cells, but not eosinophils, suggesting that the clinical response is a manifestation of direct epithelial cell injury. Importantly, there have been no reports which include histological data prior to the initiating event in these cases.
FREQUENCY OF OCCUPATIONAL ASTHMA

Estimates of the prevalence – and less frequently incidence – of occupational asthma are available for both occupational and community populations.

Occupational populations

WORKPLACE STUDIES

Most workplace-based studies use standard cross-sectional epidemiological methods; occasionally longitudinal (cohort) designs, most of them prospective, are used. Data may be derived from a purposeful study or by analysis of the records of routine health surveillance. If the methods of surveillance are insensitive, then the latter approach will underestimate the true frequency of disease. In any case, a ‘healthy worker effect’, reflecting selection into and survival within a workforce, is likely and cross-sectional approaches to estimation of the prevalence of occupational asthma in a workplace – or to examination of its determinants – will generally underestimate both disease frequency and the effects of risk factors, such as exposure. This can be overcome, to some extent, by focusing attention on relatively new employees. Despite these important reservations – and the further uncertainty of how far findings from one setting can be generalized to others – workplace-based estimates of disease frequency have provided much of our knowledge of the detailed epidemiology of occupational asthma.

SURVEILLANCE SCHEMES

Several countries – notably Finland, the UK and France (Table 72.2), but also Ireland, South Africa and parts of Spain, the United States, Canada and Australia – have established surveillance schemes for occupational asthma. These measure disease that is newly recognized and reported by specialized physicians, usually in occupational or respiratory medical practice. In some instances, the schemes are closely linked to compensation claims. Where workforce denominators are available, occupation-specific incidence rates may be estimated, although these are often crude and probably underestimate the true incidence. Reports from the longer running surveillance schemes are sometimes used to examine temporal trends or geographical variations in disease incidence within certain industries or in relation to specific agents. The findings of such analyses need to be interpreted with great care. The numerators for specific incidence rates are usually very small and there is good evidence of international variations in diagnostic practice. Nonetheless, surveillance schemes provide valuable information on the approximate size and distribution of the problem at a national level and a good estimate of the relative frequencies of important causes. In any case they have proved to be a powerful incentive for regulators.

Table 72.2 Numbers of cases of occupational asthma and estimated annual incidence rates per million workers in the UK, France and Finland from reports to national surveillance schemes, by occupational groups (may be defined differently in different countries).

General population studies

A number of epidemiological studies have set out to measure, in general (non-occupational) populations, the proportion of asthma in adulthood that is ‘attributable’ to workplace exposures. Studies of this sort estimate the prevalence of asthma, usually by self-report, in a representative sample of the community. By comparison with a referent group, usually office workers, any excess risks of asthma in specific occupational groups can be estimated and then summed to generate a measure of the proportion of communal asthma that is attributable to occupational exposures. Meta-analyses of such studies indicate attributable proportions of between 10 and 15 per cent for all incident or relapsing cases of adult asthma. Studies of incident asthma are fewer, but provide essentially similar estimates.

Epidemiological approaches of this kind employ a probabilistic, rather than individual, approach to the issue of causation. They cannot easily distinguish asthma that is induced from asthma that is provoked by an occupational exposure, nor examine whether there is selection by or of people with asthma into certain occupations. However, they are valuable in quantifying the communal risk of work-related asthma and in identifying increased risks of disease among occupational groups not traditionally recognized in clinical practice.

DETERMINANTS OF OCCUPATIONAL ASThma

An understanding of the determinants of occupational asthma beyond its distributions is essential in the development of strategies to reduce its incidence. Broadly, the potential determinants that have been studied in detail include those relating to the environment (the level of workplace exposure to the sensitizing agent) and those that reflect host susceptibility (atopic status and genotype). The limited information on any interaction between host and environment suggests that susceptible individuals have a heightened – and perhaps accelerated – response to allergen exposure. One important consequence of this is that under conditions of relatively low exposure those factors that determine individual susceptibility are more prominent.

This is likely to have important implications in settings where exposure control is improving, while the population prevalence of susceptibility (for example, atopy) is either stable or rising.

Exposure

Direct relationships between the intensity of workplace allergen exposure and symptoms indicative of occupational asthma have been described for a variety of sensitizing agents. These, and studies confined to the risks of allergic sensitization alone, are summarized in Table 72.3.

Most are of high molecular mass agents; there are fewer data relating to the exposure-related risks of work with low molecular mass agents.

While the existence of a relationship between exposure and occupational asthma is well established, there is little information on its detailed nature and almost none on meaningful threshold values. This probably reflects the difficulties in measuring relevant exposure intensities and their timing. On biological grounds alone, a ‘sigmoid’ relationship would be expected whereby the risk rises relatively steeply at the lower end of the exposure range and less steeply (or not at all) at the higher end. While this is likely to be true for most agents, there is evidence for laboratory animal exposures that the risk may be attenuated at very high exposures – possibly reflecting a form of immunotolerance.

Most studies examining exposure–response relationships are of prevalent disease in cross-sectional, occupational populations. Few have studied incident disease in working cohorts. The findings of cross-sectional surveys need to be interpreted cautiously since they are prone to an unquantifiable bias from survivor effects. Survival biases, notably the movement of employees who have become sensitized away from situations of continuing exposure, are likely to lead to an underestimate of the effects of exposure. Furthermore, few studies of any design have succeeded in measuring directly the levels of sensitizing agents in exposed workforces and fewer still have characterized the nature, in terms of particle size and deposition of these exposures.

There is very little information on the relationship between exposure and response in irritant-induced asthma. Following a spill of glacial acetic acid in a US hospital, the frequency of subsequent asthma was higher (21 per cent) in those who had incurred the greatest exposure than that in those with medium or low exposures.

</table>
(3 and 0 per cent, respectively), suggesting both that the relationship was causal and that it was dependent on the intensity of exposure.  

Several studies suggest that in some settings cigarette smoking increases the risk of sensitization or of asthmatic symptoms. They include studies of workforces exposed to ispaghula, snow-crab proteins, tetrachlorophthalic anhydride, laboratory animals and complex platinum salts. It is not always clear, however, that the effects attributed to smoking are independent of other determinants, such as allergen exposure.

**Individual susceptibility**

Even at exposures well above any threshold, not all employees develop respiratory hypersensitivity – although in some instances the proportion of workers who are affected can be very high. Thus, some employees appear to have an innately high risk.

Atopic workers are at increased risk of occupational asthma from a number of workplace allergens. The most consistent evidence is for allergens that induce an identifiable specific IgE response. Thus, atopy increases the risk of asthma or sensitization in workers exposed to flour, laboratory and other animals, detergent and other enzymes, sea foods, castor and green coffee bean, acid anhydrides and some reactive dyes. A useful summary of the evidence is provided by Nicholson et al. In contrast there is little consistent evidence that atopy increases the risk for those who work with western red cedar, glutaraldehyde, complex platinum salts or diisocyanates. As with studies of exposure, the findings from cross-sectional surveys should be interpreted cautiously since reported associations, negative or positive, may reflect selection and survival pressures which are perhaps stronger among atopic employees.

The rapid advances in genotyping have been applied, in a limited fashion, to the study of occupational asthma. Two classes of gene have received most attention: those that determine specific antigen responsiveness (genes of the HLA class II complex) and those that relate to antioxidant respiratory responses. In each case, the presence or absence of candidate genes have been compared in case-control studies of employees with or without occupational asthma. Studies of this type require very large populations and most have probably been underpowered. All the same, associations – sometimes strong – between HLA genes and specific sensitization have been reported in workers exposed to trimellitic anhydride, laboratory animal proteins, western red cedar, complex platinum salts and diisocyanates. The findings from the last of these are not entirely consistent.

Similarly, genetic polymorphisms of the glutathione-S-transferase and N-acetyltransferase groups, important in determining the antioxidant status of the respiratory tract, have been associated with occupational asthma from a number of diisocyanates.

**PREVENTION OF OCCUPATIONAL ASTHMA**

**Primary prevention**

Primary prevention eradicates or reduces incident disease. In the context of occupational asthma, it is achieved by elimination of the sensitizing agent from the workplace or where this is not possible by the reduction of exposures to levels at which sensitization does not occur. The former may be impossible, as in the example of flour in a bakery, but notable success has been achieved in some settings including occupational asthma from latex in hospitals – either by the substitution of latex gloves with synthetic alternatives or by the use of powder-free gloves which essentially prevent the release of latex particles into the air. Because there are important variations in individual susceptibility, reductions in exposure rarely eliminate incident disease altogether, but they may be highly effective in maintaining disease rates at a very low level.

The details of the exposure–response relationships for most workplace allergens are poorly understood. In all cases it is unclear whether relationships are linear or whether a ‘threshold’ of zero incidence at low exposures exists. In practice, effective prevention of occupational asthma requires the maintenance of exposures, including occasional ‘peak’ values, at as low an intensity as is feasible and lower than that which incites symptoms in sensitized subjects. Much current legislation is based on this premise and very little of it includes specified ‘safe’ thresholds – a reflection not only of the paucity of evidence in this area, but also of the essentially immunological nature of the disease.

There is very little evidence that the use of protective respiratory equipment alone is effective in the primary prevention of occupational asthma. Published examples of the primary prevention of occupational asthma are few and most describe programmes that include not only improvements in exposure control but also procedures such as targeted pre-employment screening, enhanced surveillance and the increased use of personal protective equipment. It is seldom possible to disentangle the separate effects of different components. Nonetheless, success has been reported in the detergent industry and with workforces exposed to laboratory animals, diisocyanates, acid anhydrides and latex. In most instances, a reduction in the number of newly identified cases following intervention(s) is reported without reference to the denominator, at-risk population and it is not always clear that this reflects a true reduction in disease incidence.

An alternative approach to primary prevention focuses on restricting the exposure or even employment of perceived ‘high-risk’ persons. Such restrictions are usually based on evidence of prior asthma or other allergy, usually but not always obtained by self-report. The discriminant performance of these methods – their ability to predict who will and who will not develop an occupational respiratory sensitization – is poor. Increasing understanding of the genetic determinants of occupational asthma may result in the extension of such techniques.
Secondary and tertiary prevention

Respiratory surveillance of employees working with respiratory sensitizing agents is widely practised and in many countries is mandated by legislation. The process, which aims to identify workers with occupational asthma at an early stage of their disease and thus allows appropriate action to prevent deterioration (‘tertiary prevention’), is based on the premise that early recognition and avoidance of further exposure improve the prognosis of the disease. The most widely used surveillance methods are the questionnaire and regular spirometry. Almost certainly, self-completed questionnaires are an insensitive measure of work-related respiratory symptoms. Similarly, routine measurement of spirometry is insensitive since many employees with occupational asthma will have a normal FEV₁, particularly if it is measured when they are not directly exposed to the causative allergen. There is evidence that routine spirometry detects very few cases of disease that would not otherwise or also have been recognized on the basis of reported symptoms.

In some settings, surveillance includes the use of immunological methods to measure specific sensitization: either skin prick testing or specific IgE assay directed to the workplace allergen(s). The purpose of such immunological surveillance varies. In some parts of the platinum refining industry, for example, regular skin prick testing with complex platinum salts forms part of a health surveillance programme. A positive prick test result, highly specific for platinum salt asthma, is used to identify employees who require rapid relocation away from exposure. Similarly respiratory surveillance in much of the detergent manufacturing sector includes a measure of immunological sensitization. There, however, where sensitization is a highly sensitive but not wholly specific adjunct of detergent enzyme asthma, the practice is designed to identify areas of the workplace where further attention to exposure control is necessary. A further example, in the baking sector as described by Brant et al., is the assay of serum-specific IgE antibodies to flour and α-amylase for employees who report work-related respiratory symptoms. This improves the specificity of the surveillance programme and aids the selection of those employees who require further investigation.

Any use of immunology in routine surveillance requires access to validated test methods and an intimate knowledge of their diagnostic properties, and an explicit understanding of the purpose of testing. In carefully selected instances, immunological approaches can be a useful adjunct to other methods and are likely to be increasingly used in the future.

IDENTIFICATION AND DIAGNOSIS OF OCCUPATIONAL ASTHMA

Accuracy in the diagnosis of occupational asthma is critically important. A positive diagnosis frequently leads to a change in job and too frequently to the loss of current employment or a major change in occupation. A false positive diagnosis can lead to unnecessary financial and social hardship and a lack of clinical improvement once exposure has ceased. In legal terms the burden of proof is generally set at a level of ‘more likely than not’. Most occupational health practitioners and their patients will prefer a more certain standard than this.

On the other hand, the early and accurate identification of an occupational cause of asthma has several advantages. First, it will explain the onset of new or recurrent asthma in adult life and make a search for alternative causes unnecessary. Second, it allows a rational approach to both pharmacological and non-pharmacological management, and third, it identifies, for other employees, potential risks that may be prevented.

Guidelines to the diagnosis of occupational asthma, derived from systematic review of the published literature, are available both electronically and in print. Other, consensus-developed, guidance is also available. An outline of available methods in the diagnostic pathway is shown in Figure 72.1. In essence the process is iterative and should include each of the following: an assessment of relevant exposures, the identification of an asthmatic airway response in relation to exposure(s) and, where appropriate, the identification of specific immunological sensitization. None of these is sufficient alone.

**Figure 72.1** Summary of diagnostic approaches to occupational asthma. NSBHR, non-specific bronchial hyperreactivity.
History

The prior likelihood of occupational asthma is higher in employees with exposure to a recognized sensitizing agent and familiarity with these agents and the occupations in which they are encountered is important. At the same time, patients may develop sensitivity to a rare or previously unrecognized agent and in all cases a low threshold of suspicion is sensible. Patients with occupational respiratory sensitization characteristically develop symptoms after a relatively short latent period following first exposure to the sensitizing agent. ‘First’ exposure often reflects a new job, but may reflect a qualitative or quantitative change in exposure in a long-held job. The latent, asymptomatic period, during which sensitization is presumed to be developing, is usually between three and 24 months. Symptoms that develop sooner after a new exposure are more likely to have an irritant mechanism. Thus careful attention to the timing of the onset of symptoms and any changes in exposure that may have preceded them, is diagnostically helpful.

The symptoms themselves are characteristic of asthma, but are frequently accompanied by upper respiratory symptoms of nasal obstruction, sneezing and discharge and itching or running of eyes – as well as, if the causative agent is a protein, by itching of the skin or even urticaria. Occupational rhinitis is probably more common than occupational asthma, but the two conditions frequently occur together. The frequency and intensity of nasal symptoms may be greater in cases caused by sensitization to high molecular mass agents.

A history of previous or coexistent respiratory disease does not preclude a diagnosis of occupational asthma, but raises the possibility of aggravation of pre-existing asthma or other airways disease by one of the many workplace respiratory irritants.

In cases of occupational asthma, symptoms are typically present during or immediately after periods of exposure at work and improve when away from work. This pattern may be complicated by varying shift patterns, by isolated ‘late-phase’ symptoms that are present only after a period at work and in cases where, with repeated exposures, recovery is only achieved, if at all, by an absence from work of several days or more. Further confusion can arise when the non-specific bronchial hyperreactivity that is typical of asthma gives rise to symptoms provoked by a variety of irritants encountered at and away from the workplace. In these cases, employees (and their clinicians) frequently attribute the cause of the disease to the obviously irritant exposure rather than the sensitizing agent.

In cases of irritant-induced asthma (reactive airways dysfunction syndrome (RADS)), the history is very different, partly because of constraints imposed by the current disease definition. Here symptoms develop within minutes or hours after a defined, high-intensity and sometimes dramatic exposure to a respiratory irritant, frequently in an individual without known previous respiratory disease. Unlike those with occupational sensitization, patients with irritant-induced asthma can usually identify precisely the time of onset of their disease which may or may not be many years after the onset of employment and of exposure, at lower levels, to the responsible agent.

Investigations

Relevant investigations are, broadly, either immunological or functional. The former aim to identify a specific immunological response to the putative agent, the latter to establish a relationship between variable airflow obstruction (‘asthma’) and one or more specific occupational exposures.

IMMUNOLOGICAL TESTS

As described above under Mechanisms of occupational asthma (p. 943), sensitization to almost all high molecular mass occupational agents and to some of low molecular mass is accompanied by the presence of specific IgE antibody production. This can be identified through skin prick tests with extracts of soluble antigens or in serum using standardized immunoassays. In cases of occupational asthma caused by exposure to a high molecular mass agent, the test is highly sensitive. In other words, it is almost always positive and a negative result makes the diagnosis improbable. On the other hand, a positive result can occur in the absence of clinical disease, presumably reflecting an asymptomatic state of specific sensitization. In all cases, it is important to include well-validated tests for all relevant allergens and liaison with an experienced (specialized) laboratory is valuable.

The general absence of an identifiable IgE response in diisocyanate asthma has prompted the search for alternative immunological tests for this common type of occupational asthma. They include the measurement of monocye chemotactic protein-1 (MCP-1) produced by peripheral blood mononuclear cells after stimulation with a relevant isocyanate conjugate. The results of a pilot study suggest that this method has a sensitivity of about 80 per cent and a specificity of 91 per cent, respectively far higher than and similar to methods based on specific IgE production.

This technique requires replication in other populations before it can be widely applied.

FUNCTIONAL TESTS OF VARIABLE, WORK-RELATED AIRFLOW OBSTRUCTION

The most sensitive and specific method of examining the existence and pattern of airflow limitation is through the use of serial, self-recorded measurements of peak flow or FEV₁. Workers under investigation are supplied with a portable meter and invited to make repeated measurements over a period of time including both periods at and away from work. A protocol that demands, during waking hours, two-hourly measurements for four weeks has higher sensitivity than less frequent measurements and is generally acceptable to patients. Where possible, especially in cases
where symptoms have been present for many months or years, it is helpful to include within the period of measurement a prolonged absence from work, such as a holiday of several days or more. Potential confounding by concurrent asthma treatment is avoided by asking patients to maintain the same treatment throughout the measurement period.

On completion, the readings are best plotted on a daily basis as the maximum, minimum and mean values from each day. An example of such a plot, using peak flow, is shown in Figure 72.2. The pattern of lung function in relation to work is then examined – usually visually, but sometimes by computed statistical analysis. Agreement of visual analyses by experienced clinicians is high, but there are important variations among less-experienced observers. Statistical analyses, intended to provide a more objective analysis, have proved to be little more valid or reliable than visual inspection.

Confusion and even misdiagnosis may arise if, particularly through early morning shift patterns, readings are made at different times on work and rest days. Serial measurements of lung function may also fail to distinguish immunologically mediated occupational asthma from asthma that is provoked by workplace-irritant exposures. Thus, the method should only be interpreted in the light of other diagnostic evidence.

Other techniques for assessing the pattern of airflow obstruction include the ‘cross-shift’ measurement of lung function (FEV₁ or peak flow) or non-specific bronchial responsiveness immediately before and after one or more periods at work. These methods may be less time consuming than a lengthy series of functional measurements, but have lower diagnostic specificity and sensitivity and produce a higher proportion of false positive and false negative results. As with FEV₁, bronchial responsiveness may be normal in patients with confirmed occupational asthma if measurements are made outside periods of exposure to the causative allergen.

**SPECIFIC PROVOCATION (INHALATIONAL) TESTING**

The gold standard of diagnostic tests for occupational asthma is often claimed to be the specific provocation test, whereby patients are observed and their lung function measured during and after carefully controlled exposures, under laboratory conditions, to the suspected sensitizing agent. The first use of such tests, for the diagnosis of occupational asthma, was in 1972.

Indications for specific provocation testing vary between centres. In some jurisdictions it is conducted as a necessary step in the process of establishing a diagnosis and thereby allocating compensation. In others, such as the United Kingdom and many other European countries, it is used as an occasional adjunct to the diagnostic process, particularly when other, simpler techniques have failed or cannot be used to establish a diagnosis with sufficient accuracy. If, for example, a patient is not currently exposed to
the suspected agent, but an accurate diagnosis is still required to assist in decisions about continuing employment. Serial measurement of lung function as described above will be uninformative. Alternatively, a patient may be exposed to more than one sensitizing agent at work and it may be considered important to identify which (if any) is responsible for their disease. In rare cases, the symptoms provoked by exposure at work are too severe (or unpleasant) to justify serial measurement of lung function. In such cases, the judicious use of specific provocation testing can be an appropriate and even essential diagnostic method. Finally, a further indication may be the investigation of response to an agent that is not recognized to be a respiratory sensitizer. Provocation testing solely in support of a legal claim for personal injury is difficult to justify.

Specific provocation tests are hazardous and should be undertaken only by experienced staff in specialist centres where the risks are very low. Most tests use a single-blind methodology which aims to recreate as closely as possible exposures encountered by the patient in the workplace (Figure 72.3). More recently, some centres have developed sophisticated delivery techniques of mechanized dust or fume generation. The advantage of these over the simpler techniques is yet to be established. Whichever method is used, great care must be taken over the dosing and frequency of exposures which should be of lower intensity than those in the workplace and several orders lower than occupational safety limits.

Responses to inert and active exposures are generally assessed and compared by the subsequent measurement of FEV<sub>1</sub> at frequent intervals. This is more reliable than peak flow measurement. The measurement of changes in non-specific bronchial responsiveness following exposure (using histamine or metacholine) is a very useful additional test, helping to distinguish irritant from immunologically mediated responses. The specificity of provocation testing is increased if reproducibility of the responses to repeated active and control exposures is confirmed (Figure 72.4).

Several patterns of response are taken to be indicative of specific sensitization, but their interpretation requires an experienced clinician. An immediate or early response is one in which a fall in baseline lung function occurs and recovers within one or two hours of provocation. If isolated and unaccompanied by evidence of a concurrent...
MANAGEMENT OF OCCUPATIONAL ASTHMA

Optimal management of occupational asthma will in most cases abolish or control symptoms and prevent the development of persistent disease. In general, these are achieved only by complete avoidance of exposure to the causative allergen, ideally through a change in work practice or relocation within the same workplace or industry to a non-exposed area – but in practice often requiring a major change in occupation.

Some patients, particularly those who are self-employed or those who have significant investment in a current occupation – such as research scientists working with animal models – are especially reluctant to make changes sufficient to prevent further exposure. At present, further allergen exposure even at very low intensity cannot be advised, but support to those determined to continue is likely to be beneficial. A systematic review of 39 publications with a median length of follow up of 31 months following diagnosis suggests that only one-third of patients recovered completely from their asthma after the cessation of exposure. Individual estimates ranged however from 0 to 100 per cent. The same review examined a number of potential determinants of recovery. Complete symptomatic recovery was significantly lower with increasing age at diagnosis, in studies of patients seen in specialist clinics and in patients with the longest durations of employment, or of symptomatic exposure (Figure 72.1). No studies examined the independent effects of age and exposure duration. There were no clear differences in recovery between patients with asthma caused by agents of different molecular mass or between those who were or were not smokers.

Any recovery in lung function and bronchial hyperresponsiveness seems to take place in the first two years after avoiding the causative allergen, the symptoms of most patients with occupational asthma improve, and many recover completely. However, this is not always the case. Most studies of the outcome of occupational asthma are of patients attending specialist centres. These are likely to have more severe and more refractory disease and their experience may not be representative. A systematic review of 39 publications with a median length of follow up of 31 months following diagnosis suggests that only one-third of patients recovered completely from their asthma after the cessation of exposure. Individual estimates ranged however from 0 to 100 per cent. The same review examined a number of potential determinants of recovery. Complete symptomatic recovery was significantly lower with increasing age at diagnosis, in studies of patients seen in specialist clinics and in patients with the longest durations of employment, or of symptomatic exposure (Figure 72.1). No studies examined the independent effects of age and exposure duration. There were no clear differences in recovery between patients with disease caused by agents of different molecular mass or between those who were or were not smokers.

Following avoidance of further exposure to the causative allergen, the symptoms of most patients with occupational asthma improve, and many recover completely. However, this is not always the case. Most studies of the outcome of occupational asthma are of patients attending specialist centres. These are likely to have more severe and more refractory disease and their experience may not be representative. A systematic review of 39 publications with a median length of follow up of 31 months following diagnosis suggests that only one-third of patients recovered completely from their asthma after the cessation of exposure. Individual estimates ranged however from 0 to 100 per cent. The same review examined a number of potential determinants of recovery. Complete symptomatic recovery was significantly lower with increasing age at diagnosis, in studies of patients seen in specialist clinics and in patients with the longest durations of employment, or of symptomatic exposure (Figure 72.1). No studies examined the independent effects of age and exposure duration. There were no clear differences in recovery between patients with disease caused by agents of different molecular mass or between those who were or were not smokers.

Any recovery in lung function and bronchial hyperresponsiveness seems to take place in the first two years after
avoidance of exposure. Persistence of longer duration is associated with continuing eosinophil and lymphocyte infiltration of the airways and may be related to fixed airway remodelling. However, it remains unclear why disease should persist after exposure avoidance. Retention of allergen or hapten within the lung – or extrapulmonary tissue – may promote persistent IgE production after the cessation of workplace exposure to acid anhydrides.

Other outcomes are common in occupational asthma and may be equally or even more important to the patient. Surveys suggest that about a third of patients are unemployed soon after diagnosis – a figure which is probably higher than that among other adults with asthma but that the rate of unemployment falls with passing time. Nonetheless the necessary change in job or occupation is commonly associated with a loss of income and many patients will struggle to find suitable alternative employment.

Most industrialized countries operate a compensation scheme for those who have developed occupational asthma. In some countries, such as Germany, this is funded by employers’ contributions to a central insurance association. In others, such as the UK, the scheme is financed and administered by the state. The features, criteria of eligibility and benefits of schemes vary widely between jurisdictions: some, for example, provide only a financial pension while others include provision for retraining or even primary preventive programmes in the workplace.

Key points

- Workplace exposures account for around 10 per cent of cases of new or recurrent asthma in adulthood. These cases include those where symptoms of pre-existing asthma are provoked by irritant exposures at work (‘work-exacerbated asthma’) and cases of new asthma arising directly from a – generally sensitizing – workplace agent (‘occupational asthma’).
- Several hundred agents in the workplace have been identified as capable of inducing occupational asthma; most are airborne proteins or highly reactive chemicals.
- Occupational asthma usually has a short latency and tends to afflict relatively young employees who will need expert advice on career options.
- An accurate diagnosis is essential.
- In most cases, a sufficiently accurate diagnosis can be achieved through a combination of a careful history, appropriate immunology and the comparison of serial measurements of lung function made at work and at home.
- Occupational asthma is (potentially) preventable. Preventive action should be focused on exposure control.

Byssinosis and other cotton-related diseases

CAC PICKERING AND ROBERT NIVEN

HISTORICAL BACKGROUND

Respiratory disease associated with exposure to textile dusts was first recognized by Ramazzini amongst flax and hemp workers. The term 'byssinosis', which is derived from the Greek (flax), was first used by the Parisian physician A Proust in 1877. Earlier in 1831 Kay, a Manchester physician, described cotton spinners phthisis. This condition was characterized by a work-related cough, which initially resolved on leaving the mill, later becoming more severe and persistent and associated with a sensation of un easiness beneath the sternum. The first description of the symptom pattern now associated with byssinosis, that is respiratory symptoms most severe at the start of the working week, was given in 1845 by Mareska and Heyman.

All the workers have told us that the dust bothered them much less on the last days of the week than on the Monday and Tuesday. The masters find the cause of this increased sensitivity to be in the excesses of the Sunday, but the workers never fail to attribute it to the interruption of work which, they say, makes them lose, in part, their habituation to the dust.

In 1860, in response to concern about the high death rates from respiratory disease in some Lancashire towns, Greenhow investigated the causes of this excess of pulmonary disease and described an asthma-like condition in cotton workers worse at the beginning of the working week and most severe on returning to work after a longer period away from work than a weekend. This syndrome is now generally referred to as byssinosis. Subsequently, byssinosis has been reported from most countries with a textile industry.

ACUTE BYSSINOSIS

Acute byssinosis is an acute response to cotton dust. It can be replicated in artificial cardrooms in subjects exposed to cotton dust or extracts of cotton dust for the first time. The relationship of this acute, fully reversible response to the chronic changes which develop in cotton workers exposed to cotton dust for many years remains uncertain. It was long postulated that this acute response contributed to the high labour turnover which was seen in the first year of employment in cotton spinning mills with heavy dust exposures. A recent study in a new cotton spinning factory with low levels of exposure to cotton dust and endotoxin, found that 40 per cent of new workers, naive to cotton dust, reported work-related symptoms, with cross-shift and cross-week falls in lung function. A tolerance effect was noted with continued exposure.

Textile workers may also experience other acute symptoms (mill fever) on exposure to cotton, flax or hemp dust. Mill fever characteristically occurs following a worker’s first exposure to cotton, flax or hemp dust. It consists of a fever with a non-productive cough, malaise and sneezing,
which usually lasts for a few hours, resolving despite continued exposure to dust.\textsuperscript{11} It is thought that mill fever is caused by the endotoxins from Gram-negative bacteria contaminating the cotton. This idea is supported by endotoxin exposure studies in healthy volunteers, where at high levels a febrile response is seen, similar to the symptoms described as mill fever.\textsuperscript{12}

**CHRONIC BYSSINOSIS**

**Prevalence**

The prevalence of byssinosis amongst cotton workers depends on the quality and airborne concentration of cotton dust to which workers are exposed and to the duration of their exposure. The majority of prevalence studies have been cross-sectional in design and have thus been looking at ‘survivor’ populations and, therefore, likely to underestimate the true prevalence of this disease. The reduction in dust levels over the past 30 years has led to a fall in the prevalence of byssinosis. In the late 1950s in the United Kingdom, the prevalence amongst male cardroom workers (coarse cotton) was 43 per cent and in blowroom workers 66 per cent.\textsuperscript{13} By the 1970s the prevalence (combined) had fallen to 24 per cent.\textsuperscript{14} The prevalence of byssinosis, at the time the cotton spinning industry in Lancashire cotton mills essentially ceased was 4 per cent.\textsuperscript{15}

In Australia, the prevalence of byssinosis has been reported to be low: 1.1 per cent (two of 176 employees) exposed to mean dust levels of between 0.14 mg/m\(^3\) to 0.25 mg/m\(^3\).\textsuperscript{16} An earlier study\textsuperscript{17} revealed similar low prevalence. In most developing countries, the prevalence of byssinosis remains high: Indonesia, 21–30 per cent;\textsuperscript{18} Ethiopia, 24–43 per cent;\textsuperscript{19} Sudan, 37 per cent;\textsuperscript{20} India, 30–38 per cent;\textsuperscript{21} Nigeria, 2–6.4 per cent;\textsuperscript{22} and Pakistan, 19 per cent.\textsuperscript{23}

The prevalence of byssinosis is influenced by the occupational group, being most frequent amongst opening room operatives and cardroom workers (strippers and grinders), followed by drawframe tenders, and least common amongst ring spinners.\textsuperscript{24} These occupational relationships appear to follow the early processes where contaminants are common, rather than being related to total levels of personal dust exposure.\textsuperscript{25}

In flax workers, the prevalence of byssinosis is also related to occupational group, the dustiest jobs being associated with the highest prevalences: pre-preparers, 54 per cent; other preparers, 27 per cent; wet finishers, 0.4 per cent.\textsuperscript{26} A similar relationship between dust level and prevalence has been noted in Egyptian flax workers.\textsuperscript{27}

Smoking may increase the risk of developing byssinosis and exacerbate the reduction in ventilatory capacity.\textsuperscript{28,29} Byssinosis is reported to be up to four times more common in smoking workers than in non- and ex-smoking workers.\textsuperscript{24} However, other studies have found no association between smoking and the prevalence of byssinosis.\textsuperscript{17,30}

Where the prevalence of byssinosis is low, there may be insufficient power to demonstrate weak co-factor effects, such as from smoking.

**Pathogenesis**

Although byssinosis has been recognized for over a century, and a considerable research effort has examined possible mechanisms by which textile dusts can cause airways narrowing, the pathogenesis of byssinosis is still not fully understood. The ability of textile fibres to produce byssinosis is determined by fibre type, cotton being the most potent, followed by flax, hemp and finally possibly sisal. Harvested cotton consists of a mixture of plant materials including: leaves, bracts and stems, fibre, bacteria, fungi, and other contaminants. The particles of bract have attracted particular attention since exposure to aerosols of extracts of bracts, but not other plant components, can cause acute symptoms similar to those of byssinosis and can lead to release of significant amounts of histamine from human lung tissue. The cotton bract is a specialized leaf at the base of the cotton flower. As these leaves mature they become hard and brittle and tend to shatter into small particles during harvesting, becoming adherent to the cotton fibre, later forming a major constituent of cotton dust in the mill. Many different compounds have been examined as potential causes of byssinosis. It seems definite that the compounds which cause byssinosis are water soluble. The biological activity of cotton can be greatly reduced by either steaming\textsuperscript{31} or washing\textsuperscript{32} the cotton before processing.

A number of different mechanisms have been proposed to explain the pathogenesis of byssinosis: bacterial endotoxin activity, immunological and para-immunological responses, the non-immunological release of histamine and fungus enzymes.

**Bacterial endotoxins**

The presence of large quantities of Gram-negative bacteria in cotton mills was first reported by a Home Office Commission in 1932.\textsuperscript{33} Ten years later, the relationship between the grade of the cotton and the degree of contamination by Gram-negative bacteria was first described.\textsuperscript{34} This group also identified an endotoxin-like substance in extracts from contaminated cotton and from the organism cultured from the cotton. Subsequently, a role for endotoxin in the aetiology of byssinosis was proposed.\textsuperscript{35} The predominant species of Gram-negative bacteria found in cotton dust is of the *Enterobacter* genus. Endotoxin is derived from the lipopolysaccharide (LPS) component of the outer membrane of Gram-negative bacteria, and its release has been described, both *in vivo* and *in vitro*, from various genera of Gram-negative bacteria. A number of airway responses, on challenge testing with endotoxin, have been described, indicating the presence of airway inflammation and immune responses. These include neutrophilic
Immunological mechanisms

The hypothesis that a specific immunological response is involved in the causation of byssinosis has been extensively investigated. However, the majority of studies have failed to show convincing evidence of an immunological mechanism. Skin tests using cotton dust extracts failed to differentiate between normal, atopic and byssinotic subjects. The authors used an intracutaneous skin test technique, which produced both immediate and late skin responses. There was no difference in the frequency of positive responses between any of the groups tested. Some 90 per cent of normal subjects gave a late skin response, suggesting a non-immunological mechanism. A study of groups of workers with byssinosis, asthma and chronic bronchitis, demonstrated immediate skin responses and frequent late responses. The positive skin responses were not specific to those individuals with byssinosis. The authors also performed inhalation tests with textile allergens, and only four of 39 subjects with byssinosis gave a positive reaction. Intradermal skin tests in naive subjects with cotton bract extract induced both immediate and late skin reactions. Skin biopsies taken during both responses revealed an initial oedematous phase followed by a perivascular infiltration with polymorphonuclear and mononuclear cells. Eosinophils were not a feature and mast cells were seen to degranulate during both phases.

Other authors have compared serum concentrations of total IgE in textile mill workers both with and without byssinosis. They found no difference in total IgE concentrations between the groups, and no relationship between the clinical grade of byssinosis and the level of IgE.

It has been suggested that fungal antigens may play a role in the aetiology of byssinosis. A study of the antigenic composition of aqueous cotton extracts demonstrated a significant portion of the immune response directed against known fungal contaminants of cotton dust: Alternaria tenuis, Aspergillus niger and Fusarium solani. A preliminary study using a crossed radio-immunoelectrophoretic technique suggested that some of these fungi were antigenic in man. However, skin tests using fungal extracts in textile workers have demonstrated no correlation between positive skin responses and symptoms of byssinosis.

There is at present no good evidence that atopy plays a direct role in the aetiology of byssinosis. The association between atopic status and the presence of increased airway reactivity may have a role, in rendering an individual susceptible to the chronic inhalation of a pro-inflammatory/irritant dust and the subsequent development of increasing airway reactivity associated with airway dysfunction.

The finding of late skin responses raises the possibility of IgG-mediated pulmonary responses. Precipitating IgG antibody to cotton antigen has been found in both cotton and non-cotton workers. The titre is highest in grade 2 byssinotics, lower in non-byssinotic workers and lowest in unexposed subjects. These elevated IgG antibody titres seem to be markers of exposure to cotton dust rather than indicators of disease.

A condensed polyphenol (leucoyanidin) has been isolated from the bracts of cotton plants and used in inhalation studies in byssinotic and non-byssinotic subjects. The inhalation challenge produced symptoms similar to those that they experienced in the mill, without changes in lung function, in five of six byssinotic subjects, and in none of 11 non-byssinotic workers. A study in a group of 29 byssinotic workers and 31 normal controls used the same polyphenol. The authors did not find any differences in symptoms or pulmonary function changes between the byssinotic workers and the normal controls.
Extracts of cotton mill dust have been shown to activate complement by the classical and alternative pathways. The activation of both complement pathways will generate biologically active fragments capable of releasing histamine and recruitment of polymorphonuclear leukocytes (PMN). Other in vitro experiments have demonstrated the release of prostaglandin F2 alpha from rat fundal smooth muscle and rabbit cultured alveolar macrophages, on challenge with cotton dust extract. Prostaglandin F2 alpha is a potent broncho-constrictor of human respiratory smooth muscle.

It is clear from these experimental studies that cotton dust is highly biologically active and capable of mediating an inflammatory response via a variety of different pathways. However, it remains unclear which of these pathways or combination of pathways is involved in the pathogenesis of byssinosis.

Non-immunological histamine release

The release of pharmacological mediators, such as histamine, has been postulated as an explanation for the acute symptoms of byssinosis occurring on the first day back at work. Histamine is found in the respirable fraction of cotton dust itself. However, the amounts present in a work situation are considered too small to produce airways narrowing. The levels of blood histamine have been shown to be elevated in both flax and cotton workers. This elevation occurred within two hours of starting work and was seen in all workers. Histamine levels had fallen to prechallenge levels by the second morning in all workers except those with grade 2 byssinotic symptoms. A comparison between exposures to equivalent levels of cotton and flax dusts showed cotton exposure produced significantly higher levels of blood histamine compared to flax. The histamine metabolite, L-methylimidazole-4-acetic acid was also found to be elevated in the 24-hour urinary specimens of control subjects challenged with cotton dust.

The release of histamine alone clearly does not explain the development of byssinosis, since histamine release can be demonstrated in all those exposed and immediate pulmonary responses occur on bronchial challenge with histamine, whereas byssinosis takes years to develop and immediate-type responses during a working shift are usually not demonstrable.

Fungal enzymes

Cotton dust has been demonstrated to have proteolytic enzyme activity. This activity probably originates from contaminating microorganisms. It has been suggested that airborne enzyme concentrations in cotton dust correlate better than cotton dust with airway responses in cotton workers. However, there is a low incidence of byssinosis in cotton willowing and woollen mills where there are high enzyme levels.

ATOPIC STATUS AND BRONCHIAL HYPER-REACTIVITY

One might expect that atopic individuals would be more likely to develop an allergic respiratory disease after exposure to cotton dust. There is some evidence this may be the case. Cross-sectional studies of cotton workers have revealed a low prevalence of atopy (defined by positive skin tests to common environmental allergens) compared with the prevalence in the general population. A survey of 30 workers in four cotton seed-crushing mills found a prevalence of atopy (positive skin tests to two or more of 10 common inhalant antigens) of 15 per cent. A study of 324 byssinotic subjects found a prevalence of atopy of 14.5 per cent, compared with 23.5 per cent in an age- and sex-matched control population. The prevalence of atopy in the general population depends on the age of the groups studied; at the time these studies were performed it varied from 20 to 40 per cent. The reduced prevalence of atopy among cotton-exposed populations implies they are survivor populations from which atopic subjects have been selected out.

Jones et al. evaluated the effect of atopy on the ventilatory decline across a working shift in three groups of cotton workers. In one group (those exposed to linter dust), there was a positive association between atopic status and mean declines in FEV1 and FEF25–75 across the working shift.

Atopic subjects frequently possess a high degree of bronchial hyper-reactivity and this may be an important determinant of the bronchoconstrictor response to cotton dust. Cotton workers who develop asthma and known asthmatic subjects who enter a cotton mill tend to develop rapidly increasing airways obstruction and have to leave the work (personal observation). A recent study of newly hired workers failed to demonstrate an effect of atopy on early leaving from the mill, but only included small numbers of atopic workers.

Relatively little research has examined the effect of airway reactivity on the pulmonary responses of cotton workers, although it may be important in determining the development of early respiratory disease, and perhaps the degree of disability associated with byssinosis. One study considered the acute airways constrictor response to cotton bract extract in normal subjects and its relationship to airways reactivity. The subjects who responded to cotton bract extract were significantly more reactive on methacholine challenge than the non-responder group. The baseline measurements of pulmonary function were, however, significantly lower in the responder group, and this could explain the difference between the two groups. An earlier study by the same authors, using histamine to measure airways reactivity, failed to show any significant difference in airways reactivity between responders and non-responders to cotton bract extract challenge in a group of healthy subjects.

Studies of airways reactivity in byssinotic subjects have produced inconclusive results. One study reported on histamine challenge tests in 26 byssinotic card-room workers. The workers with ‘bronchitic byssinosis’ (byssinosis
with cough and sputum) showed an important increase in airways reactivity; this was not seen in the workers with pure byssinosis. However, the bronchitic byssinotics also had higher grades of byssinosis, longer exposure to cotton dust and impaired lung function. Another study of the bronchoconstrictive effect of inhaled histamine demonstrated a response in two of 11 byssinotic subjects, in ten of 13 asthmatic subjects, and in none of ten control subjects.\(^65\) Haglind et al.\(^62\) used methacholine challenge to examine cross-shift changes in airway reactivity in cotton workers with and without byssinosis. Baseline airway reactivity was increased in the byssinotics, and 11 of the 16 showed an increase in airway reactivity across the shift. Fishwick et al.\(^65\) reported an increase in airway reactivity in 18 of 23 cotton workers with symptoms of byssinosis, 21 of 56 symptomatic non-byssinotic workers and 14 of 84 asymptomatic workers. The responders among the byssinotic group were more likely to have bronchitic symptoms. The proportion with atopy did not differ between the three groups.

**GENETIC FACTORS**

Endotoxin exposure is known to generate reactive oxygen species in the airways, which may induce oxidative lung injury and lung function decline. Reactive oxygen species are detoxified by the enzyme microsomal epoxide hydrolase (mEH). A recently reported 20-year prospective study of cotton workers examined the associations between mEH polymorphisms, endotoxin exposure and lung function decline.\(^64\) Endotoxin exposure was associated with more rapid lung function decline in individuals with the mEH His/His genotypes of both Tyr11is and His139Arg polymorphisms, both associated with lower enzyme activities. This association was noted in both smokers and non-smokers.

**CLINICAL FEATURES**

### Symptoms

Cross-sectional studies of textile spinning operatives have documented a variety of work-related ocular and upper and lower respiratory tract symptoms on exposure to cotton and synthetic fibres.\(^65\),\(^66\) These include ocular and nasal irritation, byssinosis, chronic bronchitis, persistent cough, work-related chest tightness and work-related wheeze. Work-related ocular symptoms (17.5 per cent) and work-related nasal irritation (11 per cent) seem to be the most common symptoms among both cotton and synthetic textile workers, occurring more often in cotton workers than in synthetic fibre workers.

The development of symptoms of byssinosis is rare in the first ten years of exposure to cotton, hemp or flax dusts and usually requires a period of dust exposure of between 20 and 25 years. The classical symptoms of byssinosis consist of chest tightness and breathlessness, characteristically developing on the first day of the working week over the second half of the working shift, and experienced most severely with the exertion of returning home in the evening. Others have described a rapid onset of symptoms within 30 minutes of starting work, which may be most severe over the first half of the shift. Roach and Schilling\(^67\) devised a scheme for grading the clinical stages of byssinosis (Table 73.1). The original description did not include grade 3 and this was added later.\(^68\) The Roach–Schilling clinical grading has been widely accepted and used for many epidemiological studies. However, it does not take into account the irritant effects of dust exposure or the lung function changes which may occur even in asymptomatic workers. A later classification grades byssinosis, respiratory tract irritation and acute and chronic lung function changes separately (Table 73.2).\(^69\)

<table>

</tbody>
</table>

\(^*\)‘Monday’ means the first day back at work after the weekly break. The original version of the classification did not include grade 3.

A characteristic feature of byssinosis is that it is most severe on the first day of the working week. Surveys of cotton workers have revealed a group of workers experiencing chest tightness on each working day with no variation in severity across the working week.\(^66\) The relationship between these symptoms and the classic symptoms of byssinosis is not clear.

It used to be thought that individuals progressed through the clinical grades of byssinosis, starting at grade \(\frac{1}{2}\) and, depending on their individual susceptibility and dust exposure, perhaps finishing at grade 3. However, the pattern and progression of symptoms in cotton workers has changed over the past 60 years, with the progressive reduction in cotton dust exposure. A 15-year prospective study in a Chinese cotton spinning mill, including enquiry about respiratory symptoms on four occasions, documented the intermittent nature of respiratory symptoms.\(^28\)

There was a cumulative incidence of byssinosis of 24 per cent and of chest tightness of 23 per cent. Symptoms of byssinosis were reported once by 23 per cent of workers, twice by 10 per cent, and three times or more by only 1 per cent of workers. There was a similar picture for symptoms of chronic bronchitis, chronic cough and breathlessness.
Remission of symptoms of byssinosis, despite continued exposure to cotton dust, has been described in other studies.\textsuperscript{24} Workers may complain of chest tightness in the absence of changes in FEV\textsubscript{1}, and others may have significant decrements in FEV\textsubscript{1} with no associated chest tightness.\textsuperscript{24} However, one study reported that among cotton workers without byssinosis, those with the greatest decrements in FEV\textsubscript{1} were the most likely to go on to develop symptomatic byssinosis.\textsuperscript{70}

\section*{PHYSICAL SIGNS}

On physical examination, there are no specific abnormalities associated with byssinosis. When physical signs are present they simply indicate the presence of airflow limitation. For example, there may be signs of chest hyperinflation, prolonged expiration and expiratory wheeze.

\section*{Radiology}

There are no specific abnormalities on the chest radiograph in byssinosis.

\section*{Lung function}

The changes in lung function associated with the symptoms of byssinosis were first documented in 1958.\textsuperscript{71} There is a decline in FEV\textsubscript{1} across the working shift in grades 1 and 2 byssinosis. The maximum decline in lung function across a working shift occurs on the first day of the working week, but this does not necessarily imply that the overall level of airways obstruction improves over the remainder of the week. In a study of 25 carders, including asymptomatic workers and grades ½ and 2 byssinotics, the greatest across-shift decline in FEV\textsubscript{1} occurred on the first day of the working week, but the mean FEV\textsubscript{1} was lowest towards the end of the week.\textsuperscript{72} Serial peak expiratory flow rate (PEFR) measurements in grade 3 byssinotic card-room workers may show a variety of patterns (Figure 73.1a,b) associated with wide diurnal variations in PEFR consistent with a diagnosis of asthma. Reduced mid-expiratory flow rates seem to be a sensitive indicator of airways obstruction in cotton workers.\textsuperscript{73,74} Gas transfer measurements\textsuperscript{74} were within normal limits when measured preshift in a small group of hemp, flax and cotton workers. Impairment of gas transfer, when present, appears to be related to smoking habits rather than exposure to cotton dust.\textsuperscript{75}

\section*{PATHOLOGY}

No specific pathological abnormalities have been described associated with byssinosis. Macroscopically, the lungs show heavy black pigmentation. In a study of 43 byssinotic subjects, mucous gland hyperplasia and hypertrophy of smooth muscle were found in upper and lower lobe bronchi, but not to a significant degree in segmental bronchi. Emphysema was present in less than half the cases. Some 23 per cent showed evidence of centrilobular emphysema and 14 per cent had panacinar emphysema.\textsuperscript{76} The finding of smooth muscle hypertrophy and mucous gland hyperplasia is of interest, since it is a pathological finding associated with bronchial asthma rather than chronic bronchitis.\textsuperscript{77} An autopsy study in 1980 again did not find emphysema associated with cotton dust exposure.\textsuperscript{78} These pathological findings are supported by physiological studies in smoking and non-smoking byssinotics, which reported the presence and severity of lung function changes consistent with emphysema be related to smoking habits and unrelated to cotton dust exposure.\textsuperscript{75}
MANAGEMENT

Antihistamine and a bronchodilator may reduce or prevent falls in FEV₁ across the working shift. In a comparison of the effects of disodium cromoglycate, beclometasone dipropionate and salbutamol on the ventilatory response to cotton dust in mill workers, salbutamol was found to be the most effective and disodium cromoglycate the least effective in preventing symptoms and changes in ventilatory capacity.⁷⁹

The finding in the study of Chinese cotton workers²⁸ that repeated cross-shift declines in lung function were associated with large declines in FEV₁, compared with a control population of silk workers, suggests that regular monitoring of lung function may identify this susceptible group of workers before they develop disabling loss of lung function. Ideally, their exposure to cotton dust should then cease, either by transfer to a mill handling pure man-made fibre or by finding a new job. Cessation of exposure has been found to have a protective effect on respiratory health that is independent of age, duration of exposure and smoking status.²⁸ In practice, new employment is often difficult to find and many affected workers continue their exposure to cotton dust. This exposure should be kept to a minimum by using respiratory protection and by moving the worker to the least dusty work area.

CHRONIC BRONCHITIS AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE IN COTTON WORKERS

Molyneux and Tombleson⁸⁰ observed that bronchitis (mucous hypersecretion) occurred more frequently amongst cotton workers than man-made fibre workers. A later study of 14 cotton mills and two man-made fibre mills reported a prevalence of bronchitis of between 18 and 45 per cent in cotton workers and between 23 and 26 per cent in man-made fibre workers.⁸¹ There was an association between the length of exposure and bronchitis in women, but not in men. A study of 2991 textile workers found an increased prevalence of chronic bronchitis in cotton workers aged more than 45 years, and an association with cumulative cotton dust exposure.⁸² The presence of chronic bronchitis was associated

![Figure 73.1](image_url)
with a small decrement in lung function. The authors estimated that the effect of cotton dust exposure in a non-smoking cotton worker was the equivalent of moderate smoking in a man-made fibre worker.

A study in Lancashire mills reported the prevalence of bronchitis was higher in byssinotics than non-byssinotics, after allowing for age and smoking habits.80

There is evidence that even at low levels of exposure to textile dusts, a small excess loss of lung function is demonstrable, which may be greater in man-made fibre than in cotton workers. In a longitudinal study of a large population of cotton and man-made fibre workers, with low cotton dust exposures (only 1 per cent of the population had symptoms of byssinosis), a dose–response accelerated decline in FEV1 and FVC was observed in smoking cotton yarn workers (the highest exposure group), but not in non-smokers in the same work area, nor in workers in other cotton work areas.83 The declines demonstrated in current smokers were 41.2 mL per year at average dust exposures of 150 μg/m3, 49.3 mL per year at 200 μg/m3, and 57.4 mL per year at 250 μg/m3. Exposure measurements in this US study are not equivalent to personal dust exposures measured in UK studies. Accelerated declines in FEV1 among cotton workers appear to be produced by a synergistic effect between cotton dust exposure and current smoking. Accelerated lung function decline is also related to higher across-shift decreases in FEV1.83,84

MORTALITY AND MORBIDITY IN COTTON AND TEXTILE WORKERS

The long-term effects of exposure to cotton and flax dusts on lung function in textile workers, with and without byssinosis, have been a matter of some controversy. Early epidemiological studies in the United Kingdom, when exposure levels to cotton dust were high, revealed evidence of excess morbidity amongst cotton workers. In 1908, Collis85 reported a study of strippers and grinders from 31 mills, with a prevalence of an asthma-like condition of 74–91 per cent. He noted that it was unusual for these men to remain in the cardroom after the age of 45 years. In 1930, Hill86 reported high death rates from respiratory disease amongst strippers and grinders, compared with ring room workers and warehousemen. A survey of cardroom workers in 1955 reported a high prevalence (14 per cent) of severe respiratory disease.57 More recently, Elwood et al.88 reported that prevalence and incidence of disability pensions for respiratory and other diseases were increased among cotton mill workers with a minimum exposure to cotton dust of five years.

Early mortality figures are difficult to interpret, as the occupation of the deceased was recorded as their last occupation, and many individuals with respiratory disability left the cotton industry to take up lighter jobs. Over the last 30 years there have been improvements in working conditions in textile mills, with marked reductions in dust levels. More recent mortality studies have failed to demonstrate an increased mortality amongst textile workers89,90 or workers with byssinosis.91 Given this failure to demonstrate an excess mortality amongst textile workers and the evidence from studies of normal populations that respiratory symptoms and lung function are strongly associated with mortality,90 one possible conclusion is that under prevailing industrial conditions exposure to cotton dust is not associated with significant permanent respiratory impairment. A Finnish study of disability pensions found no excess in mortality for respiratory disease in a cohort of cotton workers.92 A study of a group of cotton workers initially identified between 1968 and 1970 reported that both the total mortality and the mortality due to respiratory disease were less than expected.93 However, respiratory disease mortality was raised in those who had reported symptoms of byssinosis.

The available evidence suggests there is a small subgroup of textile workers (those with byssinosis) who develop respiratory disability with an associated excess mortality due to respiratory disease.

MEASUREMENT OF DUST EXPOSURE

Measurement of cotton dust exposure has not been internationally standardized. The United States standards for dust exposure monitoring have involved the use of work area dust sampling, but using a vertical elutriator to allow measurement of the respirable fraction of dust. This has the advantage of targeting the proportion of dust which is most likely to penetrate the lower airways. The disadvantage is that the equipment is large and cumbersome and can only be used to measure area samples. The samplers may be positioned some distance from the individual worker and therefore may give poor estimates of actual exposure in the personal breathing zone. The UK used a similar work area sampling technique until the 1990s and it is the basis for all the early literature about byssinosis and cotton dust exposure.

A comparison of area and personal sampling techniques in cotton workers found a nearly eight-fold difference in measured dust levels between the two techniques in the opening processes, with personal sampling exposures being much higher than area sampling exposure estimates.94 The difference between area and personal sampling was less in other processes: five-fold in carding, four-fold in other cardroom processes, 1.4 times in ring spinning and 2.5-fold in winding. Since respiratory disease in cotton workers is much more frequent in the early stages of processing, this difference between area and personal sampling is important in terms of setting exposure standards. There is now a personal exposure dust standard for cotton in the UK.

PREVENTION

The most important preventive measure is a reduction in dust levels. It was originally calculated that approximately
10 per cent of workers exposed to cotton dust for 40 years at a concentration of 0.5 mg/m³ (as measured using work area dust sampling with a 2-mm pitch gauze prefilter) would develop byssinosis. Efficient exhaust ventilation with filtering of recirculated air is an important preventive measure. Over the past ten years, there have been progressive reductions in cotton dust exposure levels in the USA, such that now byssinosis is a rare disease. Attention is focused on preventing dust-related chronic decline in lung function. The results of the Tulane longitudinal study suggest that byssinosis is a rare disease. Attention is focused on preventing dust-related chronic decline in lung function. The pre-processing of cotton to prevent byssinosis has also been investigated. Cotton steaming reduced the biological activity of cotton dust and also the dust levels in the early stages of processing. However, fine dust particles may be released later in the manufacturing process, leading to an increased incidence of byssinosis in these work areas. More recently, the bactericidal treatment of raw cotton in the field before harvesting has been evaluated and shown to be highly efficient at reducing the growth of bacteria during transportation and storage, thus potentially reducing endotoxin exposure during the cotton spinning process.

Key points

- Byssinosis is a disease of occupational aetiology which is asthma-like, with bronchial reactivity and airways obstruction, developing after many years of occupational exposure to cotton dust.
- The aetiological agent involved in causing byssinosis is unknown; however, the agent is water-soluble and is likely to be a contaminant of cotton rather than the fibre itself. Bacterial endotoxin is the most likely agent.
- Chronic cotton dust exposure is associated with symptoms other than those known as classical byssinosis. COPD and chronic bronchitis are more common in cotton workers irrespective of smoking habit.

Extrinsic allergic alveolitis

PAUL CULLINAN AND ANTHONY NEWMAN TAYLOR

INTRODUCTION

Extrinsic allergic alveolitis (EAA) is an immunological disease of the gas-exchanging parts of the lung and the connecting small airways in response to an external antigen. The disease is also known as hypersensitivity pneumonitis (HP), the two labels being synonymous. In most cases, the antigen is airborne and exposure is through inhalation; most such antigens are biological in nature, but the disease may also occur after exposure to an airborne, low molecular mass chemical. Occasionally EAA is attributed to an ingested medicine.

DISEASE FREQUENCY

A firm diagnosis of EAA requires an appropriate history of exposure. This may sometimes be difficult to elicit, especially in chronic cases. It also requires access to fairly sophisticated immunological, radiological and pathological technology. As a result of these diagnostic challenges, information on the frequency and distribution of the disease is patchy and particularly so in general populations. Perhaps the best source of community-based data is a general practice register in the UK covering several million. Analysis of 271 new cases between 1991 and 2003 suggested an overall annual incidence of 1 per 100 000 total population. This rate varied from 0.4 per 100 000 in those aged less than 45 years to 2.4 per 100 000 in those aged 65–74 years. There was very little difference in overall incidence between males and females and little evidence of temporal variation across the 12 years of study. The data did not allow any identification of causative agents. Population-based information derived from mortality data is available from the United States for a period covering 22 years. Age-adjusted death rates increased from 0.9 per 100 000 in 1980 to 2.9 per 100 000 in 2002; the highest rates were in Wisconsin (10 per 100 000). It is unclear whether this rise reflects a true increase in disease incidence or a change in the methods of disease ascertainment or labelling. In 26 states with information on occupation, proportional mortality rates were significantly higher among agricultural production workers, especially those working with livestock in whom the proportional mortality rate was increased almost 20-fold.

Other information on disease frequency is largely from groups with specific exposures, most of them occupational. In general, estimates of disease prevalence are derived from cross-sectional surveys, often with incomplete information on the size of the base population – and thus response rates. ‘Healthy worker’ survival pressures may also operate, but are difficult to quantify. There are fewer longitudinal studies from which measures of incidence can be derived. In all cases measures of the frequency of EAA depend on the methods by which it was ascertained. Although the number of reported causes of EAA is large, most are uncommon. Furthermore, the risk of many of the classical microbial causes of extrinsic allergic alveolitis has been considerably reduced by changes and improvements in work practices.
EAA can be common among farmers with exposure to hay, but the frequency of disease depends closely on farming practices, climate and probably other factors. In Ireland the annual incidence of hospital-diagnosed EAA among farmers was estimated at about 1.5 per 100 000 between 1982 and 1996. Rates fell to about one-quarter of this level between 1997 and 2002, a decline attributed to changes in the production methods of cattle feeds. In Finland, between 1980 and 1982, 512 new cases of farmer’s lung were registered – two-thirds of them in women. Estimates of annual incidence were far higher than in Ireland (ranging from 8 to 60 per 100 000), but varied both geographically and temporally, being closely related to daily rainfall and season – the highest incidence rates were in the spring (April). Similar prevalence rates have been measured among French9,10 and US dairy farmers.11

EAA is often persistent but rarely fatal; hence its prevalence is generally higher than its incidence. Estimates of the prevalence of disease among farmers tend to vary in the manner above. In Scotland, the prevalence of EAA in farmers – identified by questionnaire alone – varied between 23 per 1000 farm workers in East Lothian and 86 per 1000 in the wetter Ayrshire and Orkneys. About half of the cases in the latter two regions had serum-specific precipitating antibodies to an appropriate antigen. Similar prevalence rates have been measured among English, French9,10 and US dairy farmers.11

There are fewer data on apparently less common forms of occupational EAA. In 1978, budgerigar fancier’s lung was described as the most important cause of EAA in Britain, with an estimated prevalence among current budgerigar owners of between 0.5 and 7.5 per cent.12

CAUSES OF EXTRINSIC ALLERGIC ALVEOLITIS

The list of recognized causes of EAA is long; several of the more common are shown in Table 74.1. Most occupational causative agents are organic, but the list also includes a small number of low molecular mass chemicals, the most important of which are diisocyanates. The colourful names given to EAA caused by many different organic dusts reflect the varied work settings in which exposure occurs. However, by definition, the tissue response in the lungs and the clinical manifestations of the disease are essentially the same, whatever the cause.

The attribution of cause to a particular agent is rarely simple. In general, it is dependent on the identification of the agent in the workplace environment – most convincingly in air – and on the recognition of a specific serum immune response in those with clinical manifestations of the disease. Serum immunological responses are not, however, specific for the disease, being found in variable proportions of exposed workers without evidence of disease. Moreover, different agents may be responsible for EAA in the same occupational setting, apparently dependent on local conditions and working practices. Thus, in addition to its most commonly recognized causes (Saccharopolysspora rectivirgula and Thermoactinomyces vulgaris) farmer’s lung may be attributable to a wide variety of bacterial and fungal species.13 To complicate matters further, the nomenclature of some important causative agents changes frequently. Thus, S. rectivirgula was formerly known as Faeni rectivirgula, and before that as Micropolyspora faeni.

Some important varieties of EAA are of unknown cause; indeed the diagnosis is not infrequently made on clinical, radiological or pathological grounds without an identified causative agent. For example, several outbreaks of EAA among metal workers in the United States and the United Kingdom have been described. Although it seems that in each outbreak the source of the antigen was a water-based, metal-working fluid, it remains unclear which component – or more probably microbiological contaminant – was responsible. Finally, EAA is not necessarily an occupational disease. The most common type of disease in Japan is known as ‘summer-type EAA (or HP)’ and is attributed to domestic exposures to Trichosporon cattaneum and possibly Cryptococcus albidus.14

This form of disease appears to be confined to southern Japan and has a strong seasonal pattern, being clinically evident only in summer months. It has been linked to residence in older, wooden homes. Domestic exposures to Aspergillus and other species have also been reported to cause EAA,15–17 as have Cladosporium and other species in ‘hot tub’ lung.18

These issues aside, there are some conditions that appear to be necessary for the induction of EAA:

- Antigen size: The aerodynamic diameters of the causative agent must be sufficiently small to allow penetration into and retention within the alveoli; for example, the spores of S. rectivirgula, the major cause of farmer’s lung, are about 2 µm in diameter and those of Aspergillus clavatus, the cause of malt worker’s lung, are about 3.5 µm in diameter. These dimensions are considerably smaller than those of the moulds, such as Alternaria alternata and Cladosporium herbarum, that give rise to asthma.
- Antigen persistence: The organic dusts (spores and animal proteins) which cause EAA are poorly degradable and able to persist in the lungs for long periods.
- Exposure conditions: EAA usually occurs in circumstances where the inhaled dose of organic dusts is very high. For example, measurements in barns when bales of mouldy hay are opened suggest that up to 750 000 spores of respirable size may be deposited in the lungs during each minute of exposure.19

Nonetheless, only a proportion of exposed persons develops EAA. This may be a reflection of innate susceptibility (or resistance), perhaps related to genetic factors located in the major histocompatibility complex region.20,21

PATHOLOGY

Relatively little is known about the pathology of acute EAA since histological specimens are rarely collected in that
setting. The pathological changes in chronic disease are better described. The characteristic pathological finding in EAA is a granulomatous inflammatory response centred on the peripheral bronchioles and extending peripherally – and often patchily – into adjacent alveoli (Figure 74.1). The inflammatory exudate consists primarily of plasma cells, lymphocytes, macrophages and monocytes; characteristically, foamy macrophages are more abundant in alveoli and lymphocytes in the interstitium. Macrophages and cells derived from them (epithelioid and giant cells) accumulate in foci (‘granulomata’) within the bronchiolar and interstitial

inflammation. Although the appearances of the non-necrotizing granulomata are similar to those found in sarcoidosis, they tend to be smaller and more poorly differentiated than in that disease. Moreover, the bronchocentric nature of EAA and the formation of granulomata within areas of interstitial inflammation distinguish the granulomatous response from that of sarcoidosis.

With avoidance of exposure, the granulomata resolve in some three to four months. If avoidance of exposure occurs at a sufficiently early stage in the disease process the remaining inflammatory response in the lungs can resolve.

In other cases, the inflammatory exudate may organize by interstitial fibrosis, causing irreversible damage to the lungs. For reasons which are unknown, fibrosis in allergic alveolitis, as in other granulomatous lung diseases, such as tuberculosis and sarcoidosis, predominantly involves the upper lobes causing lobar shrinkage and cyst formation. The determinants of progression to fibrosis are not clear, but it may particularly occur after repeated symptomatic exposures to the specific cause.22

IMMUNOPATHOLOGY

Understanding of the immunological basis of EAA has advanced considerably in recent years but remains incomplete. The original hypothesis that the disease was the outcome of local complement-fixing immune complexes formed between inhaled antigen and circulating antibody deposited in the lungs, was based on several observations:

- the presence of specific, precipitating IgG antibodies (precipitins) in the sera of patients with EAA;
- the provocation by inhaled antigens of a late alveolar response with a time of onset and duration which paralleled the time course of the late ‘oedematous’ skin reaction;
- the finding of immunoglobulin and complement by immunofluorescence in lung tissue of patients with farmer’s lung 36 hours after inhalation of the causative agent.23

However, the explanation of EAA solely as an immune complex-mediated response was unsatisfactory for two major reasons. First, granuloma formation, a characteristic component of the pathological response in EAA, was more typical of a T-lymphocyte than immune complex-dependent inflammatory reaction. Second, depending on the sensitivity of the serum assay, IgG antibody could be detected in up to 50 per cent of individuals exposed to causes of EAA but without disease.

The nature of the immunological response in EAA and, in particular, the role of the T-lymphocyte has been clarified by the study of fluid recovered from the lungs during bronchoalveolar lavage (BAL). The proportion of lymphocytes recovered at BAL from patients with EAA is, as in sarcoidosis, greatly increased above normal. Whereas in normal individuals some 85–90 per cent of the cells recovered are macrophages, in sarcoidosis the proportion of lymphocytes may be increased to 50 per cent and in allergic alveolitis to 60–70 per cent or more. In sarcoidosis, the ratio of CD4:CD8 T lymphocytes is increased from the normal value of about 2:1 to 5:1. In EAA, the CD4:CD8 ratio can be normal or low and CD8 T-lymphocytes can comprise 40 per cent and CD4 T lymphocytes 30 per cent of the total lymphocytes recovered to give a CD4:CD8 ratio of less than one.24 Incubation with pigeon serum of T-lymphocytes recovered by lavage from the lungs of a patient with pigeon fancier’s lung stimulated their transformation,25 and in animal models, the disease can be reproduced by transfer of sensitized T-lymphocytes.26

The increase in the proportion of lymphocytes recovered at BAL and the reversed CD4:CD8 T-lymphocyte ratio has, however, also been observed in healthy asymptomatic farmers and pigeon breeders. In one study of 28 farmers with increased BAL lymphocytes, none of 27 studied two to three years later – all of whom had remained on their farms – had developed farmer’s lung.27 Thus the T-lymphocyte response in the lungs by itself is no more able to explain the disease than the presence of IgG antibody in serum.

The explanation for the apparently contradictory evidence above is probably complex and possibly differential.28 Thus, humoral mechanisms may be relatively more important in the early stages of acute disease, whereas T-cell mediated responses may predominately in more chronic forms. It is likely that in the latter the regulation of responses – and the genetic variants that determine this – is important.29 For example, pigeon fanciers with EAA differ from asymptomatic exposed individuals with similar increases in BAL lymphocytes in that they show a defect in antigen-specific T-lymphocyte suppressor function.30 This defect may allow inhaled allergen to provoke a T-lymphocyte dependent inflammatory response; in the asymptomatic person with BAL lymphocytosis, translation of the immunological response into granulomatous inflammation may be inhibited by antigen-specific suppressor T-lymphocytes.

The risk of developing both specific IgG antibody and allergic alveolitis in those exposed to its causes has been consistently reported to be lower in cigarette smokers than in non-smokers.3,31 This apparent protection may be a reflection of impaired alveolar macrophage function.

CLINICAL, RADIOLOGICAL AND PHYSIOLOGICAL FEATURES

The clinical features of EAA, however caused, depend on the pattern of exposure to the cause and on variation in the
severity and nature of the individual response. Although several clinical classifications of the disease have been proposed, they are used inconsistently and in practice the distinction of just two presentations is useful: acute (or subacute) EAA that is potentially reversible and chronic disease that is irreversible. Even these labels should be used with care since it is not necessarily the case that ‘chronic’ disease follows ‘acute’ disease.

**Acute (reversible) extrinsic allergic alveolitis**

Acute allergic alveolitis typically follows exposure to antigen in high concentration. In a typical case, as in the farmer who feeds mouldy hay to cattle in a cowshed, symptoms do not occur during the period of exposure, but several hours later when breathlessness and ‘flu-like symptoms – fever, constitutional upset, muscle pains and headache – develop and predominate. With recurrent attacks, considerable weight loss may also occur. In the absence of further exposure to their cause, symptoms usually start to improve within 48 hours, but may persist for a week or more before resolving completely. Where exposure continues, the (sub-acute) symptoms do not resolve, but become increasingly severe. On examination during the acute episode, scattered inspiratory crackles and on occasions inspiratory squeaks may be heard over the lungs, but in some cases no abnormal sounds are audible.

A variety of patterns of changes, including no visible changes, on the chest radiograph may develop during the acute disease. A patchy, bilateral ground glass pattern can occur, which is often difficult to detect unless a previous (or subsequent) radiograph is available for comparison. The generalized haze is associated with a loss of sharpness of outline of the vascular shadows, particularly in the lower lung zones; the apices may be spared. Micronodular (less than 3 mm) or nodular shadows, either widespread or more prominent in the lower zones may also occur (Figure 74.2). On occasions, nodules can merge into larger areas of patchy consolidation. In the absence of further antigen exposure, these acute shadows can take four to six weeks or longer to resolve.

High resolution computed tomography (HRCT) scanning of the chest is more sensitive than standard chest radiography and is abnormal in almost all cases. The changes reflect those seen on chest x-ray and presumably the underlying pathological processes. In acute EAA, the typical findings are of a ground glass patchy infiltration predominantly in the lower lobes. A ‘mosaic’ pattern, most evident on expiratory scans, may be apparent (Figure 74.3). With avoidance of further exposure to the causative agent, the changes of consolidation are the first to resolve; micronodules tend to clear less rapidly.

The important abnormalities of lung function in acute allergic alveolitis are a reduction in lung volumes (‘small, stiff lungs’) and impairment of gas transfer. Total lung capacity (TLC) and residual volume (RV) are reduced as are vital capacity (VC) and forced expiratory volume in 1 second (FEV1). The FEV1/FVC ratio is maintained or increased. Both transfer factor for carbon monoxide (TLCO) and gas transfer coefficient (KCO) are reduced. Of these abnormalities, the reduction in TLCO is the most sensitive indicator of disease severity. In addition, the alveolar–arterial $P_{O_2}$ gradient is increased at rest and widens with exercise. In severe cases, $P_{O_2}$ at rest may be sufficiently reduced for patients to be cyanosed; $P_{CO_2}$ is normal or reduced. Lung function in patients with acute alveolitis generally improves during four to six weeks of avoidance of exposure, but can continue to improve for up to six months. During the acute illness the blood neutrophil count, erythrocyte sedimentation

![Figure 74.2 Chest radiograph in acute extrinsic allergic alveolitis (farmer's lung).](image1)

![Figure 74.3 High resolution computed tomography scan of chest in acute extrinsic allergic alveolitis with mosaic pattern.](image2)
rate (ESR) and C-reactive protein are usually increased, but rarely by very much.

Recurrent episodes of alveolitis follow intermittent exposures to antigenic dust in high concentration and may give rise to a 'subacute' presentation. While it is widely believed that progressive disease occurs in those continuously exposed to high concentrations of antigen, the evidence for this – from longitudinal study of individual patients or populations – is very limited.22

**Chronic (irreversible) extrinsic allergic alveolitis**

Chronic allergic alveolitis is distinguished from acute disease by the development of irreversible pulmonary fibrosis. It may result from recurrent episodes of acute alveolitis or repeated exposures, over a long period, to antigen in concentrations insufficient to provoke acute symptoms, but sufficient to cause progressive pulmonary damage. The commonly cited example of this latter pattern of presentation is the budgerigar fancier exposed to low concentrations of bird dust in her home, who only comes to medical attention when pulmonary fibrosis has caused sufficient loss of respiratory reserve to cause symptoms.

The dominant symptom of chronic allergic alveolitis is breathlessness on exertion. Other than weight loss which can be considerable, systemic symptoms are usually absent. Finger clubbing is unusual. Scattered inspiratory crackles and squeaks may be audible over the lungs.

Chronic irreversible changes develop on the chest radiograph. Linear shadows, honeycombing and lung shrinkage occur, particularly in the upper lobes, with compensatory dilatation in the lower lobes (Figure 74.4). These findings are mirrored with greater sensitivity on HRCT (Figure 74.5).

The abnormalities of lung function are similar to those in acute alveolitis, but may improve little with avoidance of exposure to their cause, and can progress in its absence. Lung volumes (TLC, RV and VC) are reduced, FEV₁/FVC is maintained or increased and TLCO and KCO are reduced. The magnitude of the reduction in TLC and TLCO correlate with the profusion of abnormalities on the chest radiograph.35 Arterial \( P_{\text{O}_2} \) is reduced and in severe cases patients are cyanosed. The alveolar–arterial gradient is increased and widens on exercise. Pulmonary hypertension can develop in patients with widespread pulmonary fibrosis and patients may present at this stage of the disease.

**DIAGNOSIS OF EXTRINSIC ALLERGIC ALVEOLITIS**

The diagnosis of extrinsic allergic alveolitis is based on a combination of the following:

1. Identification of a potential source of antigen in the patient’s working (or domestic) environment.
2. A pattern of clinical symptoms linked to exposure to the above with, importantly, a pattern of improvement after avoidance of exposure to the causative antigen. Such improvement may be confounded by hospitalization and treatment.
4. Characteristic cytology of BAL (lymphocyte count >30–40 per cent), where available.
5. Characteristic histopathological changes, where the appropriate material is available.
6. Demonstration of specific IgG antibodies, including precipitins, to the causal antigen in the patient’s serum.
7. A positive response to specific inhalation challenge under experimental conditions.

Few of the above are diagnostically specific for EAA and in any case it is rare that all are available. Specific inhalation challenge testing, for example, is very rarely undertaken and the response to antigen avoidance is often confounded by concurrent steroid treatment. Thus, in many cases, a diagnosis is made on incomplete evidence and there is almost certainly wide variation in diagnostic practice.36 Nonetheless, the diagnostic value of the combination of various clinical, laboratory and other tests in distinguishing acute EAA from other interstitial lung disease has been studied in considerable detail.37 In the absence of an independent, gold standard diagnostic test, there is a certain circularity of argument in any such study, but its findings are instructive. Just six measures, most of them derived from a clinical history, were significantly associated with a diagnosis of acute EAA, the most powerful of them being an appropriate exposure history. Estimates of the probability of disease using these simple measures are summarized in Table 74.2.

Traditionally, reflecting early studies of the immunopathology of EAA, specific laboratory tests have focused on the identification of precipitating IgG antibodies (‘precipitins’) using methods based on the Ouchterlony technique. This method is essentially qualitative and is time consuming. More recently, indirect enzyme immunoassay methods for the detection of any specific IgG antibodies have become available, some of them commercially so. These are far more easily automated and provide a quantitative measure. Broadly speaking, the two approaches are in agreement, although the latter may be diagnostically more sensitive, and less specific.38,39

Specific IgG antibodies, whether precipitating or otherwise, are in general a more sensitive than specific index of EAA. In cases of EAA, their detection is further dependent on the interval since last exposure to the causative antigen. In farmer’s lung, precipitins to causative antigens are found in the serum of between 75 and 100 per cent of cases during an acute episode, but in only about 50 per cent after two years from the last acute episode and in only one-third of cases after five years.22 In pigeon fancier’s lung, IgG titres fall rapidly after allergen avoidance.38 Thus, in acute disease with recent exposure, the test has a high sensitivity with a low false negative rate. In chronic disease, the sensitivity is far lower. For example, precipitating antibodies may be found in just 20 per cent of farmers with EAA whose last acute attack was more than 36 months previously.40 Conversely, the measurement of specific IgG antibodies has a low specificity (a high false positive rate); the majority of farmers, for example, who have serum precipitins do not have farmer’s lung. In a random sample of Quebec dairy farmers, 8 per cent had serum precipitins, but only four of the 56 with precipitins had farmer’s lung.41 Similarly, one-third of US dairy farmers without overt evidence of disease

Adapted from Ref. 37.
Differential diagnosis

The most important differential diagnoses in acute EAA are febrile microbial respiratory illnesses which cause widespread shadows on chest radiograph. These include pneumonias caused by influenza virus, by *Mycoplasma* and by *Legionella*, psittacosis and Q fever. In the immunocompromised patient infection with *Pneumocystis carinii* should be excluded before starting treatment with corticosteroids. Important differential diagnoses in chronic EAA include other forms of interstitial lung disease, such as non-specific interstitial pneumonitis (NSIP), usual interstitial pneumonitis (UIP) and sarcoidosis.

OUTCOME OF EXTRINSIC ALLERGIC ALVEOLITIS

The important long-term consequence of EAA is pulmonary fibrosis which can be disabling and shorten life. Because of its relative frequency and important economic consequences, the risk of developing disabling pulmonary fibrosis and the factors determining its occurrence have been particularly investigated in farmer’s lung. One large study followed up 144 patients for an average period of 15 years during which time some 10 per cent died of causes associated with their disease. Of those alive at the end of follow up, 40 per cent had radiographic evidence of chronic alveolitis, less than one-quarter had exertional dyspnoea, and about one-third reduced TLCO, the most sensitive index of impaired lung function in EAA. The development of disabling fibrosis particularly occurred in those with a history of recurrent (more than five) episodes of acute alveolitis. Continuing to farm and disease of long duration were not associated with worse lung function. Provided adequate precautions were taken to minimize exposure to mouldy hay and other sources of thermophilic actinomycetes, the majority of farmers were able to remain on their farms without developing disabling pulmonary fibrosis.22 The results of several other studies support this finding. One compared the outcome five years after an attack of acute EAA in 24 farmers who had left their farms with 37 who had remained. Mean TLCO improved in those who had left their farms, but not in those who remained. However, there was wide variation between subjects in both groups and the majority of farmers were able to continue to farm without developing disabling disease.45 A similar follow-up study of 86 cases of farmer’s lung in Finland found that lung function improves during the six months after an acute episode, but that after five years there was no difference in lung function between the two-thirds who had continued to farm as compared to those who had left. Corticosteroid treatment accelerated the rate of improvement following an acute attack, but did not produce any long-term improvement in lung function.46

In 1981–82, 43 asymptomatic Quebec dairy farmers were identified; 23 had serum-specific precipitins and 19 had an increased lymphocyte count on BAL – none had abnormal radiology or lung function. Twenty-seven were re-examined 20 years later; none had stopped farming for reasons of respiratory ill health.47 There was no evidence of clinically important disease or of reductions in lung function in any suggesting that the presence of precipitins or BAL lymphocytosis alone have no adverse consequences.

The prognosis of acute pigeon fancier’s lung seems to be good. A decade of observation of 21 patients with the disease (18 of whom continued to keep pigeons) suggested a favourable clinical course in most. Continuing high levels of specific IgG antibodies suggested that avoidance of exposure could not easily explain this pattern.48 In contrast, in a cohort of 78 patients with chronic pigeon fancier’s lung, almost 30 per cent died of their disease within five years of diagnosis.49 These observations suggest that those with insidious disease, without acute symptoms, may develop more severe pulmonary fibrosis.

MANAGEMENT OF EXTRINSIC ALLERGIC ALVEOLITIS

The aims in management of cases of EAA are to ensure maximum restoration of lung function and to prevent the development or progression of pulmonary fibrosis. Patients with acute EAA should avoid all exposure to the cause of their disease until maximum restoration of lung function has occurred. Corticosteroids accelerate the rate of recovery in acute disease, but do not seem to provide additional long-term benefit.50 Treatment should be discontinued within six months of an acute episode. An initial dose of prednisolone of 1 mg/kg body weight should be reduced within four to eight weeks to 20 mg on alternate days which can be continued for three to six months. The starting high dose should be maintained until maximum resolution of the chest radiograph and sustained improvement in lung function are obtained.

Occasionally, patients develop a progressively fibrosing disease which should be treated with longer-term, regular oral steroids supplemented when appropriate by an immunosuppressant drug, such as azathioprine or cyclophosphamide.

Long-term management is primarily based on avoidance of exposures which are believed to increase the risk of progressive pulmonary fibrosis. It is clear from studies of farmers that only a minority with EAA develops disabling pulmonary fibrosis and the majority is able to continue to farm without this occurring. If a farmer wishes to continue
in employment it is reasonable to support this provided: (1) he or she takes appropriate measures to minimize exposure to mouldy hay (including the use of effective respiratory protection, such as laminar flow equipment when handling stored hay, straw and grain); (2) lung function is monitored regularly, at the minimum before and after each winter season. Should lung function show progressive deterioration during the winter and incomplete resolution in the summer, he or she should be strongly advised against continuing farm work.

A similar approach may be taken with other occupational causes of extrinsic allergic alveolitis, where complete avoidance of exposure is only obtained at the expense of an individual’s job.

The situation is less straightforward in situations, such as bird fancier’s lung, where an exposure is unrelated to occupation, and thus continuation, or otherwise, of exposure is not contingent on employment. In these situations, it seems more reasonable to advise avoidance of all further contact with the source of exposure. However, particularly in the case of pigeon fanciers, the birds may be the focus of a social life with which the individual is unwilling to part. In this situation, it may be appropriate to apply the same rules as for occupational alveolitis: minimal exposure with the use of respiratory protection when exposed and serial measurement of lung function (in particular of gas transfer) to monitor the effectiveness of this strategy.

STATUTORY COMPENSATION

In the UK, extrinsic allergic alveolitis is prescribed for ‘employed earners’ in certain occupations. These are defined as those that involve:

- exposure to moulds or fungal spores, or heterologous proteins by reason of employment in agriculture, horticulture, forestry, cultivation of edible fungi or maltworking, or
- loading or unloading, or handling in storage of mouldy vegetable matter or edible fungi, or
- caring for or handling birds, or
- handling bagasse or
- exposure to metal-working fluids.

Employed earners (i.e. not the self-employed) who develop EAA as a consequence of employment in which they have been exposed to one of these groups of agents are entitled to disablement benefit.

PARTICULAR TYPES OF EXTRINSIC ALLERGIC ALVEOLITIS

Farmer’s lung

Farmer’s lung is the most frequently recognized occupational form of EAA. It is usually, but not always, the outcome of an allergic response to thermophilic actinomycetes which cause vegetable matter to mould during storage. Actinomycetes are Gram-positive, filamentous bacteria that resemble fungi in their morphology and are the only known bacteria to produce antigenic spores. Species that are thermophilic, with growth favoured by high humidity and temperatures of between 30 and 65°C, include *S. rectivirgula* (formerly *Micropolyspora faeni*), *Thermoactinomyces vulgaris*, *Saccharomonospora viridis* and *Thermoactinomyces sacchari*, among others. Inhalation of spores and mycelial fragments typically occurs when mouldy hay, straw or grain is handled in enclosed and poorly ventilated buildings. Crops become mouldy when they are harvested damp and stored with a high water content. Moulding generates heat, the maximum temperature achieved being dependent upon the water content of the hay. Stored with a water content of between 35 and 50 per cent, the temperature of hay can reach 65°C, sufficiently high to permit the growth of thermophilic actinomycetes. This general relationship between water content, heating and microbial growth applies also to other crops and vegetable matter, such as straw, grain, bagasse and mushroom compost, which can support the growth of microorganisms whose spores cause EAA.

The prevalence of farmer’s lung is related to local rainfall and to farming methods. In general, the disease is most prevalent in areas of high rainfall and where economic circumstances (as on small and undercapitalized farms) do not allow drying of crops before storage or the prevention of wetting during storage. Opening bales of hay and straw during animal feeding and bedding, especially in under-ventilated buildings, is the most common circumstance incurring high exposure. The estimated prevalence of the disease will also vary with the criteria used to identify cases. It appears to be uncommon in contemporary UK farming.

Farmer’s lung can be prevented by drying crops adequately before storage, by preventing their becoming damp and ensuring good ventilation during storage. To prevent significant moulding, hay must be stored with a water content of less than 20 per cent. The disease can also be prevented by the substitution of silage for hay. Respiratory protection should be worn by farm workers when working with mouldy crops in conditions likely to generate spores into the air in high concentration and in particular by those who have experienced an attack of farmer’s lung in the past.

Bird fancier’s lung

Bird fancier’s (or breeder’s) lung is caused by inhaled avian serum proteins (IgA may be most important) present in the birds’ excreta and secreta, and in pigeons particularly, the bloom from their feathers. It primarily occurs amongst individuals who breed and keep pigeons for racing and those who share their homes with caged birds, especially, although not exclusively, budgerigars. EAA has also been
reported in those exposed to chickens, turkeys, ducks, geese, pheasants, parrots and turtle doves.

Typically, protein containing dust is disseminated into the air during the cleaning of pigeon lofts and budgerigar cages. Antigenic dust is also generated continuously by birds when active and inhaled by owners and others observing the birds in their cages. Budgerigar fancier’s lung may be the most important cause of EAA in Britain, with an estimated prevalence among current budgerigar owners (in 1978) of between 0.5 and 7.5 per cent.12 This is similar to the prevalence of farmer’s lung among farm workers; the greater number of budgerigar owners in the community, however, suggests that alveolitis caused by birds is the more common disease.51

**Metal-working fluids and extrinsic allergic alveolitis**

Metal-working fluids (MWF) are used for lubrication, cooling and waste removal during high-speed metal machining processes. Their use is very widespread in manufacturing occupations. In the United States, for example, there are estimated to be more than a million workers with potential exposure.52 Traditional MWF were ‘straight’ insoluble petroleum oils, but these have been replaced by emulsions of water with soluble, synthetic or semi-synthetic oils. During machining and similar processes, the MWF is readily aerosolized and both respiratory and dermal exposure can occur. Modern fluids are designed to reduce such ‘misting’. A significant problem with MWF, and perhaps particularly with synthetic varieties, is contamination by bacterial, mycobacterial and fungal organisms.53 Effective management of MWF systems requires processes designed to reduce or eliminate microbial contamination, including regular biocidal treatment.

In addition to a limited number of case reports, there is literature describing several outbreaks of extrinsic allergic alveolitis among metal machinists. Most of these have been in US factory populations,54–57 but there are also reports from the UK,58 including one of a relatively large outbreak in a car engine plant.59,60 Investigations using simple epidemiological approaches suggest a causative role for a component of metal-working fluids, but immunological studies have failed consistently to identify any particular agent.

**Mushroom worker’s lung**

Mushroom worker’s lung is caused by the inhalation of microbial spores generated during commercial mushroom cultivation. Mushrooms are cultivated commercially on compost, a mixture of wheat straw and fresh animal manure. After decomposition outdoors, the compost is heated indoors by steam to 60°C at 100 per cent humidity, conditions ideal for the growth of thermophilic organisms. After around five days of these conditions, mushroom spawn is added to the compost and mechanically mixed, generating large numbers of spores. The mushrooms are grown in sheds at a temperature of about 20°C and 90 per cent humidity. After the mushroom crop is picked, the spent compost is removed and dumped outdoors. Exposure to microbial spores primarily occurs during spawning, particularly when done by hand and during disposal of spent compost. The specific microorganisms responsible for the disease have not been identified with any certainty, but may be microbes growing in the compost, from the mushrooms or both.

Activities that lead to high mould exposure include mixing compost, spawning and compost disposal. The risk of developing mushroom worker’s lung has decreased since the introduction of mechanical, as opposed to manual, spawning. Chronic mushroom worker’s lung appears to be very uncommon.

**Malt worker’s lung**

Malt worker’s lung is caused by Aspergillus clavatus, a contaminant of barley to which maltmen in whisky distilleries or breweries may be exposed during malting. In a distillery, barley is dried in hot air kilns, stored in silos for at least eight weeks and dehydrated in steeping tanks with a mild fungicide. In the traditional ‘open floor’ malting process, the barley is then spread out on open floors and allowed to germinate. Heat is generated by respiration of the germinating barley and the temperature maintained by regularturning and raking of the barley. Germination is stopped by putting the barley into a hot air kiln, in which the malt is dried and turned.

Exposure to the spores of A. clavatus occurs primarily among those turning barley on the malt floor and in the malt kilns. In modern maltings, these processes have been partly or wholly mechanized and both exposure to Aspergillus and the risk of malt worker’s lung have been greatly reduced. Chronic malt worker’s lung seems to be very uncommon.

**Bagassosis**

Bagasse is the fibrous cellulose residue of sugar cane which remains after the sugar has been extracted. It is used in the manufacture of several different materials which include paper and particle boarding. After sugar extraction, bagasse is stored for about a year, often outdoors, in bales. Storage with a water content above 27 per cent permits moulding, heat generation and the growth of thermophilic microorganisms including T. sacchari.

Exposure to T. sacchari primarily occurs in those involved in the removal, opening and milling of stored bagasse. Moulding of bagasse can be prevented by pretreating the
fresh material with 1 per cent propionic acid. Bagassosis is now uncommon, although sporadic outbreaks continue to be reported.

‘Ventilation pneumonitis’

Extrinsic allergic alveolitis can occur in the inhabitants of air-conditioned homes and among those working in air-conditioned office blocks. The majority of cases reported to date have occurred in the United States where the disease is caused by thermophilic Actinomyces growing in reservoirs of humidification systems where water recirculates at temperatures which are sufficiently high to permit their growth. The conditioned air acts as the vehicle of antigen dissemination. ‘Ventilation pneumonitis’, like other forms of extrinsic allergic alveolitis, can cause progressive pulmonary fibrosis. It should be distinguished from ‘humidifier fever’ which causes similar acute symptoms and does not develop in humidifier fever. The symptoms of humidifier fever have a characteristic periodicity: they occur on the first day back at work after a weekend or holiday absence and improve, despite continuing exposure during the working week. Abnormalities on the chest radiograph and progressive pulmonary fibrosis do not develop in humidifier fever.

Key points

- In the general population extrinsic allergic alveolitis – synonymous with hypersensitivity pneumonitis – has an annual incidence of about 1 per 100,000.
- Rates are higher among those working in the many occupations where a risk of disease has been identified; but are very dependent on local behavioural, climatic, microbiological and other factors.
- The disease has ‘reversible’ (acute) and ‘irreversible’ (chronic) presentations; the relationship between these types is uncertain.
- While immunological measurements of specific IgG antibodies are undoubtedly helpful in identifying a causative antigen, they must be interpreted in the light of a careful clinical history with particular attention to environmental exposures.
- Most causes of EAA are microbial; both occupational and respiratory specialists should be alert to new sources of exposure – recently identified examples include with metal-working fluids and residence in a mouldy home.

Inorganic dusts: general aspects

PATHOGENESIS OF INORGANIC DUST DISEASES

The effects of inorganic dusts on the lung airways are relatively minor compared with those produced by the organic dusts (see Chapter 42, Organic chemicals) and by cigarette smoking. The main effects of inorganic dusts are in the lung parenchyma. The term ‘pneumoconiosis’ is used for all dust damage to the alveolar part of the lung, including the airways that have no mucociliary lining. By convention, the term does not include bronchitis, asthma or cancers. Exposure to inorganic dusts can also lead to effects outside the lung, such as cancers associated with asbestos, and cardiovascular effects of exposure to very small particles (see Chapter 70, Health effects of ultrafine particles). The features of lung disease due to occupational exposure to inorganic dusts depend not only on the dust itself, but also on features of the exposed individual, such as cigarette smoking, infection with tuberculosis, and genetic susceptibility. Relevant features of the dust, apart from its chemical composition, include the particle size; very small particles (less than 0.1 microns), such as encountered in general air pollution, are toxic at much lower levels of exposure than the conventional particles (0.1–10 microns) more usually encountered in the occupational setting (Chapter 70, Health effects of ultrafine particles). The shape of the dust particles is also important; fibrous dusts have different effects related to the length and width of the fibres. According to the World Health Organization (WHO) definition, a fibre is any particle longer than 5 μm, thinner than 3 μm, and with an aspect ratio greater than 3:1.

There are several common features in the process of lung damage due to retained inorganic dusts. The timing and relative importance of these depends on the dust load and the toxicity of the particular dust.

- The lung is damaged when alveolar macrophages die and the system fails to clear the dust landing beyond the mucociliary system.
- Where macrophages die, substances are released from the dying cells that provoke an inflammatory reaction – reactive oxygen species, cytokines and growth factors – all of which contribute to the damaging of the surrounding epithelial cells and stimulating abnormal growth of fibroblasts, for example. While often initially reversible, if this process occurs repeatedly in the same site, permanent damage is done to the structure of the lung. The site of the damage is determined by how far the macrophages get before they die. In a few cases, the macrophages die in the alveoli and the damage occurs there. However, it is more usual for them to die in aggregations around the centrilobular bronchioles or along the lymphatics leading to the hilar lymph nodes either via the interlobular septa and the pleura or along the bronchovascular bundles.
- The severity and form of the damage depends on the toxicity of the dust and the amount of exposure. Although cumulative exposure (exposure × time) is important, prolonged low level exposure is not necessarily as damaging as a short-term high exposure, especially if the dust is inherently very toxic.
- If the dust is of low toxicity, the pathological process may halt after exposure. However, for most dusts there is a progression (even if slow) of the pathology after exposure ceases, due to continuing reaction to the retained dust.
- The accumulation of dust in the phagocytic cells of the lung leads to release of inflammatory mediators from neutrophils and other cells. The resulting migration and activation of leukocytes leads to proteolysis of fibronectin and subsequent laying down of fibrin,
the dust disease. In the case of the asbestos-related cancers, ageing of the normal lung) rather than progression of age' and may indeed be due to falling respiratory reserve. Radiographic changes may be non-specific or suggestive of non-occupational disease. In some cases, immune mechanisms may be involved in the tissue reaction to retained dust and this is discussed below in relation to specific dusts.

INVESTIGATION AND DIAGNOSIS

The diagnosis of occupational lung disease may be delayed or missed altogether because it is not considered. Without a history of exposure, the clinical features and radiographic appearances may be non-specific or suggestive of non-occupational disease.

Occupational history

Unlike diseases due to inhalation of organic dusts, most forms of pneumoconiosis do not cause immediate symptoms and most require prolonged exposure and have a long latency after first exposure. Therefore, the cause must be sought in past occupations (see Chapter 3, The occupational history). A general job classification, such as ‘joiner’ or ‘fitter’, is of no help without hearing what the worker actually did, what the industry was and what the dust conditions and the nature of the materials were.

The symptoms of bronchitis (persistent productive cough) may develop early, but it is usually many years before the worker notices either symptoms or disablement from the underlying disease. Radiographic changes may not develop until 10–20 years after exposure starts and may appear and progress long after exposure ceases. By the time the breathlessness of the pneumoconiosis is noticed, the symptoms may be attributed by the worker to ‘old age’ and may indeed be due to falling respiratory reserve (ageing of the normal lung) rather than progression of the dust disease. In the case of the asbestos-related cancers, the latent interval may average 40 years or more. Recent occupations are often unimportant, but past and present smoking habits are always important.

Symptoms

Breathlessness on exertion is often the only symptom. Cough and sputum can occur due to the dust exposure itself, but are frequently due to concomitant smoking. Complicated pneumoconiosis with cavitation of necrotic masses leads to the expectoration of large volumes of dirty material (once euphemistically called ‘melanoptysis’ in coalworkers) and sometimes to serious haemoptysis. The cavities left behind may become secondarily infected, causing a cough productive of copious foul sputum, similar to bronchiectasis.

Pneumoconiosis almost never causes pain. However, the chest tightness of a restrictive pathology (as in asbestosis or severe silicosis) can be mistaken for the ‘tightness’ of angina pain.

Signs

There are no physical signs in simple pneumoconiosis. They begin to appear as the disease becomes ‘complicated’. Chest movement will be restricted a little if there is interstitial fibrosis or extensive pleural scarring which may also cause some dullness. Even the large masses of complicated pneumoconiosis before and after cavitation are usually not detectable on physical examination because they are relatively central and are surrounded by emphysematous lung.

Conf盆ent fibrosis, such as occurs in asbestosis, is indistinguishable from other interstitial fibrotic lung disease and is associated with limited chest expansion, basal end-inspiratory ‘dry’ crepitations, cyanosis, polycythaemia and sometimes clubbing of the fingers.

Investigations

Ordinary haematological and biochemical tests are of no value in pneumoconiosis as they become abnormal only in extreme situations. The erythrocyte sedimentation rate and the plasma angiotensin converting enzyme level may indicate the activity of the destructive lesion in the lung, but have no diagnostic specificity. Tuberculin and Kveim tests, if positive, may indicate that the chest disease is tuberculosis or sarcoidosis, respectively, but there is no reliable way of distinguishing between beryllium pneumoconiosis and sarcoidosis in a worker with exposure to beryllium, except by performing a beryllium lymphocyte transformation test.

Examination of the sputum and bronchial lavage may yield confirmation of the occupational history in that the dust cells (dust-loaded macrophages) can be examined under the electron microscope and the nature of the dust...
identified. Asbestos bodies can be detected with the light microscope. They usually indicate amphibole exposure (which may be confirmed with the analytic electron microscope) and their profusion is a useful indication of the lung asbestos burden, but is not necessarily indicative of active disease. The cell count in the lavage fluid is increased in various forms of pneumoconiosis, but this is non-specific.

The role of biopsy is discussed below for individual diseases. On the whole, because of the focal nature of dust diseases, percutaneous and transbronchial biopsy have proved disappointing for diagnosis because the biopsy may miss the foci of disease. To determine the precise nature of the dust and its relationship to the pathology may require sophisticated electron microscopy of material taken at thoracotomy. However, it is rarely justifiable to undertake a thoracotomy to obtain a biopsy for diagnostic purposes. Biopsies obtained by thoracoscopy are less invasive and may represent an acceptable alternative in selected patients. On the other hand, in modern pneumology, ‘crystals’ or ‘fibres’ are often found in lung biopsies obtained for diagnosing interstitial lung disease, and it is not always easy in such cases to assign a causal role to these materials, which may or may not be incidental.

**Chest radiography**

Fortunately, most patients with a chest complaint have a chest radiograph and it is at this stage that either the radiologist or the clinician may realize that the disease is occupational. Even then, because many occupational lung diseases have non-specific radiographic features, cases are missed (see Chapter 33B1, Asbestos and asbestos-related diseases). The radiograph is useful in the diagnosis of the individual case, although the degree of radiographic abnormality is poorly related to the pathological severity of disease or the loss of lung function for many dusts. Some dusts produce dramatic radiographic shadows with little or no loss of lung function. In simple coalworkers’ pneumoconiosis, the radiographic appearance of small, rounded opacities relates well to dust exposure, but almost not at all to lung function. In asbestosis, the radiographic abnormality is a poor guide to the pathological severity of disease. However, the chest radiograph is of particular value for epidemiological purposes. Radiographic surveys combined with exposure, lung function and pathology information have helped to determine whether certain patterns of change are associated with particular occupations. This sort of research has also helped to establish the relationships between radiology, lung function and pathology in groups of workers.

**The ILO classification of radiographs of the pneumoconioses**

Since 1930, the International Labour Office (ILO) in Geneva has sponsored a classification of the radiographic changes in pneumoconiosis which is used to describe the pattern and severity of the change in groups of workers. In principle, it is not intended as a method of diagnosis or of estimating the severity of an individual case. Despite many modifications, most recently in 2002, there remains a subjective element in how an individual reader classifies a particular film. The reading is also dependent on the quality of the film (in particular how dark or light it is). Films should be read in batches mixed with controls and ‘trigger’ films. The readings are then analysed statistically to examine the relationship, if any, between radiographic changes and dust exposure measurements (or estimates of level of dust exposure). It is also possible to relate the radiographic changes to measurements of lung function in the population. Each batch of radiographs should be read independently by three trained observers and all the readings should be taken into account in the analysis. The readers should not be aware of any other information about the individuals whose films they read, to avoid bias. The method of reading is to compare each film with a set of standard films supplied by the ILO in Geneva. A brief description of the classification is given in Chapter 68, Imaging in occupational lung disease.

**Lung function tests**

Lung function tests are used in two ways in inorganic dust diseases: (1) to study exposed populations of workers and to follow individuals over time (in which case spirometry is the suitable measure) and (2) to diagnose individual cases of lung disease, in which case a battery of tests and comparison with predicted values is useful.

**FOR SURVEYS AND MONITORING**

In spite of their lack of specificity, the simple spirometric tests (forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV₁)) are useful measures for either population surveys or long-term monitoring. Comparison with ‘predicted’ values for age, sex and height is not especially helpful. Measurements in groups of exposed workers can be compared with those in non-exposed workers and individuals can be compared with themselves over time. These tests are not particularly good indicators of parenchymal lung disease and they can be markedly affected by other conditions, such as asthma and chronic obstructive pulmonary disease due to smoking. They have proved useful and robust measures for several reasons:

- The equipment is cheap, easy to keep standardized and widely available.
- The tests are easy to learn and not frightening for the subject so that reliable, repeatable readings can usually be achieved after a few minutes’ practice. Repeat tests at six-monthly or yearly intervals take less than five minutes.
• It is easy to train technicians to do the test properly, maintain the apparatus and calculate the results. Modern spirometers usually do the calculation automatically.

Electronic spirometers, now widely available, also give information about the whole of the flow-volume curve, allowing more sophisticated analysis of the curve to study dysfunction of the smaller airways. Unfortunately, the predicted results for the indices of small airways function from the flow-volume curve are much less reliable than the simple FEV₁ and FVC.

FOR DIAGNOSIS IN INDIVIDUAL CASES

In the diagnosis or assessment of the lung function deficit and disability in an individual case, a wide range of tests can be useful. Simple pneumoconiosis with dust macules forming around the centrilobular airways may or may not produce abnormalities in tests for small airways narrowing or compliance, depending on the severity. Early alveolar lesions or interstitial fibrosis may produce a reduction in gas transfer capacity. In practice, damage at either level produces abnormalities in both types of test, and either can be used as a measure of loss of lung function. Both types of test have proved useful in the detection of early disease in relatively young workers. Increasing age increases the scatter of findings in the ‘normal’ population. Much of this is due to cigarette smoking (and in the past to urban atmospheric pollution). The high proportion of smokers among workers in dusty occupations means that these tests may be of little diagnostic value in older individuals.

When lung function tests are used in individual diagnosis it is useful to compare with the values predicted for age, height and sex, derived from large studies for normal individuals. The normal populations used usually do not include smokers. Predicted values derived from one population may not be applicable to another ethnic group and it is important to use the most appropriate predicted values for an individual.

Post-mortem examination

Histological examination of autopsy material and the study of the dust extracted from the lung after death have been major sources of information about the nature and causes of occupational lung disease in the last 100 years. Although chest physicians with special experience may have little difficulty with the diagnosis of a pneumoconiosis during life, in the light of the occupational history, the chest radiograph and the pattern of lung function loss, the diagnosis is still often made by the pathologist on the basis of the post-mortem appearances and histology.

Until the 1990s, because of the arrangements in the United Kingdom for the granting of widows’ pensions, most compensated cases of occupational lung disease came to autopsy, providing a source of important information to further understanding of these conditions. Similar material has been available in South Africa, but in many other countries it is difficult to obtain autopsy material and this has limited the study of the pathology of the pneumoconioses. With the discontinuation of the pension for widows of men dying with a pneumoconiosis, many fewer cases of suspected or confirmed occupational lung disease now come to autopsy in the UK. Studies comparing post-mortem lung pathology with radiographic appearances and lung function during life would now be very hard to mount.

A special technique helps the study of post-mortem lung pathology in suspected cases of occupational lung disease. The lungs are removed en bloc with the trachea and with the parietal pleura still attached if it is adherent. Any tears in the visceral pleura are oversewn and the lungs are fixed in inflation via the trachea either with formol-saline or with formalin vapour. After fixation (which takes several days) the lungs are cut into 1.0-cm thick slices and examined in detail before taking representative histological blocks. The slices may be recolourized with alcohol and photographed under water to provide a permanent record of the texture of the lung. Alternatively, they can be impregnated with gelatine and used to prepare ‘Gough’ paper-mounted whole lung sections (Figure 75.1).

Key points

• Disease related to inhalation of dusts occurs when the lung defences are overwhelmed; cellular mechanisms result in a mixture of tissue destruction and fibrosis, depending on the characteristics of the dust.
• Diagnosis requires a careful occupational history; the relevant exposure may have occurred many years ago and may not be apparent without a good knowledge of likely exposures in different occupations.
• Symptoms and signs are usually non-specific, but radiographic changes can be helpful, although they are often not a good indicator of disease severity.
• Lung biopsy is generally not appropriate for diagnostic purposes and may be unhelpful because it may miss the affected areas; lung histology with mineral analysis can be diagnostic.
ACKNOWLEDGEMENTS

Anne Cockcroft would like to acknowledge the contribution of the late Peter Elmes who authored the chapter on inorganic dusts in the seventh and eighth editions of Hunter’s Diseases of Occupations.

Asbestos and asbestos-related diseases

INTRODUCTION

Long (\(>8\mu\text{m}\)), thin (\(<0.25\mu\text{m}\)) particles (fibres) inhaled into the lung, especially if more than ten times as long as they are thick, are potentially capable of causing fibrosis and cancer, depending upon their chemical composition, toxicity and biopersistence. By far the most important are the asbestos family. Their industrial use started in the 1870s and there has been increasing awareness of the frequency and severity of their health hazards since 1930. Asbestos-related diseases have a long latency and remain common, and in many countries are continuing to increase in frequency.

Asbestos has been used in a wide variety of end products, including insulation materials, cement, brake linings, paint, textiles, gas masks and gaskets, until it was banned in the United States and European Union in the 1990s. Since then, in these countries, the most important exposures to asbestos have been to the material used in the past in the construction industry when it becomes disturbed by maintenance workers or during the demolition of old buildings. However, in much of the developing world, asbestos remains widely used and chrysotile asbestos continues to be mined in and exported from Russia and Canada.

ASBESTOS MINERALS

‘Asbestos’ is the general industrial term encompassing six different fibrous silicates and includes the serpentine mineral chrysotile which is structurally different from the rest, which are the amphiboles. They all result from the leaching by water of siliceous minerals and recrystallization in the interstices of the parent rock. Therefore, their metal content shows some variability within the limits set by the crystal lattices; the nomenclature is not very precise. Four varieties of asbestos have been used commercially: chrysotile (white), crocidolite (blue), amosite (brown) and anthophyllite. However, a number of other amphiboles, tremolite and actinolite, occur in a variety of commercially exploited minerals. They are all relatively inert to chemical attack, are poor conductors of heat and withstand temperatures up to \(300–400\degree\text{C}\), a property which has made them widely used to increase the fire resistance of buildings, ships and protective clothing.

Chrysotile (white asbestos)

Chrysotile is relatively abundant and easy to mine, producing bundles of soft flexible fibres up to several centimetres long. The longer fibres have been, and in some countries still are, used to make textiles and the shorter fibres for reinforcing cement and plastics and for insulation, friction materials and filters. The fibres split up easily to smaller bundles and eventually to individual fibrils. Each fibril consists of double sheets of brucite (\(\text{Mg(OH)}_2\)) and silica (\(\text{SiO}_2\)) rolled up like a scroll around a small core of amorphous magnesium silicate and forming a curved tube between 25 and 50 nm in diameter. The brucite forms the
outer surface; in acid conditions, magnesium leaches out and the fibre disintegrates.

Chrysotile has always provided at least 90 per cent of the asbestos in commercial use and is mined in large deposits in central Russia and Quebec in Canada. Smaller deposits are mined in western Canada and the United States, in the Mediterranean basin, in southern Africa and in Australia. Some deposits, particularly those in the Mediterranean basin and a large one in western China, are associated with fibrous tremolite. This is less obvious in the Quebec deposits and it is not clear to what extent this has contaminated the chrysotile. Tremolite is a calcium magnesium silicate which crystallizes either as a platey talc (see Chapter 81) or as an amphibole fibre.

**Crocidolite (blue asbestos)**

Blue asbestos is mined in the Republic of South Africa, mainly in the Northern Cape and Western Cape provinces. Other deposits, notably one at Wittenoom in Western Australia, have been mined on a smaller scale. Crocidolite is found in banded ironstone which also yields commercial iron ore which crocidolite may contaminate. It is the fibrous form of the sodium iron silicate riebeckite. The bundles of fibres are much shorter and stiffer than chrysotile and readily split to straight fibrils with a minimum diameter of about 100 nm. It is much more resistant to acid and has slightly higher heat tolerance, but is not easily used for textiles unless supported by chrysotile. It was used where acid resistance was important and is still used in some countries in the manufacture of large-diameter asbestos cement pipes.

**Amosite (brown asbestos)**

Amosite is the commercial name for the fibrous grunerite (iron magnesium silicate), an amphibole mined in the Republic of South Africa; there are deposits elsewhere, but few are commercially viable. As mined, the fibres are coarse, but split down to 100 nm in use. It is used in insulation and as a reinforcement for plastic tiles, etc. It is too harsh for some forms of machine processing and is seldom used in cement or textiles for that reason.

**Anthophyllite**

This amphibole is the fibrous form of another iron magnesium silicate. It has been used mixed with clay for making pottery in Finland from prehistoric times and the same deposit was still worked until the end of the twentieth century. Its properties are similar to amosite and it has ceased to have any commercial value. Its occurrence is widespread and occasionally causes environmental problems where it contaminates the soil and becomes airborne.

**ASBESTOSIS**

Famously, the first report was by a woman factory inspector in 1898. William Cooke published a report of asbestos being associated with disease in 1924. He described a patient who had worked in the Rochdale asbestos factory and developed a fibrotic lung disease. Thomas Oliver subsequently termed the lung condition ‘asbestosis’.

**Diagnosis of asbestosis**

Asbestosis is a non-malignant, fibrotic parenchymal lung disease which can be static or slowly progressive. Progressive asbestosis can lead to profound respiratory disability and death from respiratory failure. Because histopathology is often not available in suspected cases of asbestosis, the diagnosis is usually based on clinical features and a history of significant occupational exposure. When pathologic material is available, the diagnosis is confirmed by the presence of both asbestos bodies and parenchymal fibrosis. Asbestos bodies can also be found in the lung tissue of urban dwellers, but are not associated with surrounding lung parenchymal fibrosis.

The features that lead to a diagnosis of asbestosis include a history of asbestos exposure with a latent interval between exposure and disease (usually 15 years or longer); chest radiograph evidence of small irregular opacities; a restrictive pattern demonstrated by pulmonary function testing; and a diffusion capacity below normal. Not all the features need be present to establish a diagnosis.

**Physical signs and symptoms**

**FINGER CLUBBING**

Finger clubbing can be associated with asbestosis, but it may also be a feature of other lung diseases, including idiopathic pulmonary fibrosis, cystic fibrosis and bronchogenic carcinoma. Less common causes of finger clubbing include bronchiectasis, cirrhosis, tuberculosis and lung abscess. In fact, finger clubbing is rare in asbestosis. However, when present, it is associated with a poor prognosis.

**BREATHELESSNESS**

Breathlessness of insidious onset is a common early symptom of asbestosis. Chest pain occurs occasionally in advanced cases, with a significant restrictive defect or
extensive pleural thickening. The presence of persistent chest pain should prompt an investigation to exclude an asbestos-related pleural effusion, lung cancer metastatic to the chest wall, or a mesothelioma.

NON–PRODUCTION COUGH

Non-productive cough is common, particularly as the disease advances, but a productive cough can be present in cigarette smokers who also have chronic bronchitis. Haemoptysis is not a feature of asbestosis. If haemoptysis occurs, it is important to exclude a concomitant bronchogenic carcinoma or other lung diseases commonly associated with haemoptysis (e.g. tuberculosis, pneumonia or pulmonary embolus).

WEIGHT LOSS

As with many lung diseases, advanced asbestosis usually results in weight loss, due to the significant caloric expenditure associated with tachypnea.

INSPIRATORY CRACKLES

The most consistent physical finding in patients with asbestosis is inspiratory crackles. Crackles (or rales) heard on chest auscultation are usually present in asbestosis, but can also be heard in patients with any interstitial lung disease, heart failure, bronchiectasis or pneumonia. Determining at what part of the respiratory cycle crackles are present has been suggested to be helpful in distinguishing among the lung diseases associated with this physical finding, but in fact there is considerable overlap. Crackles associated with asbestosis are typically fine and occur with each inspiratory effort, but this does not distinguish them from crackles due to any diffuse pulmonary fibrotic lung disease. In early disease, the crackles are mainly heard over the lower lung zones, but as the disease progresses they can be heard over all lung zones.

OTHER PHYSICAL SIGNS

Wheezes are not a feature of asbestosis and, if present, suggest the presence of chronic obstructive pulmonary disease or asthma. Both these conditions can coexist with asbestosis. A pleural rub can be heard in patients with diffuse pleural thickening. Cyanosis can be present in severe disease, as in any cardiopulmonary disorder that causes hypoxia. In advanced asbestosis, signs of right-sided heart failure (with raised jugular venous pressure, ascites and lower extremity oedema) develop.

Radiographic appearance

Chest radiographs are essential in the diagnosis of asbestosis. Asbestosis is generally characterized by lower lobe involvement with the presence of small irregular opacities (s, t, or u lesions). In advanced disease, these parenchymal abnormalities can be seen in all lung zones, but the first abnormalities are typically seen in the lower zones. As the disease progresses, the linear opacities become thicker and may ultimately obliterate the vascular markings; honeycombing can be seen, especially in the subpleural areas of the lower lobes. Large opacities are not seen in asbestosis, unless silica or coal dust exposure also occurred; the presence of large opacities raises the possibility of a lung malignancy.

The radiographic changes of asbestosis are similar to those of other diseases causing diffuse pulmonary fibrosis. The clinical course can give some hint about the aetiology of the diffuse lung infiltrates. For instance, rapid clinical progression would favour a diagnosis of idiopathic pulmonary fibrosis, rather than asbestosis.

Pleural abnormalities (either thickening or plaques) are commonly present together with the parenchymal changes of asbestosis. Diffuse pleural thickening is usually seen in the lower and middle third of the chest and is often asymmetric. It often leads to costophrenic angle obliteration and is, in fact, distinguished from pleural plaques by the presence of costophrenic angle abnormalities. Pleural plaques, either calcified or non-calcified, are discrete and do not extend into the costophrenic angle. Oblique radiographs can help to distinguish pleural thickening from overlying fat.

Rounded atelectasis is a radiographic finding highly characteristic of asbestosis. It represents a folded area of pleura which traps the adjacent lung tissue. Rounded atelectasis may be mistaken for a lung mass and lead to unnecessary further investigation. Because of its characteristic appearance on computed tomography (CT) (‘comma sign’), rounded atelectasis can usually be confidently diagnosed by experienced chest radiologists based on CT findings (see Chapter 68, Imaging in occupational lung disease, Figure 68.12). If uncertainty remains, serial CT scanning can help exclude a malignancy.

Computed tomography scanning has increased the diagnostic sensitivity for asbestosis (see Chapter 68, Imaging in occupational lung disease, Figure 68.11a,b). High-resolution computed tomography (HRCT) scanning reveals parenchymal and pleural abnormalities not detected by plain radiography. CT scanning can help to distinguish en face pleural plaques from parenchymal lesions and to identify parenchymal abnormalities when pleural changes obscure the lung parenchyma on plain chest radiographs. Unfortunately, CT scanning does little to help distinguish asbestosis from other fibrotic lung diseases, such as idiopathic pulmonary fibrosis, collagen vascular-associated interstitial lung disease, and drug-induced lung diseases. Studies that support the higher sensitivity of HRCT in diagnosing asbestosis are limited by low specificity. When using HRCT, the challenge to the clinician is whether or not to assign clinical significance to marginally abnormal CT scans.
Pathophysiology

The physiological abnormalities associated with asbestosis are due to the parenchymal fibrosis that characterizes the disease. Typically with advanced asbestosis, there is reduced lung compliance with a restrictive ventilatory defect. There is usually a reduction in the residual volume (RV) and the total lung capacity (TLC). However, because some patients with asbestosis also have emphysema (characterized by increased RV and TLC), a normal or even increased RV and TLC can be present, depending on the relative contribution of each disease. This situation results in a mixed obstructive–restrictive defect. Because of replacement by scarring of the gas exchange surface at the alveolar level, a reduction of the diffusing capacity is often present, and some authors have identified a reduced diffusing capacity as an early indicator of disease. Furthermore, because of the presence of low lung compliance, minute ventilation is increased, with an increased respiratory rate and reduced tidal volume. The ventilation changes are particularly marked at the lung bases, the area of the lung most involved in asbestosis. All the abnormalities of respiratory mechanics are exacerbated by exercise and exercise testing is one way to unmask occult disease. The pathophysiological findings associated with asbestosis are non-specific and can be found in any of the restrictive lung diseases.

The role of the small airways in the pathophysiology associated with asbestosis remains unclear, largely because much of the information comes from cohorts with a high prevalence of cigarette smoking. While structural abnormalities have been demonstrated in the small airways of exposed workers,9 the findings are often confounded by the effects of cigarette smoking in the populations studied. Furthermore, studies which purportedly demonstrated a small airways effect from asbestos exposure relied on the FEF25–75, which is an effort-dependent test that has large variability. In a study by Begin et al., analysing a non-smoking asbestos-exposed cohort, the workers did have an increase in airflow resistance, but this predominantly occurred in patients who also had restriction. In the non-smoking asbestos-exposed cohort, the workers did have an increase in airflow resistance, but this predominantly occurred in patients who also had restriction. In the non-smoking workers who did not have restriction, physiological abnormalities have been demonstrated in the small airways of asbestosis.10

Pathological findings

When other causes of diffuse interstitial lung disease are a serious possibility, a lung biopsy (preferably by obtaining adequate tissue through a surgical approach) should be considered. A diagnosis of asbestosis is confirmed by the finding of asbestos bodies together with parenchymal fibrosis. However, asbestos bodies are mainly formed on amphibole fibres over 20μm long and their number underestimates the lung burden of thinner fibres. They are a poor indicator of the presence of chrysotile. Lavage of the airways in asbestosis yields increased numbers of polymorphs, as well as asbestos bodies and fibres.

Prognosis

While asbestos itself may progress to respiratory failure and death, the major cause of death in individuals with asbestosis is asbestos-related malignancy: lung cancer or mesothelioma. Between 1952 and 1976, an analysis of men certified as having asbestosis in the United Kingdom reported that for all causes the observed number of deaths was 2.6 times expectation and for lung cancer 9.1 times expectation; 39 per cent of the deaths were from lung cancer, 9 per cent mesothelioma and 20 per cent asbestosis.11

MESOTHELIOMA

Mesothelioma can be either benign or malignant. Nearly all malignant mesotheliomas are due to asbestos exposure. Such exposure can be brief and low level, such as living near an asbestos factory or a wife washing the clothes of an asbestos worker (Chapter 77, Epidemiology of asbestos-related diseases). Diffuse malignant mesothelioma is a progressive disease, which can affect the pleura, peritoneum, pericardium or tunica vaginalis.

Radiographic appearance

Pleural mesotheliomas generally present radiographically as a unilateral pleural effusion. In some cases, the pleural effusion is accompanied by the appearance of a pleural-based mass, or masses, which may look nodular (see Chapter 68, Imaging in occupational lung disease, Figures 68.9 and 68.10). Mediastinal structures may be shifted away from the side of the tumour or toward the tumour side when the predominant tissue reaction to the mesothelioma is pleural fibrosis. Pleural mesotheliomas may or may not be associated with concomitant pleural plaques or asbestosis. As the tumour advances, compression of adjacent organs, such as the heart, can occur, as can distortion of the central airways and destruction of adjacent ribs.

Pathology

Pleural biopsy, ideally by video-assisted thoracoscopic surgery (VATS), is the diagnostic gold standard for mesothelioma. Using VATS, tumour studding of the pleural surface can be appreciated, and the surgeon is able to perform biopsies under direct vision. Another benefit of this procedure is the ability to mobilize the lung and to perform cytoreductive pleurectomy.12 The diagnosis can be difficult in individual cases. There are several types of malignant mesothelioma: an epithelial type, which can be mistaken for adenocarcinoma; a sarcomatous type, which can mimic other sarcomatous cancers; and a mixed type.13 Immunochemical staining techniques can help to confirm the diagnosis in individual cases.
Asbestos and asbestos-related diseases

Prognosis

The prognosis for patients with diffuse malignant mesothelioma is very poor. The tumour grows inexorably, compressing the lungs and mediastinal structures. Distal metastasis is rare, but the tumour may spread into the chest wall, sometimes along the track of needles used to aspirate pleural fluid (Figure 76.1). Most patients die within two years, usually of respiratory failure or bronchopneumonia. Extrapleural pneumonectomy has been the traditional operative approach, but the results have been disappointing. Response rates to chemotherapy have traditionally not exceeded 30 per cent, but newer agents, for example antimetabolites such as pemetrexed, appear more promising. Response rates of up to 45 per cent have been achieved when these agents are used in combination with platinum compounds.

LUNG CANCER

From a clinical perspective, lung cancer in an asbestos-exposed individual is similar to that found in non-exposed people. For example, it might present with haemoptysis, or a mass detected on the chest radiograph, or with the effects of secondary spread elsewhere.

Pathogenesis

The role of asbestos in lung cancer development probably involves common biochemical pathways that lead to both fibrosis and carcinogenesis. While initially thought to be 'scar carcinomas' (i.e. tumours that arise in a scarred area of lung due to transformation of the fibrotic tissue into cancerous tissue), lung cancers that occur in association with asbestos exposure probably do so as a result of molecular pathways that cause damage to DNA, leading either to fibrosis or to cancer development. Whether an individual patient develops fibrosis or cancer or both probably depends on the nature and the extent of the cellular damage. In a study of lung cancer in patients with cryptogenic (idiopathic) fibrosing alveolitis, Turner-Warwick et al. found a relative risk of lung cancer of 14 in male smokers with lung fibrosis, compared with smokers without lung fibrosis. This suggests that lung fibrosis, from whatever cause, may be a marker for those with excess cancer risk. Similar studies have shown an excess cancer risk in patients with another fibrosing lung disease (scleroderma), allowing for age and smoking.

In support of the idea that lung fibrosis and lung cancer may be due to a common mechanism, rather than the cancer arising from the fibrotic process, it is notable that, while the fibrosis of asbestosis affects predominantly the lower lung zones, lung cancers associated with asbestosis do not seem to have a predilection for any particular lung zone. Furthermore, while most 'scar carcinomas' are adenocarcinomas, the lung cancers associated with asbestosis can be of any cell type and are pathologically indistinguishable from cancers attributable to cigarette smoking.

Benign asbestos-associated pleural disease includes parietal pleural plaques, diffuse pleural fibrosis and benign asbestos pleural effusions. In any individual patient, a combination of the pleural diseases may be present. While most cases of pleural disease are seen after asbestos exposure in the occupational setting, there can be pleural changes in individuals with lower levels of exposure occurring in the non-occupational environment. The precise mechanism by which asbestos exposure leads to pleural disease occurring is poorly understood but probably involves the translocation of inhaled fibres to the pleura, where they cause an inflammatory reaction on the parietal pleural surface. The inflammatory reaction can lead to fibrosis or development of a pleural effusion.
PARIETAL PLEURAL PLAQUES

The association of pleural plaques with asbestos exposure was first described by Sparks in 1931. Plural plaques are localized, discrete areas of dense fibrosis located on the parietal pleural surface, generally on the diaphragmatic pleural surface or along the lateral chest wall or, more rarely, on the pericardium. They may calcify. Plaques on the lateral chest wall are usually sharply demarcated from the adjacent lung parenchyma and are termed 'in profile' plaques. Plaques on the anterior or posterior chest wall are known as 'en face' plaques. There is a long latency and it is uncommon for pleural plaques to occur within 20 years of first exposure to asbestos.

Radiographic appearance

Pleural plaques appear on the chest radiograph as areas of discrete pleural thickening with or without calcification (Chapter 68, Imaging in occupational lung disease, Figure 68.7). They are more easily detected when calcium is present, creating a dense, 'white' appearance on the chest radiograph. The revised 2000 International Labor Office (ILO) classification describes plaques as, by definition, not involving the costophrenic angle. Pleural plaques are most easily seen when in profile. The width of in profile plaques can vary from about 0.5 to 1.0 cm. *En face* plaques on the anterior and posterior thoracic wall appear as hazy, ill-defined opacities overlying the lung parenchyma. Pleural plaques can be confused radiographically with shadows due to the serratus anterior muscle or due to excess subpleural fat in obese individuals. Pleural fat pads typically start at the lung apex and extend down the lateral chest wall. Other diseases which cause pleural calcification and which can be confused with pleural plaques due to asbestos exposure include tuberculosis, chronic empyema and trauma to the chest wall; in all of these cases, the pleural changes are typically unilateral. If there is uncertainty about the presence of pleural plaques, oblique chest radiographs can be helpful. CT scans are more sensitive in detecting pleural abnormalities (Chapter 68, Imaging in occupational lung disease, Figure 68.7). However, due to cost, the use of routine CT scanning is impractical.

Functional significance

Most individuals with pleural plaques are asymptomatic and have no measurable physiologic impairment. Many of the studies purporting to demonstrate functional impairment due to pleural plaques did not make a distinction between individuals with localized pleural plaques alone and those who also had diffuse pleural thickening, or were unable to exclude the presence of concomitant parenchymal lung disease not detected by routine chest radiography. Several authors have reported no additional functional impairment associated with pleural plaques, over and above those associated with underlying parenchymal abnormalities. A study of railroad workers exposed to asbestos reported a decrease in FVC associated with the presence and the extent of the plaques. However, there were more smokers and older workers in the group with plaques. The presence of parenchymal fibrosis in individuals with pleural plaques seems to be the important factor leading to lung function deficits.

Prognosis

Some studies have shown a higher risk of mesothelioma among people with pleural plaques. However, it remains unclear whether this is simply because both pleural plaques and mesothelioma are associated with asbestos exposure, or whether the presence of pleural plaques actually indicates sufficient exposure to increase the risk of mesothelioma development.

The association between pleural plaques and lung cancer has also been debated in the medical literature. A study of asbestos cement workers found the presence of pleural plaques was not associated with an increased lung cancer risk. A meta-analysis of 13 studies concluded that people with asbestos-related pleural plaques did not have an increased risk of lung cancer in the absence of parenchymal asbestos. A more recent study of Finnish construction workers also concluded the risk of lung cancer was not increased by the presence of pleural plaques. However, a study from Sweden, which controlled for the presence of asbestos, concluded that pleural plaques not only implied significant exposure to asbestos, but also were associated with an increased risk for mesothelioma and a small increased risk of lung cancer.

DIFFUSE PLEURAL THICKENING

Radiographic appearance

Diffuse pleural thickening can be seen on plain chest radiographs (Chapter 68, Imaging in occupational lung disease, Figure 68.8), but is more easily seen on CT scans. According to the 2000 ILO classification system, diffuse pleural thickening by definition includes involvement of the costophrenic angle. Thickening of the visceral pleura can be either unilateral or bilateral. If unilateral, the differential diagnosis includes pleural fibrosis from previous pneumonia with pleural reaction, empyema, trauma and mesothelioma. Bilateral pleural thickening can also be seen in collagen vascular diseases, such as rheumatoid arthritis, scleroderma or systemic lupus erythematosus. Up to one-third of patients with diffuse pleural thickening may have had a previous benign asbestos-related pleural effusion or pleurisy.
Functional significance

Several authors have reported an association between diffuse pleural thickening and restrictive lung function abnormalities\(^\text{38}\) or a reduction in diffusing capacity.\(^\text{39}\) One study reported obstructive lung function loss in men with pleural disease.\(^\text{40}\) Overall, most patients with diffuse pleural thickening are asymptomatic. Some may have breathlessness, cough with sputum production and chest pain.\(^\text{51–53}\)

BENIGN ASBESTOS PLEURAL EFFUSION

An asbestos-related pleural effusion was first reported in the medical literature in 1964.\(^\text{44}\) The pathophysiology of these effusions is not entirely clear, but probably involves pleural inflammation from direct toxicity to mesothelial cells by asbestos fibres. Inhaled asbestos fibres can also indirectly cause pleural injury by the release of growth factors and inflammatory cytokines from the lung.

Patients who present with a pleural effusion, particularly those with a history of asbestos exposure, should undergo diagnostic thoracentesis with cytological analysis. If a clear aetiologic of the effusion is not forthcoming, pleural biopsy should be considered, particularly to exclude the presence of mesothelioma.

Several authors have studied pleural effusions among asbestos-exposed populations, sometimes in comparison with non-exposed populations.\(^\text{45–48}\) The latent period for the development of these effusions is relatively short, often less than 20 years, and they are the most common asbestos-related abnormality within 20 years of first exposure. The incidence increases with increasing degrees of asbestos exposure, up to around nine per 1000 person-years for heavy exposure. The effusions may be recurrent. Many are asymptomatic and transient (lasting a matter of months), so their true incidence is probably higher than that estimated in prevalence studies. Those with symptoms most commonly complain of chest pain, fever, cough and breathlessness. The effusions are usually blood-stained. Follow-up studies of cases of asbestos pleural effusion over two to three decades have reported a low incidence of subsequent mesothelioma, not necessarily on the same side as the effusion. Asbestos effusions do seem to be a risk factor for the development of diffuse pleural thickening.

CHRONIC AIRWAYS OBSTRUCTION

Although asbestos has traditionally been considered to cause a restrictive lung function impairment, some authors have reported airways obstruction in asbestos-exposed workers who have normal radiographs with no clinical evidence of asbestosis.\(^\text{49,50}\) The mechanism by which asbestos may cause airway obstruction is unclear, but may involve the deposition of asbestos in the small airways, leading to an inflammatory response that causes airway fibrosis.\(^\text{51–53}\)

Whatever the mechanism, the confounding effects of cigarette smoking have been a limitation of many of the studies investigating this issue. One such study by Weill et al.\(^\text{54}\) reported a dose–response relationship between asbestos exposure and small airways dysfunction, but did not find evidence of clinically significant obstructive disease. In a study of asbestos insulators, the authors concluded that reduced FVC and reduced FEV\(_1\)/FVC were both more frequent in insulators who smoked (compared with non-smoking insulators or smokers in the general population), suggesting an interaction between asbestos and smoking in producing both these physiologic abnormalities. However, airways obstruction in the absence of radiographic abnormalities and/or cigarette smoking was uncommon.\(^\text{55,56}\) Other studies have been unable to find differences in the prevalence of obstruction in smoking and non-smoking groups.\(^\text{55,56}\) Some authors have concluded that there is evidence of airways obstruction related to asbestos exposure,\(^\text{57,58}\) but others have challenged this conclusion.\(^\text{59}\)

If there is a direct asbestos effect on the airways, it probably only involves the small airways, and is small and clinically insignificant, particularly when compared to the effect of cigarette smoke on airway function.\(^\text{60,61}\) Airway fibrosis following asbestos inhalation has been demonstrated in animal models, but the significance of this for humans is unclear. Significant respiratory disability in asbestos-exposed workers is due to a restrictive, rather than an obstructive, process.

HEALTH SURVEILLANCE FOR ASBESTOS WORKERS

Although the importation and use of asbestos is now banned in industrialized countries, exposure to old asbestos, especially in the construction industry, remains a potential hazard. As well as strict controls to prevent exposure and protect workers, health surveillance of those working with asbestos-containing materials is a requirement in most industrialized countries. In the United Kingdom, work with asbestos (e.g. stripping old asbestos-containing materials from buildings) requires a licence from the Health and Safety Executive, and the licence requires employers to provide health surveillance and maintain the records for 40 years.\(^\text{62}\) The pre-employment and periodic examination of workers includes enquiry about respiratory symptoms, examination of the chest, chest radiography when indicated and lung function testing.\(^\text{63}\)

People who are not asbestos workers, but discover they have been inadvertently exposed to asbestos (for example, from frayed insulation material), or have had some other unforeseen but minimal exposure to asbestos at work, are understandably anxious and concerned about possible effects on their health. Although the type of asbestos may be known, there is often little, if any, reliable information concerning the amount of asbestos which may have been
inhaled. They can be reassured that the risk to their health is very low; it is advisable that their general practitioner documents the incident in their medical record. Chest radiography and lung function testing are not appropriate after an inadvertent exposure, given the very low risk and the long latency of asbestos-related lung effects.

Key points

- Four varieties of asbestos have been used commercially: chrysotile (white), crocidolite (blue), amosite (brown) and anthophyllite.
- Asbestosis is a type of interstitial fibrosis; it can lead to death from respiratory failure, but the major cause of death in people with asbestosis is lung cancer or mesothelioma.
- Mesothelioma is a tumour of the pleura (or rarely peritoneum) that usually leads to death within two years; diagnosis is confirmed by histology, but sometimes it is difficult to differentiate mesothelioma from other cancers.
- Lung cancer related to asbestos exposure is clinically similar to lung cancer from other causes.
- Pleural plaques, which may calcify, are a marker of asbestos exposure, but do not themselves cause any loss of function.
- Diffuse pleural thickening, by definition, includes involvement of the costophrenic angle on the chest radiograph; extensive pleural thickening may lead to some restrictive lung function deficit.
- Asbestos exposure has little, if any, effect on the airways.

Epidemiology of asbestos-related diseases

ROBIN M RUDD

INTRODUCTION

During the first half of the twentieth century, there was a rapid increase in the use of asbestos for a variety of purposes, exploiting its properties of fire resistance and poor conduction of heat, electricity and sound. The hazards to health were first recognized in factories manufacturing asbestos products. In the United Kingdom, the Asbestos Industry Regulations (1931) was the first legislation to control asbestos exposure at work in such factories. However, perhaps strangely in retrospect, it was not until much later that it was widely recognized that end users and bystanders to use of asbestos materials were also at risk. Use of asbestos continued to increase until the late 1960s to early 1970s in industrialized countries. In the UK, stricter controls were imposed by the Asbestos Industry Regulations (1969), but it was not until the mid-1970s that use of more effective precautions became widespread. Peak asbestos imports into the UK occurred in 1973. In 1979, the Advisory Committee on Asbestos recommended the gradual substitution of asbestos by other materials, a ban on the use of sprayed asbestos and control of the asbestos removal industry.\(^1\) In the UK, the Asbestos (Prohibition) Regulations (1985) banned the importation, supply and use of amosite and crocidolite and, in 1999, an amendment to the regulations extended them to chrysotile with certain exceptions in safety specific areas until January 1, 2005, by which date the marketing and use of all asbestos became illegal throughout the European Union. The use of asbestos has also virtually ceased in North America, but its use is still widespread throughout the developing world to which the epidemic of asbestos-related disease will spread.

By the time precautions began to be introduced in the late 1960s, a ‘second wave’ of asbestos disease was becoming rampant among workers in ship building and repair, and the construction industry who had worked with, or in proximity to, those using asbestos materials. Later, a ‘third wave’ affected those less directly exposed, such as building maintenance personnel who incidentally encountered and disturbed asbestos in place, the hazards of which were widely recognized later with measures to enforce mandatory documentation of asbestos in buildings and a requirement for removal or effective encapsulation. A ‘fourth wave’ of disease now may be affecting those who merely worked in buildings where asbestos materials were poorly maintained, with cases of mesothelioma appearing among staff at hospitals and schools.

ASBESTOSIS

In subjects heavily exposed to asbestos, such as insulators, a very high prevalence of radiographic evidence of asbestosis has been recorded. A study of 2907 US insulators between 1981 and 1983 found that 11.6 per cent had pulmonary opacities without pleural abnormalities and 48.7 per cent had pulmonary and pleural abnormalities.\(^2\) Because of the reduction in exposures from the 1970s onwards, the nature of asbestosis diagnosed is changing. There are fewer cases of severe disease and more cases of mild disease. This changing picture is reflected in UK statistics where the annual number of new awards of Industrial Injuries Disablement benefit for asbestosis increased from 335 in 1996 to 575 in 2006, a 72 per cent
increase, while the annual number of deaths attributed on death certificates to asbestosis rose from 68 in 1996 to 104 in 2006, a 53 per cent increase. In a recent French study of 5545 subjects exposed to asbestos in various occupations, asbestos was identified on high resolution computed tomography (HRCT) in 6.8 per cent. The prevalence of asbestosis increased with cumulative exposure estimated from the occupational history.

### Latency

The latency between commencement of exposure and appearance of asbestosis is inversely related to the dose of asbestos received. Dose is usually expressed as the product of mean airborne fibre concentration encountered and duration of exposure in working years, commonly taken to be 2000 hours per year. The interval between the onset of exposure to asbestos and the development of symptoms of asbestosis is commonly 20 years or longer, although in earlier years when continuous heavy exposure occurred, fibrosis occasionally became evident as early as five years after the first exposure. New lung and pleural lesions continue to appear more than 40 years after first exposure. Asbestos fibres remain in the lungs for long periods, many permanently, and disease may appear and progress long after exposure has ceased.

### Dose and response

The long latent period contributes to the difficulty in determining the attack rate among exposed people and its relation to the dose of asbestos inhaled. There are relatively few studies in which reliable estimates of exposure are provided. An additional complicating factor is the variable means of ascertainment of the disease. In early years, it was diagnosed on variable combinations of detection of basal crackles on auscultation of the lungs, chest x-ray abnormalities and lung function abnormalities. The minimum criteria for the diagnosis varied between studies. In recent years, asbestosis has often been diagnosed on the basis of minor abnormalities on a computed tomography (CT) scan without clinical or plain radiographic signs.

In 1985, Doll and Peto adjudged the best evidence concerning the relation between incidence of asbestosis and dose to be a study of Rochdale asbestos textile factory workers. The frequency and severity of asbestosis increased with increasing dose of asbestos where dose comprises the product of intensity of exposure in fibres per millilitre and duration of exposure in working years. Among these workers who were exposed predominantly to chrysotile, there was a 1 per cent prevalence of certified asbestosis, possible asbestosis and lung crackles after doses of 72, 55 and 43 fibres/mL per year, respectively. This study was relied upon by the UK Advisory Committee on Asbestos (1979) which concluded that the annual incidence of certified (i.e. clinically evident) asbestosis after a cumulative dose of less than 100 fibres/mL per year, i.e. a working life of exposure to less than 2 fibres/mL, was 0.5 per cent and that cases of ‘possible asbestosis’ occurred after less than 50 fibres/mL per year. The Royal Commission on Matters of Health and Safety Arising from the Use of Asbestos in Ontario (1984) concluded that the minimum threshold dose for the development of clinical asbestosis is around 25 fibres/mL per year, and Doll and Peto agreed. These conclusions were based largely on studies of workers exposed to chrysotile.

However, there is evidence that asbestosis may occur after lower levels of exposure exclusively to amphiboles. In a study of 807 South African amphibole miners among 64 men who had sustained cumulative exposures between 2 and 5 fibres/mL per year, five cases were found. These may be questioned on grounds of possible erroneous diagnosis, but diagnoses of asbestosis in 16 and 28 per cent of men with cumulative exposures in the ranges 5–10 and 10–20 fibres/mL per year, respectively, are harder to ignore. In Western Australian crocidolite miners, mortality from asbestosis began to increase with exposures of less than 4 fibres/mL per year.

A study of 678 household contacts of American amosite asbestos workers found that compared with controls there was a significantly increased prevalence of small opacities on the chest x-ray (17 versus 3 per cent), as well as of benign pleural changes (26 versus 2 per cent). Among those with small opacities, crackles were heard over the lungs in 10 per cent. The frequency of radiographic abnormalities was higher in wives than in other relatives, reflecting their heavier exposure from laundering work clothes. These observations imply that household exposure could be quite heavy rather than minor as sometimes suggested.

There is variation in individual susceptibility to asbestosis. Smoking increases the risk of development of radiographic signs suggesting asbestosis and of progression of asbestosis. Lung structure is probably also important in determining individual susceptibility. A case–control study in Quebec showed that cases were shorter than controls, possibly because shorter men have shorter tracheas which are less effective in trapping inhaled fibres, so that more fibres reach alveolar areas. Differences between subjects in retention of asbestos fibres probably contributes to differences in susceptibility to disease.

Increasing knowledge of the genetic basis for disease suggests that genetic polymorphisms which determine the response to oxidative stress, an important mechanism in asbestos-induced disease, affect susceptibility to asbestosis.

### ASBESTOS–INDUCED AIRWAY DISEASE

Evidence of small airways dysfunction has been found in asbestos workers who have never smoked, in studies including unexposed non-smoking control subjects.
Patients with asbestos-related pleural disease commonly have airflow limitation, even when non-smokers, reflecting asbestos airway disease. This is generally of insufficient degree to cause breathlessness, however.

## BENIGN PLEURAL DISEASE

### Pleural plaques

Pleural plaques occur much more frequently in subjects with known exposure than in the general population without identified exposure to asbestos. Plaques may occur after occupational exposure at a lower level than is required to cause asbestosis, and are found in household contacts of asbestos workers and in people exposed to environmental contamination with asbestos. The frequency of plaques reported varies according to method of ascertainment. Autopsy studies show a higher prevalence of plaques than plain radiographic surveys, because direct observation is diagnostically more sensitive than chest x-ray, and partly because a population studied at autopsy is generally older and more likely to have sustained occupational exposure than one undergoing chest radiography. For example, in a Swedish study, plaques were found in 6.8 per cent of autopsies, of which only 12.5 per cent were detected by radiography. In a UK study of a general urban population, plaques were reported from 4.2 per cent of routine autopsies, but this figure rose to 11.2 per cent when a specific search for plaques was made in a subsequent series. Computed tomography is more sensitive than plain radiography. In a study of 5545 asbestos-exposed subjects with no history of asbestos exposure was significantly more common in subjects with otherwise labelled 'idiopathic' pleural effusion than in control subjects, supporting a causal link.

The prevalence of plaques increases with time since first exposure and with cumulative exposure, in accordance with findings from an earlier study using chest x-rays.

In certain areas, such as parts of Finland, Turkey and Greece, plaques occur with much increased frequency. This has been attributed to the presence of asbestos in the soil and outcropping rocks. Plaques are more common in urban than in rural dwellers. Among an urban population, the frequency and extent of plaques at autopsy increases in relation to lung asbestos fibre content.

The latent period between first exposure and appearance of plaques is similar to that for asbestosis. In a group of 624 asbestos workers from various industries, plaques were seen in none within ten years, in 10 per cent by 19 years, in 29 per cent by 29 years, in 32 per cent by 39 years and in 58 per cent by 49 years. In a study of 1117 insulation workers, pleural calcification was found in none of 346 men less than ten years after first exposure, in only 1.1 per cent of 379 men less than 20 years, in 10.4 per cent up to 30 years, in 34.5 per cent up to 40 years and in 57.9 per cent more than 40 years after first exposure. The prevalence of plaques has been reported to be higher in smokers, but among insulation workers this relationship was not apparent.

## ACUTE ASBESTOS PLEURISY AND PLEURAL EFFUSION

In an early study, a history of pleural effusion thought to be due to asbestos was found in 21 per cent of subjects recorded to have had asbestos exposure. A history of asbestos exposure was significantly more common in subjects with otherwise labelled 'idiopathic' pleural effusion than in control subjects, supporting a causal link. Benign pleural effusion may occur less than ten years after first exposure to asbestos, but the mean latency from first exposure was 26 years in a series of 20 cases. The risk of benign effusion increases with the dose of asbestos received.

## DIFFUSE PLEURAL THICKENING

Diffuse pleural thickening is a less common manifestation than pleural plaque formation. A survey of 5545 asbestos-exposed subjects by HRCT which found pleural plaques in 15.9 per cent identified diffuse pleural thickening in only 0.7 per cent. It is less clearly dose related than asbestosis or the malignant diseases and its occurrence may be determined largely by host susceptibility factors. A wide range of fibre counts is observed in association with the condition, but mean counts appear to be somewhat lower than in groups of patients with asbestosis. Amphibole counts were higher than usually seen in non-occupationally exposed individuals in six of seven cases in this series. In another series, in which fibre counts were comparable to those seen in mild asbestosis, amphiboles were the main fibre type in the lungs, although chrysotile was the main fibre type in the pleura.

## MALIGNANT MESOTHELIOMA

In 1960, Wagner and colleagues described 33 cases of diffuse pleural mesothelioma and all but one had experienced probable exposure to crocidolite. In 1964, a case–control study of patients who had died of mesothelioma at the London Hospital found evidence of asbestos exposure in a majority of cases. Interestingly, some of the patients had not worked with asbestos but had been exposed via dust brought home on the clothes of asbestos workers or from residence in the vicinity of a local asbestos factory.

Much evidence has since accumulated indicating that asbestos exposure is responsible for the great majority of mesotheliomas. The risk of mesothelioma is not affected by smoking. Among subjects with no history of asbestos exposure, the annual incidence has been estimated at around one per million population and a few childhood cases, apparently unrelated to asbestos have been described. A review suggested that the estimated background risk may be inflated by cases due to unsuspected environmental exposure.
A recent study in the United Kingdom obtained occupational and residential histories from 622 mesothelioma patients and 1420 population controls. This reported a lifetime risk among apparently unexposed people of one in 1000, much higher than has been reported previously. Approximately half the male cases were construction workers with the highest lifetime risk of one in 17 for carpenters. The risk was doubled in relatives of exposed workers. Surprisingly, the study found that 14 per cent of male and 62 per cent of female cases were not attributable to identified asbestos exposure. The authors pointed out that their findings show a female mesothelioma death rate by age 70 more than three times higher than in the United States. If, as seems likely, this difference reflects greater asbestos exposure sustained by UK women, this implies that more than two-thirds of mesotheliomas in UK women are due to asbestos, far more than were identified by the occupational and residential histories obtained. The authors suggested that the other asbestos-induced cases may be a result of environmental asbestos exposure or unidentified occupational exposures. The latter is very probably at least a contributory factor because the main analysis was based upon job titles rather than self-reported exposure in order to minimize the effect of recall bias. This is likely to have missed less obvious exposures, for example those sustained as a result of working in what would appear to be low risk occupations, but in buildings containing poorly maintained asbestos. The male death rate for men aged 45–49 is also three times higher in the United Kingdom than in the United States and this is thought likely to be a result of much greater use of amosite in the UK. Australia’s death rates for mesothelioma are similar to the UK and so were their use of amosite and crocidolite.

In the recent UK study, residence within one mile of a source of environmental exposure was not associated with a significantly increased risk of mesothelioma. However, sites such as asbestos product factories, disposal sites, power plants and shipyards were lumped together, and the effect of high exposure sources, such as asbestos product factories, is likely to have been diluted by inclusion of the other sites. A case–control study suggested that exposure derived only from residence in the vicinity of asbestos plants in Yorkshire (United Kingdom) accounted for 3 per cent of mesothelioma cases in the area. A population case–control study in three European countries found an odds ratio for mesothelioma of 11.5 for living within 2000 m of an asbestos source. A population-based case–control study in Italy found that residents around an asbestos cement plant had a relative risk of 10.5 for mesothelioma.

In people with heavy exposure, the risk of mesothelioma is high. Mortality from mesothelioma among employees at an asbestos textile factory before 1964 was estimated at 7.3–10.8 per cent for men and 9.1–12.0 per cent for women. In insulation workers whose exposure began before age 20, the death rate from mesothelioma may be as high as 15 per cent. Situations which might be assumed to be associated with low level exposure, such as domestic contact with contaminated clothing and working in an office with a deteriorating sprayed asbestos ceiling, have been shown to be capable of giving rise to fibre levels in the lung comparable to those found in people with occupational exposure.

The incidence of mesothelioma in the UK and other industrial countries is still rising and it is likely to continue to do so (Figure 77.1). In Great Britain in 2006, there were 1740 male and 316 female deaths. The expected number of mesothelioma cases among males is projected to increase to a peak of 2038 in the year 2016, decreasing thereafter (Figure 77.2). Projections for females are more uncertain. This increase reflects the increasing use of asbestos, largely without protection, until the early 1970s. A similar picture applies to Western Europe, where asbestos use remained high until 1980 and where it has been predicted that mesothelioma deaths will almost double from 5000 in 1998 to 9000 by 2018.

**Dose and response**

Several studies have shown an increase in risk of mesothelioma with increasing cumulative exposure. However,
there is no clear evidence for a threshold dose of asbestos below which there is no risk of mesothelioma. Among workers at an asbestos factory in east London, where approximately 8 per cent of deaths were due to mesothelioma, the risk increased with both the duration of exposure and the estimated intensity of exposure. Similar findings were reported in and among gas mask assemblers and in crocidolite miners in Western Australia.

A case–control study found a significant excess of mesothelioma at levels of exposure far below limits adopted in most industrial countries during the 1980s and an increasing risk with estimated cumulative exposure. A review of cohort studies found evidence for a non-linear relation between dose and risk of mesothelioma. The peritoneal mesothelioma risk was proportional to the square of cumulative exposure and the pleural mesothelioma risk was sublinear.

Pleural mesothelioma is much more common than the peritoneal form, although the ratio between the sites is variable from entirely pleural to only about 2:1 in favour of pleural in different series. Factors favouring the peritoneal site are longer and heavier exposure, and exposure to amphiboles. Clinical evidence of asbestosis of the lungs is found in association with peritoneal mesothelioma more commonly than with pleural mesothelioma, supporting the observation that, on average, exposure has been heavier in peritoneal cases.

Latency

Using data from a study of North American insulation workers, a model was formulated for predicting mesothelioma incidence in a cohort. The incidence of mesothelioma increased with time since first exposure to asbestos in proportion to a power function of the time elapsed. This could be explained on the assumption that each brief period of exposure causes an addition to subsequent incidence which increases approximately as the cube of time since the exposure occurred. The formula derived from the study was consistent with evidence from other studies, although any power of time between 2.5 and 4 fitted as well. This means that a dose of asbestos received early in life produces a much larger lifetime risk of mesothelioma than the same dose received later in life. The formula also implies that inhaling a given dose over a shorter period gives rise to a larger risk than the same dose over a longer period. There is some evidence to suggest that the risk does not increase indefinitely and there may be some decline after 35–50 years.

In two UK series in which 85 per cent and 87 per cent of cases had a history of definite or probable asbestos exposure, mean latent intervals between first exposure and death were 38 (range, 3.5–53) years and 41 (15–67) years. The case with the shortest latency of 3.5 years was not well documented and there must be doubt as to its validity. The latency between first exposure and appearance of disease is unrelated to the heaviness of exposure.

Fibre type

A review of cohort studies concluded that relative potencies for crocidolite:amosite:chrysotile are 500:100:1. It has been suggested that the mesotheliomas occurring in workers exposed only to chrysotile may have been caused by small quantities, usually less than 1 per cent, of tremolite contaminating the chrysotile. This forms part of the so-called ‘amphibole hypothesis’ to the effect that most, if not all, asbestos-induced mesotheliomas are caused by amphiboles. The main evidence for this hypothesis has come from Canadian studies. In Quebec, the risk of mesothelioma was higher among workers in central mines where tremolite contamination was higher than among workers in peripheral mines where it was lower. Analysis of lung tissue from chrysotile workers showed that tremolite was the predominant fibre type retained compared with controls. The amphibole hypothesis has been questioned and it has been argued that even though chrysotile is a less potent cause of mesothelioma than amphiboles, because it accounts for a
large majority of asbestos used commercially, it may never-
theless be an important cause of pleural mesothelioma.68

There is evidence of some risk from chrysotile. A case–control study from Australia demonstrated an increase in risk of mesothelioma with increasing counts of crocidolite, amosite and chrysotile, including cases in which only chrysotile was present.69 Human cases in which chrysotile was the only type of asbestos in the lungs have been reported from Japan.70 A World Health Organization review of the evidence concluded that chrysotile poses a risk for mesothelioma in a dose-dependent manner with no evidence of a threshold below which there is no risk.52 Another recent review concluded that the evidence that chrysotile causes mesothelioma fulfils the criteria for causation according to the Bradford Hill causation model.71

NON-INDUSTRIAL MESOTHELIOMA

In the Cappadocian region of central Anatolia in Turkey there are two villages, Karain and Tuzkoy, where mesothelioma causes approximately 50 per cent of all deaths.72 Many of the deaths occur in middle-aged subjects, although the youngest cases occurred in a 12-year-old boy and in a 15-year-old girl.73 Exposure to a carcinogenic agent from birth was suspected. The materials responsible were found to be a fibrous zeolite called erionite and possibly tremolite present in the volcanic tuff which is quarried and used for building. The observation that mesothelioma occurred in certain families prompted detailed kinship studies which implicated a genetic factor determining suscepti-

ability, probably in an autosomal dominant way.70 This observation may help to explain variation in susceptibility to asbestos-induced mesothelioma. Naturally occurring asbestos minerals, including tremolite and perhaps chrysotile, have also been reported to cause mesothelioma in other countries, including in Greece and Cyprus.74,75

LUNG CANCER

Since the 1930s, there have been anecdotal reports of an increased incidence of lung cancer in asbestos workers. In 1955, Doll and colleagues reported a high risk of lung cancer in workers in an asbestos textile factory.76 In this study, subsequently extended,77 men exposed to asbestos for ten years or more before 1933 had a ten-fold increased risk of lung cancer. Many other studies have subsequently confirmed an increased risk in asbestos workers.

There is an important synergistic interaction between asbestos and smoking in the causation of lung cancer. A study of mortality among insulation workers in the United States demonstrated that the mortality from lung cancer was five times greater in men exposed to asbestos and there was a multiplicative interaction with a ten-fold increase from smoking, so that mortality was increased greater than 50-fold in asbestos-exposed smokers.78 Saracci79 reviewed several studies and concluded that the data support the view that the effects of asbestos exposure and smoking on the risk of lung cancer are multiplicative. Since this review, several other studies have been published and the conclusions remain broadly similar.80–83 The excess risk of lung cancer from asbestos is higher in non-smokers and very light smokers than in heavier smokers.84

Dose–response relation

Most epidemiological studies, which have considered the relation between dose of asbestos and the risk of lung cancer, have produced results consistent with an approximately linear relation between dose and mortality with no threshold dose below which there is no increased risk of lung cancer.5,7,79 However, a review of cohort studies found the lung cancer risk increased in proportion to somewhere between the dose of asbestos and its square.58 Age at the time of exposure does not affect the relative risk produced by asbestos exposure.5

Fibre type

Amphiboles are substantially more potent than chrysotile in causing lung cancer in humans. A review of cohort studies estimated that the risk of lung cancer increases by about 5 per cent for each fibre/mL per year of exposure to commercial amphiboles, i.e. amosite or crocidolite. The relative risk associated with chrysotile varies between industries. South Carolina chrysotile textile workers were at a much higher risk of lung cancer than miners and millers of the same variety of asbestos.85 It has been hypothesized that the physical characteristics of fibres, depending on the processes to which they have been subjected, may affect the lung cancer risk. However, an electron microscopic study of lung tissue from these two populations indicated that differences in fibre dimensions could not explain the higher risk of lung cancer in asbestos textile workers.86 A co-carcinogenic effect of mineral oils used in textile plants to control dust has been suggested as another possible explanation and an increase in risk of cancer after mineral oil spraying was introduced in the Rochdale textile plant in the UK lends some support to this hypothesis.58 However, the size of the risk observed could not fully explain the very high risk in the Carolina cohort of chrysotile textile workers. For chrysotile cohorts, there is wide variation in risk estimates. Doll and Peto estimated a 1 per cent increase in cancer risk per fibre/mL per year for chrysotile textile workers, based on the Rochdale and Carolina data.5 In a review of cohort studies, an estimate of 0.5 per cent per fibre/mL per year has been suggested as the upper limit to the risk from chrysotile with a best estimate of 0.1 per cent per fibre/mL per year, for other than the Carolina cohort.58
Latent period between exposure and onset of lung cancer

The latent period is variable. Some cases may occur as soon as five to nine years after first exposure. Doll and Peto suggested the risk rises until at least 30 years after first exposure. However, Hodgson and Darnton suggested there is probably little change in lung cancer risk between ten and 40 years from first exposure with a possible decline thereafter. A study of American asbestosis factory workers suggested that the latent period may be shorter when first exposure occurs at older ages. A study of Quebec chrysotile miners and millers found no evidence for a relation between latency and dose.

Lung cancer and asbestosis

The risk of asbestosis and the risk of lung cancer are both related to the dose of asbestos inhaled, so the conditions frequently occur in the same individual. The risk of asbestos-induced lung cancer was first identified in people with asbestosis and in the context of ideas about ‘scar cancers’ which were then current, but now anachronistic, the view became prevalent that the lung fibrosis of asbestosis led to the development of cancer. Twenty-five years ago, Doll and Peto suggested that in the light of modern knowledge of carcinogenesis the idea no longer seemed plausible, and with increasing knowledge of the molecular basis of carcinogenesis, the idea that causation of cancer is wholly dependent upon the presence of fibrosis has become increasingly implausible. A detailed discussion of the biological evidence is beyond the scope of this article.

A review of older epidemiological studies noted that two supported the view that asbestosis was necessary for the attribution of lung cancer to asbestos and seven supported the view that it was not. All the studies had methodological weaknesses and none was considered definitive. Additional information comes from case–control studies which suggest a doubling of risk at levels of exposure lower than suggested by the cohort studies reviewed by Hodgson and Darnton. A German population-matched, case–control study found a relative risk of 1.94 (95 per cent CI 1.1–3.43) for men with cumulative exposure exceeding 10 fibres/mL per year after adjusting for smoking. A Swedish population-matched, case–control study found significantly elevated cancer risk at levels of exposure far below those necessary to cause asbestosis. For exposure of 4 fibres/mL per year, the relative risk of cancer was 1.90 (95 per cent CI 1.32–2.74). The demonstration of a significantly elevated risk of cancer at levels of exposure below those necessary to cause asbestosis clearly invalidates the proposition that asbestosis is a necessary precursor of asbestos-induced lung cancer.

However, recent evidence has substantiated the suggestion from the reanalysis of the South African data that the presence of asbestosis further increases the risk of lung cancer above that arising from asbestos exposure. In a study of former workers and residents exposed to crocidolite at Wittenoom in Western Australia, there was a significant increase in risk of lung cancer with dose of asbestos in those without radiographic evidence of asbestosis, but the presence of asbestosis was associated with a further increment in risk.

Criteria for attribution of lung cancer to asbestos

The Helsinki criteria were formulated by an international panel of experts. The presence of asbestosis diagnosed on radiological or pathological evidence is a sufficient, but not necessary, criterion for attribution of lung cancer to asbestos. In the absence of asbestosis, an alternative criterion is sufficient cumulative exposure to asbestos to more than double the risk of lung cancer, assessed on the basis of the occupational history, or by measurement of the asbestos content of lung tissue. The most precise occupational history criterion was an estimated cumulative exposure of 25 fibres/mL per year or more. This criterion was later criticized on the grounds that account was not taken of fibre type and the level chosen represented the upper end of the estimated range of risk of lung cancer in relation to dose. Several of the senior authors reviewed the position in the light of more recent evidence and reaffirmed the criterion where exposure has been predominantly to amphiboles, but acknowledged that the threshold is higher for other mixtures of fibre types. From the risk estimates estimated from the review of cohort studies by Hodgson and Darnton, exposure to around 40 fibres/mL per year for an equal mixture of amphiboles and chrysotile is sufficient to more than double the risk of lung cancer. Cumulative exposure is the basis for the award of state benefit for asbestos-induced lung cancer in Germany, France, Belgium, Norway, Sweden, Finland, Denmark, Quebec and Australia (AWARD criteria) and Japan. In the United Kingdom, it is accepted by the Industrial Injuries Advisory Council that asbestosis is not necessary to attribute lung cancer to asbestos and exposure for designated periods in prescribed occupations is sufficient for the award of state benefit.

OTHER MALIGNANT DISEASES

There is controversy as to whether asbestos increases the risks of other cancers. The 1987 International Agency for Research on Cancer (IARC) review of the strength of evidence for a causal relationship between asbestos exposure and various cancers found 'sufficient' evidence to infer a causal relation between asbestos exposure and both laryngeal cancer and gastrointestinal cancer. The 2006 US Institute of Medicine (US IoM) Committee on Asbestos found the evidence was 'sufficient' for laryngeal
cancer and 'suggestive but not sufficient' for gastrointestinal cancer.\textsuperscript{100} In the UK, the Industrial Injuries Advisory Council reviewed the evidence in 2008 and noted that, although some studies had shown an increased risk of laryngeal cancer, few had shown a risk factor of greater than two-fold and the council concluded that there was insufficient evidence to make laryngeal cancer a prescribed disease, eligible for state compensation.\textsuperscript{101}

In the Great Britain Asbestos Survey, which from 1971 onwards monitored mortality among workers covered by regulations to control asbestos exposure, standard mortality rates (SMR), but not proportional mortality rates (PMR) were elevated for cancers of the larynx, oesophagus and colorectum.\textsuperscript{102} These disparities suggest that the elevated SMRs were likely to have been due to confounding factors, such as smoking. However, both the SMR (166) and PMR (114) were significantly elevated for stomach cancer raising the possibility of a weak causal link.

### Key points

- All types of asbestos cause all the asbestos-related diseases.
- Amphibole asbestos, e.g. crocidolite (blue) and amosite (brown), are far more potent than chrysotile (white) in causation of mesothelioma and lung cancer.
- There is no evidence of a threshold dose of asbestos below which there is no increase in risk of mesothelioma.
- A much larger dose of asbestos is needed to cause asbestosis than is capable of causing benign pleural disease and mesothelioma.
- A dose of asbestos sufficient to cause asbestosis is sufficient to approximately double the risk of lung cancer.
- The risk of lung cancer from asbestos exposure increases with cumulative dose and is not confined to people who have developed asbestosis of the lungs, although the presence of asbestosis further increases the risk.

ZEOlITES

This group of commercially valuable minerals is formed by recrystallization from water which has percolated through sedimentary deposits of volcanic ash (tuffs), or basic lavas originally formed in fresh water and marine environments. They are hydrated aluminium silicates with other metal ions within their open crystal lattice and act as catalysts, absorbents, etc., in the petrochemical industry, filters for sewage and water, water softeners, soil improvers and nitrogen adsorbers for oxygen concentrators. For most of these purposes, non-fibrous zeolites with an amorphous or cuboidal crystal structure are used. They are even synthesized in this form with the precise characteristics needed for the particular use. The mineral deposits contain a mixture of volcanic glass and a variety of crystalline forms of zeolite, and may be associated with small amounts of quartz and silicates. There are many different fibrous crystal forms, but they are seldom present in sufficient quantity for commercial exploitation, some only occurring in geodes. However, one, erionite, has been found in large workable deposits in several places between the mountain ranges of the western United States and in the North Island of New Zealand.

The risk due to erionite was recognized from the studies of Baris et al. on the incidence of mesothelioma in scattered villages in Cappadocia in Turkey. The whole area consists of narrow valleys cut into the thick layer of volcanic tuff with flat uplands in between. The incidence of mesothelioma varied from nil to over 50 per cent of the adult population in villages within a few miles of each other. Only the villages where fine fibrous erionite was present were affected and the average age at death from mesothelioma was 45 years. A 23-year prospective study found mesothelioma accounted for 45 per cent of deaths in two exposed villages.

Experimental studies have confirmed that erionite fibres are very active in producing mesotheliomas and that this activity is very strongly size-dependent. Environmental exposure to erionite should be prevented, and commercial exploitation should be prevented completely.

FIBROUS CLAYS

There is a group of clays and soft rocks which are used in the manufacture of quality tiles and ceramics. They are of special value because they consist of very fine fibre crystals, mostly less than 0.1 mm in diameter and 5 mm long. However, many of the deposits contain a proportion of fibres long enough to cause mesothelioma, and this has been confirmed by intrapleural studies in animals. It is not known how long these fibres survive in the lung.

The clays are often extracted damp and then dried, milled and marketed as a fine powder with or without calcining. Other uses are as adsorbents for insecticides, for mopping up oil spills and as cat litter. There is a wide range of potential exposure which is continuous only for small groups of workers and occasional for the rest. Little information about fibre exposure is available and what epidemiological information exists indicates pneumoconiosis with some high exposures, but as yet no evidence of lung cancer or mesothelioma.

The main group are the aluminium silicates sepiolite, attapulgite, palygorskite and meerschaum, names which do not seem to correspond to different clearly defined minerals. The fibres break up easily and may not survive the normal milling procedure.

Wollastonite is a harder material mined mainly in the United States for use in the ceramics industry and as a filler to prevent cracking in cements, plasters and paints. It is a calcium silicate which formed into a mixture of platey and
fibre-like crystals. Again the commercial product is milled and contains few if any ‘fibres’ sufficiently long to cause concern. Problems may arise if the method of processing or use is changed to preserve the elongated crystals or if other deposits are exploited.

SYNTHETIC MINERAL FIBRES

The health risks associated with the industrial use and consequent environmental contamination by asbestos led to an increased production and use of man-made fibres to replace asbestos for uses such as insulation, filtration, fire protection and friction materials. The most common man-made (or manufactured or synthetic or artificial) fibres are man-made vitreous fibres (MMVF), but there are also a number of other synthetic fibres, such as carbon/graphite fibres and silicon carbide fibres and whiskers, as well as synthetic polymers, such as Kevlar para-aramid fibres.

Also called (inappropriately) man-made mineral fibres (MMMF), MMVFs comprise glass fibres (glass wool, continuous glass filament and special purpose glass fibre), mineral wool (i.e. rock wool and slag wool) and refractory ceramic fibres. More than 80 per cent of the total production of MMVFs is made up by the insulation wools (glass, rock and slag wool). They are obtained by melting glass (with stabilizers and modifiers or fluxes), rock (basalt, granite, slate, limestone), slag (from metallic ore refining) or kaolin clay (or combinations of alumina/silica often with zirconium), and producing fibres by rotary or other processes. Various materials are used as additives and the fibres are often held together with binders (e.g. phenol-formaldehyde resin). The size characteristics of MMVFs are such that their mean diameters exceed the sizes considered to be respirable (3 μm), except for refractory ceramic fibres and glass microfibres. In addition, airborne concentrations have been reported to be generally lower than 1 fibre/mL air during manufacture, although higher levels are possible during applications. Another reassuring feature of MMVFs compared with asbestos is that their biopersistence (durability) in the lung is much lower, again with the exception of refractory ceramic fibres.

A number of structural similarities between some of these fibres and asbestos, as well as experimental data in vitro and in laboratory animals, led to concern that these asbestos substitutes may in fact be as hazardous as asbestos. Fortunately, this does not appear to be the case, although working with man-made fibre is not free from health risks.4,5 Occupational (and residential) exposure to MMVFs is well known to lead to acute skin and eye irritation, as well as upper respiratory tract irritation. However, neither interstitial fibrosis nor chronic obstructive pulmonary disease has been demonstrated to result from exposure to them. Pleural changes have not been shown to occur either, except in the case of the more persistent refractory ceramic fibres, for which a study of a cohort of production workers found a progressive relationship between plaques and cumulative exposure to refractory ceramic fibres, taking into account the possible exposure to asbestos.6 With regard to malignant lung disease, an IARC monograph published in 20027 concluded that there is inadequate evidence in humans for carcinogenicity of various forms of MMMF, although there is evidence of carcinogenicity in animals for some types of MMMF; the committee classified special-purpose glass fibres such as E-glass and ‘475’ glass fibres and refractory ceramic fibres as possibly carcinogenic to humans, while insulation glass wool, continuous glass filament, rock (stone) wool and slag wool were not classifiable as to their carcinogenicity to humans.

The human health effects of synthetic fibres other than MMVF.s, are much less well studied. With the exception of silicon carbide fibres, which may lead to pneumoconiosis, no human disease has been reported following exposure to these fibres. However, an outbreak of interstitial lung disease (mainly non-specific interstitial pneumonia) has been described in workers exposed to microfibres made of nylon.8 Nylon is not generally included among the man-made fibres, but like Kevlar, it is a synthetic fibre.

Key points

- Environmental exposure to erionite has led to an epidemic of mesothelioma, for example in Cappadocia in Turkey.
- While human evidence of carcinogenicity is lacking, the IARC has classified certain types of man-made fibres as possibly carcinogenic to humans.

Quartz and related dust

Quartz dust is among the most toxic of the non-fibrous mineral dusts and can cause fatal disease (acute silicosis) after exposure for only a few months to very high concentrations which may not even be perceptible to the naked eye. Heavy exposure to fine dusts containing quartz in the drilling of rock in mining and quarrying can therefore be highly dangerous and workplace exposure to quartz containing dusts has been subject to regulation for many decades in industrialized countries. Longer-term exposure to lower concentrations of quartz can lead to fibrogenic disease and silicosis used to be commonplace in many dusty industries; it remains common in less developed countries. Many mixed dusts produce disease due to their quartz content.

Silicon dioxide (SiO₂) is ubiquitous in the earth’s crust. Silicosis results from the inhalation of one of the three crystalline forms of silicon dioxide. Quartz is by far the most common, the other two being cristobalite and tridymite. Amorphous (non-crystalline) forms of silica dusts dissolve fairly rapidly in the tissue and do not cause the progressive pulmonary disease produced by crystalline forms, although the dissolved silica may damage other tissues, such as the kidney.

Quartz is found free as (silica) sand which is the residue left by the erosion of igneous rocks, like granite, in which the quartz crystals formed when larva cooled. Pure quartz is colourless, but traces of metal in the melt have produced various gemstones, such as citrine and cairngorm. Quartz is very hard and is virtually insoluble in tissue fluids and in most acids and alkalis.

Toxicity of quartz

The mechanisms by which apparently inert insoluble particles of quartz damage cells include direct cytotoxicity, with release of lipases and proteases, activation of oxidant production by pulmonary macrophages, activation of mediator release from alveolar macrophages leading to production of cytokines and reactive species, and secretion of growth factors from alveolar macrophages.1–3 Freshly ground respirable particles will kill phagocytic cells in culture, and kill the cells lining the alveoli of experimental animals and of humans at high levels of exposure. At lower levels, especially when the quartz is diluted with an inert dust, the macrophages will take up a few active particles with the inert ones and survive long enough to move into the alveolar wall or to the centrilobular interstitium before dying. At greater dilution, some of the quartz mixed in with the other dust will be cleared by the macrophages to the bronchial mucus escalator.

Resuspended quartz dust, such as that which blows off the Sahara desert, is relatively inert and much of it is cleared from the lung without causing damage, although pneumoconiosis in Bedouin has been described.4 Similarly, quartz mixed with metal oxides, as encountered in iron ore mining, does not show the expected toxicity. Experimentally, this has been shown to be due to the adsorption of a layer of the metal oxide on to the crystal. Experimental studies have since shown that these coatings, applied before inhalation, will delay the onset of fibrosis and reduce its severity, but that the coating is eventually lost and the particles become actively fibrogenic.5

In the hope that metals, such as aluminium, and some polymers might make quartz dust less toxic, such compounds...
have even been administered to workers who have already inhaled quartz dust in the hope that silicosis may be prevented or even cured. Long-term use of aluminium powder as a prophylactic inhalation in Canadian uranium miners was abandoned after 30 years because of lack of evidence of its efficacy. (Metallic aluminium powder has been shown to be fibrogenic in animals in the same size range as quartz (0.5–5 mm) and cases of pulmonary fibrosis have been reported from industry.) Aluminium citrate given parenterally has been shown both in laboratory animals and on clinical trial in humans to reduce the severity of silicosis. However, the known toxicity of aluminium to the central nervous system precludes its long-term parenteral use (see Chapter 13, Aluminium).

ACUTE SILICOSIS

This is also known as ‘silicotic alveolar proteinosis’ or even ‘silicotic alveolar lipoproteinosis’. High level exposure to active dust causes immediate damage in the alveolus with death of the type I and II alveolar lining cells, as well as the macrophages. Protein fluid, followed by inflammatory cells, leaks from the capillaries into the alveoli, mingling with the surfactant. Resolution does not occur and the alveoli become obliterated with fibrous tissue. This acute alveolitis may present within weeks of the start of exposure. The first symptoms are breathlessness and dry cough which get gradually worse despite all treatment. The radiograph shows patchy pulmonary oedema, but with the shadows gradually hardening and the affected areas shrinking. Lung function tests indicate a restrictive lesion with falling gas transfer leading to hypoxia and cyanosis. The disease is often fatal, sometimes within a few months, the prognosis being dependent on the amount of active dust already retained before the exposure stopped.

As there is no safe or effective treatment for this (or any other) form of silicosis, acute silicosis should never be allowed to occur in any country. There are documented incidents of large numbers of men dying of acute silicosis in the face of high, uncontrolled silica exposure in tunnelling, the most notorious being at Hawk’s Nest in the United States. Acute silicosis is still reported, for instance, where a small enterprise is set up to sand blast metal parts or to make silica flour without dust control.

The lesions of acute silicosis can also be seen in parts of the lung in cases of chronic active silicosis when the exposure has been high and recent. This intermediate disease is known as ‘accelerated silicosis’ and outbreaks of this condition have occurred even recently in the United Kingdom.

CHRONIC (ACTIVE) SILICOSIS

This disease was once widespread in industrial countries. It is now uncommon in developed countries mainly due to the use of safer alternative materials. Where this is not possible (hard rock mining, tunnelling, etc.), the adoption of modern methods of dust control and the enforcement of international standards have minimized the risk. In developing countries, many sources of risk still exist and the disease is still a major problem.

In the late 1980s, the pathology of silicosis and silicate dust pneumoconiosis was reviewed in some detail by an international panel of pathologists and much of this is still relevant.

Symptoms are a late manifestation of the disease. By the time breathlessness is noticed or is sufficient to interfere with labouring work, the radiograph shows widespread change. The first shadows to appear are the medium to large size of small, rounded opacities (‘q’ or ‘r’ on the International Labour Organization (ILO) scale) and are either evenly distributed or more frequent in the upper zones. Hilar node enlargement is common. The histology of the lesions in the lung is diagnostic; they are discrete nodules made of concentric layers of dense collagen tissue with a core containing birefringent quartz particles. They seldom grow to more than 1 cm in diameter. Larger masses consist of a conglomeration of these nodules as do the enlarged hilar lymph nodes. The nodules first form in the centrilobular area and then along the lymphatics both to the pleura and the hilar nodes with lines of less organized fibrous tissue linking them together. In the absence of further exposure, the nodules may become inactive and calcify from the periphery inwards. However, it may take 20–30 years for nodules to form, become quiescent and calcify; few workers with active silicosis live this long. A similar phenomenon in the hilar nodes gives rise to the appearance of ‘eggshell calcification’ (‘ec’ in the ILO symbols). A short period of relatively high exposure can give rise to hilar gland enlargement and nodules in the pleura with adhesions and pleural thickening, before there is a build up of nodules in the lung parenchyma. Figure 79.1 is a chest radiograph showing the appearances of silicosis.

The onset of breathlessness is usually due to the beginning of coalescence of individual nodules through the contraction of the linking fibrous bands. In the absence of complicating tuberculosis, there may be a dry cough and no pain. Lung function testing shows a restrictive pattern with loss of gas transfer capacity. Eventually, hypoxia and cyanosis occur, first on exercise and then at rest. Death is usually due to cor pulmonale. There are usually no physical signs in the chest and clubbing is not a feature. Depending possibly on the presence of amorphous silica in the dust, severe silicosis may be associated with liver and renal damage.

The accelerated form of silicosis can produce symptoms within a year of the start of exposure, when the lungs may show some of the features of acute silicosis, and when some deaths may occur within five years. In the last 50 years, it has been uncommon in the United Kingdom to see radiographic changes starting before 10–20 years from first exposure and leading (in the absence of tuberculosis) to life-threatening lung impairment before the retiring age. The longer the interval between first exposure and the onset
of symptoms, the slower they tend to progress and the greater the likelihood of the subject living to the retiring age and beyond. If the dust is relatively pure quartz, then little will be seen on the radiograph until the first nodules (‘r’ shadows) appear 5–15 years after first exposure. When there is heavy admixture of inert dust then a simple small opacity pneumoconiosis (‘p’ or ‘q’) may appear first. It is possible for workers exposed to quartz to leave their occupation after five or more years, free of symptoms, with a normal chest radiograph and lung function tests at that time, and then to develop classical silicosis and die of respiratory failure or complicating tuberculosis many years later.

**CHRONIC (INACTIVE) SILICOSIS**

Just as there is no clear distinction between acute and chronic (active) disease so there is none between chronic (active) and chronic (inactive). It is a matter of the level and duration of exposure. The presence of other dusts, cigarette smoking and environmental pollution outside the workplace can also modify the effect of the quartz.

When workers are exposed for many years to a dust which is occasionally contaminated with quartz or which contains, most of the time, a very small proportion of quartz (or quartz activity is being suppressed by the presence of other minerals such as aluminium, iron oxide, etc.), their pneumoconiosis shows mixed features. On the radiograph, a simple pneumoconiosis with mainly ‘p’- and ‘q’-sized rounded opacities may be present after 20–30 years. A few workers may show ‘r’ shadows in the upper zone and hilar gland enlargement. These ‘r’ shadows may become more profuse, tend to coalesce to form irregular masses or they may remain static and calcify. The hilar nodes may show eggshell calcification without obvious ‘r’-sized parenchymal shadows ever appearing. In workers with a long exposure history and who show these mixed features, it is unwise to give a good prognosis without following the case for at least ten years after exposure has ceased. Histology of such lungs often shows silicotuberculous nodules in various stages of development, some dating from early exposure and others arising more recently with scope for further development. Calcification is probably the only sure indication that a silicotic lesion is no longer active.

**Silicotuberculosis**

When active tuberculosis is common in the community, many patients with silicosis develop a combined disease with an extremely poor prognosis called ‘silicotuberculosis’. This is now rare in developed countries, but remains common in many developing countries, and is even increasing in developing countries with a serious HIV epidemic. Conventional chemotherapy for tuberculosis may delay progression, but patients can die with their infection still active in spite of chemotherapy that would eradicate the disease in patients without silicosis. Among South African gold miners, the presence of silicosis has been shown to increase the risk of tuberculosis and to exacerbate its clinical course. Some years ago Westerholm calculated that the risk of developing tuberculosis after the diagnosis of silicosis in Sweden was up to 15 times the risk for the general population. A study of mortality among silicosis claimants in California (cases from 1945 to 1975 followed from 1946 to 1991) found a grossly elevated mortality from tuberculosis among these patients with silicosis. The risk in the individual is related to the severity of the silicosis. It remains high for at least 15 years after the diagnosis of silicosis and probably for a lifetime. The mechanism is unknown, but *in vitro* studies indicate that macrophages are less able to engulf and kill tubercle bacilli when quartz dust is present. Silicosis causes damage to the lymphatic drainage of the lung which is important for the control of tuberculous infections; there may be an additional constitutional factor.

The detection of active tuberculosis in patients with early asymptomatic silicosis is not difficult because the onset of cough, sputum, night sweats, malaise and weight loss may be enough to bring the patient to the clinic. On the chest radiograph, new soft upper zone shadowing should show up clearly against the pre-existing ‘r’-sized rounded opacities. A raised sedimentation rate and the presence of tubercle bacilli in the sputum confirm the diagnosis. The diagnosis is difficult in advanced silicosis, especially patients who smoke, as they probably already have a cough, sputum and loss of weight. Confluent silicotuberculous nodules in the upper zone with associated emphysema may
mimic the appearance of cavities and make new infiltrates difficult to see on conventional radiographs. Confluent silicotic nodules (unlike the masses of progressive massive fibrosis in coal miners and those of Caplan’s syndrome) rarely cavitate in the absence of tuberculosis. Haemoptysis and cavitation of the lung masses (confirmed by computed tomography (CT) scan, if possible) are strong indications of active tuberculosis. The organisms may be hard to identify on sputum smear or culture from the sputum and it is often necessary to treat such cases on suspicion, without microbiological confirmation of the diagnosis. Treatment is as for pulmonary tuberculosis (for example, following the British Thoracic Society guidelines in the United Kingdom). There is evidence that treatment should be more prolonged than for tuberculosis in the absence of silicosis. It can be difficult to gauge effectiveness of treatment in the absence of organisms in the sputum, as the radiographic shadows may not regress.

Prevention of silicotuberculosis

Prevention of silicotuberculosis is difficult. The main risk of silicosis now is in developing countries where the general risk of tuberculosis is high and most of the population are exposed to the tubercle bacillus in childhood. Occupational exposure to quartz dust then carries the risk of reactivation of latent infection or new infection. The overcrowded and insanitary conditions prevailing for migrant workers in mine compounds contribute to the spread of the disease. In a developing country where most children are already tuberculin skin test positive before they start breathing in quartz dust, there is obviously no point in giving BCG when work starts. The use of BCG among tuberculin skin test negative mine workers exposed to silica in Eastern Europe apparently had an adverse effect, although a benefit was reported for copper miners in Africa. Some authors have reported benefit from prophylactic chemotherapy, for example with isoniazid for people with silicosis, and recommended its use, but this may be impractical in developing countries where the majority of the cases now occur. Careful monitoring of patients with silicosis is important, with treatment on suspicion of infection, even without microbiological confirmation.

**RISKS AND PREVENTION OF SILICOSIS IN DIFFERENT OCCUPATIONS**

**Grinders**

When the cause of lung disease in grinders (Figure 79.2) was recognized as being due to their exposure to silica dust (for example, knife grinders in Sheffield), the first move was to change from dry to wet working; later, sandstone or millstone grit grinding wheels were replaced by synthetic silicon carbide. Although harder than quartz, this produces a dust which is very much less fibrogenic and its use has virtually eradicated silicosis from this occupational group. As even silicon carbide dust can cause lung fibrosis, most grinding work should still be done wet and exposure must be kept well below the limits for ‘nuisance dusts’.

**Masons and polishers**

Wet working can be effective in controlling silicosis among monumental masons and men who polish granite and other quartz-containing rock for architectural and decorative use, but failure to control dust exposure can lead to accelerated disease.

In some traditional workplaces, materials like precious stones, jade and metals are polished with dangerous powders. Silicosis has been reported from a workshop where jade was polished (dry), using a mixture containing silica flour. The silicosis risk can be avoided by using a non-fibrogenic polishing powder.

**Miners**

Hard rock mining for metals, such as tin, gold and copper, was another occupation recognized early as causing silicosis, and similarly the cutting of shafts and ‘drivages’ (passages or roadways) through hard rock to gain access to coal seams and other ores. Civil engineering tunnelling first for canals and then railways and now for motorways and underground railways, hydroelectric schemes, etc., are situations where the risk may vary from week to week depending on the rock strata encountered. The most important step was the introduction of hollow drills which could not be used without water flowing down the centre (Figure 79.3). However, in hard rock situations, it is not possible to inject water into the rock face to prevent dust formation when charges are fired. This can be dealt with by positive ventilation and waiting periods after shot firing to allow the dust and toxic fumes to be cleared by the ventilation before the workers go back in.

**Pottery and refractory making**

Silicosis was common in the UK area in Staffordshire known as the ‘Potters’ where the making of crockery and ceramics was concentrated. It resulted partly from the grinding of quartz-containing minerals, like ‘china stone’, for mixing with the clay for making porcelain. The main problem was the use of silica sand and silica flour as a parting medium to prevent the pots from sticking together or to the stands while they were being fired. Not only did the dust from applying the silica sand and flour cause silicosis, but by the time firing was complete the quartz was converted to cristobalite and the workers handling the items after firing were at even greater risk. Refractory bricks for
lining furnaces were made of silica sand and caused silicosis during manufacture and use when the lining of furnaces had to be renewed at regular intervals by digging out the old bricks (a very dusty job). The spent bricks contained cristobalite, as well as quartz, and fibres of mullite are also formed which may contribute to the lung damage. All these risks could be avoided by dust suppression, but this is technically very difficult especially when cleaning the lining out of an old furnace. Alternatives for prevention include automation and changing to ingredients and parting media that are not fibrogenic.

Moulders and fettlers

Traditionally, iron and brass were cast by pouring the metal into moulds formed of damp sand. When cool, the mould was broken open, leaving some of the sand embedded in the surface of the metal. This was first knocked off with a hammer and chisel (fettled) and the surface finished by grinding. Both these processes released sufficient quartz dust to cause chronic active silicosis in a proportion of the workers. It was a slow, labour-intensive process and was replaced by sand blasting, which caused acute silicosis. The sand was replaced by steel shot, but there was still the sand on the casting and silicosis still occurred. Even the replacement of silica sand as a main casting medium by less fibrogenic material such as 'green sand' has not completely solved this problem. If castings are to be cleaned in this manner, the work has to be completely enclosed in a specially ventilated cabinet. High-precision casting, such as is demanded of the light alloy components for the motor industry, has moved towards the use of binders in the moulding medium and various separating agents to produce a clean smooth casting.

There are a number of other jobs with likely exposure to quartz, including work in geology laboratories, or in mineralogy, road work and construction work. There is a wide variation in risk of exposure and in the type of controls required to control the exposure effectively.
HEALTH SURVEILLANCE OF WORKERS EXPOSED TO SILICA DUST

As described in Chapter 80, Epidemiology of silica-related disease, current exposure limits, although already stringent in developed countries, may still not be stringent enough to prevent development of silica-related diseases in some industries. Therefore, health surveillance of exposed workers is still important and is a legal requirement in most industrialized countries for workers with more than minimal exposure to respirable crystalline silica. In the United Kingdom, in certain occupational settings where the risk of exposure to quartz is known to be insignificant and with good controls in place, such as in mineralogy laboratories, health surveillance is not required under the Control of Substances Hazardous to Health (COSHH) regulations.

The details of recommended health surveillance for silica-exposed workers vary between countries. Recommended pre-employment screening includes enquiry about previous exposure to silica and other dusts and about respiratory symptoms, examination of the chest, a chest radiograph and ventilatory lung function testing. Because of the increased risk of tuberculosis, in many countries a tuberculin skin test is recommended; this is not recommended in situations where the community rate of tuberculosis is high or where there is a programme of BCG vaccination, where a positive skin reaction is not helpful as an indicator of active tuberculosis. In the United Kingdom, tuberculin skin testing is not recommended as part of health surveillance for silica-exposed workers. A positive history or radiological evidence of past or present pulmonary tuberculosis are good reasons for advising against employment involving significant exposure to quartz, for example in mining. At follow-up examinations, the cumulative dust exposure for each individual, details of respiratory illnesses and changes in smoking habits should be added to the results of the clinical examination, radiograph and ventilatory lung function tests.

The recommended frequency of health surveillance varies between countries. Follow-up examinations with a chest radiograph, spirometry and a clinical examination of the chest are recommended every one to four years, with the recommended frequency increasing after longer exposure, when silicosis is more likely to develop. Guidelines in many industrialized countries recommend that workers with a significant cumulative exposure to respirable crystalline silica should be offered continued follow up after they leave or retire, even if they have a normal chest radiograph and lung function at the time, as progression of silicosis can continue after exposure ceases, and they are at risk of developing silicotic tuberculosis or lung cancer (see Chapter 80, Epidemiology of silicosis-related diseases).

The development of radiographic changes suggestive of silicosis, especially if accompanied by an unexpected drop in ventilatory capacity, should lead to the worker being removed from dusty work and to a re-examination of the working conditions. The worker should be advised against further exposure to quartz in any employment, and acquainted with the procedure for claiming appropriate statutory benefit where such a scheme exists (see Chapter 8, Compensation schemes). Chemoprophylaxis against tuberculosis should also be considered.

Key points

- Acute silicosis due to high exposure to quartz is a rapidly developing acute alveolitis which is often fatal. This disease is now rare.
- Chronic silicosis is now rare in developed countries, but remains a serious problem in developing countries with poor dust control mechanisms.
- The chest radiograph in silicosis shows small rounded opacities with hilar lymph node enlargement and sometimes ‘egg shell’ calcification; coalescence to mass lesions may occur later.
- Silicosis greatly increases the risk of tuberculosis; silicotuberculosis is a serious complication and can be difficult to treat. Tuberculosis chemoprophylaxis should be considered for people with silicosis, where this is feasible.

Epidemiology of silica-related disease

KYLE STEENLAND

INTRODUCTION

Crystalline respirable silica is one of the best known and well-characterized occupational toxins, because of its long history of causing silicosis. In the last 20 years, epidemiologic data are reasonably conclusive that silica also causes lung cancer and quite suggestive that silica leads to renal disease. Furthermore, some data also link silica to autoimmune diseases, such as rheumatoid arthritis (RA), systemic lupus erythematosus and scleroderma.

Exposure to silica is still common. For example, in the United States about 2 million workers (2 per cent of the workforce) are estimated to be exposed, principally in foundries, ceramic and brick, granite, mining and sandblasting. It is estimated that 100 000 of these workers have exposure above the National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit of 0.05 mg/m³.1,2 While high-silica exposure has been traditionally associated with dusty trades, such as mining and brickmaking, significant exposure also occurs in construction, a common occupation.3

SILICOSIS

Silicosis usually refers to chronic (or ‘simple’) silicosis, defined by the presence of small rounded opacities of ILO category 1/1 or greater on x-rays. This disease may be asymptomatic, but can often progress to symptomatic disease. Acute silicosis is symptomatic disease resulting from a short-term, very high exposure and is rare nowadays. Progressive massive fibrosis characterized by large opacities on x-ray may also occur as a complication of chronic silicosis. Another sequel can be tuberculosis; rates of tuberculosis are higher among silicotics (‘tuberculo-silicosis’).

That silica causes silicosis is not in doubt. However, despite a large body of epidemiologic literature documenting silicosis in different populations, not until the last 10–15 years have we had quantitative exposure–response data allowing us to evaluate whether current exposure standards are adequately protective.

Table 80.1 provides estimates of the risk of silicosis morbidity (defined as an x-ray with ILO category 1/1 or greater) from studies with quantitative exposure–response data. These risks are those estimated to occur after an exposure of 45 years at the current standard for 100 per cent pure quartz in the United States (0.1 mg/m³ respirable crystalline silica). Studies without follow up after employment (when many cases occur), or without sufficient time since first exposure, may substantially underestimate the risk. Acute silicosis can occur rapidly after short-term high exposures, but chronic silicosis has a variable latency period (time since first exposure), so that some cases occur much later than others even given equivalent cumulative exposure. Cross-sectional studies tend to underestimate risk, because workers with disease may not survive or may not be present in the workplace if the survey is workplace based.

Lifetime risks in Table 80.1 vary widely, but all are above the risk level that many regulatory agencies accept. For
example, the US Occupational Safety and Health Administration (OSHA) generally accepts an excess risk of up to one in 1000 (0.1 per cent) (of exposed individuals developing disease).6 Given that there is no background risk for silicosis among the non-exposed, absolute and excess risk are the same. The wide variation of risk between studies in Table 80.1 probably mainly reflects differences in study design and length of follow up, but may also reflect the different capacity of different types of silica to produce silicosis. In a number of settings, appreciable clay coatings of the silica may occur, which may decrease the risk of silicosis and other diseases caused by silica. There is support from animal data for this phenomenon,7 and International Agency for Research on Cancer (IARC)8 cited it in noting the variation in lung cancer risk across silica studies. Chen et al.9 for example, provide data on not only respirable silica but also cumulative surface-available respirable silica, for which the estimated lifetime risk of silicosis increases from 15–20 to 25–30 per cent.

Churchyard et al.10 studied South African gold miners with an average silica exposure level of 0.05 mg/m³, half the current standard in many countries. They typically had a long duration of exposure (median 21 years). Even though the study was cross-sectional and did not include follow up after employment, these miners had a 19 per cent prevalence of silicosis. These data again strongly indicate that the current exposure standard in many countries is too high to prevent silicosis, and suggest that in fact the standard needs to be below 0.05 mg/m³ (the current NIOSH recommended level). Greaves5 has recommended a standard of 0.01 mg/m³ under the assumption that such a level would reduce lifetime risk of silicosis to approximately two in 100, still too high but a compromise with what is technologically feasible and practically possible.

There are additional data from three studies regarding exposure–response analyses for silicosis mortality. The largest of these is by t’Mannetje et al.,11 which analyses silicosis mortality from an IARC study of 18 000 workers in six cohorts (170 deaths, underlying cause). The estimated risk of death by age 75 years due to silicosis was 1.9 per cent after a lifetime of work (age 20–65 years) at the current standard (0.1 mg/m³). This result, this time for death rather than x-ray abnormality, is again well above the one in 1000 risk accepted by US OSHA. A second study by Hedlund et al.12 studied 7729 miners, with 58 deaths from silicosis. The crude death rate from silicosis as an underlying cause was 20/100 000, similar to that in the IARC study by t’Mannetje (29/100 000). A third study by Tse et al.13 analyses non-malignant respiratory disease mortality, a category broader than silicosis mortality, and does not provide detailed results for exposure–response by cumulative silica exposure.

**LUNG CANCER**

Since the 1980s, there have been many cohort studies focusing on lung cancer and silica exposure. A meta-analysis of 17 studies of silica and lung cancer by Steenland et al.14 found a modest combined relative risk for the exposed versus non-exposed of 1.3, after excluding studies with known confounders (e.g. studies of foundry workers, who are exposed to many other known carcinogens). A similar meta-analysis of 19 studies of silicotics (with presumably high levels of silica exposure) found a relative risk of lung cancer of 2.3, compared with non-exposed populations.14 In 1997, IARC classified silica as a definite lung carcinogen (group 1), but noted that not all studies were consistent, and the carcinogenic potential of silica might be affected by the physical properties of the silica particles.8 The US NIOSH and the US National Toxicology Program (NTP) later also decided that silica was a human carcinogen.15

Another recent meta-analysis covers 45 studies published after the 1997 IARC classification and after the previous meta-analysis by Steenland et al. Pelucchi et al.16 found a pooled relative risk for lung cancer among the silica-exposed compared with non-exposed of 1.34 and 1.41 for cohort and case–control studies, respectively. For silicotics compared with non-exposed populations, these relative risks increased to 1.69 and 3.27, respectively. Thus,
these results are broadly similar to the earlier literature and tend to confirm the decisions by IARC, NTP and NIOSH to classify silica as a known human carcinogen. Another meta-analysis restricted to silicotics was published by Lacasse et al.,17 and found a combined standardized mortality ratio (SMR) of 2.45 (1.63–3.66) across 27 studies comparing silicotics with non-exposed populations. This was reduced to 1.52 (1.02–2.26) for never-smokers (ten studies had never-smokers).

Since the Pelucchi et al. meta-analysis,16 there have been a few more publications regarding silica and lung cancer, the most important of which is a recent large case-control study in Eastern Europe.18 This study included 2800 lung cancer cases, about 15 per cent had been occupationally exposed to silica during their lifetime (based on self-reported work history, followed by expert review and creation of a job–exposure matrix), compared with 10 per cent among controls. The odds ratio for occupational exposure to silica was 1.37 (95 per cent confidence interval (CI) 1.14–1.65).

Despite the many epidemiologic studies showing an increased lung cancer risk, the overall conclusion about silica’s carcinogenicity has remained somewhat controversial (for example, see Hessel et al.19) due to some inconsistency in the literature, where not all studies show a positive association with lung cancer. Nonetheless, controversy has been receding as the evidence has mounted.20 One element which has diminished the controversy has been several studies showing positive exposure–response relationships. Positive exposure–response trends are important supporting evidence for a causal relationship.

Steenland et al.21 published a large exposure–response analysis of silica exposure and lung cancer based on ten occupational cohorts with good exposure data assembled by NIOSH. This was a pooled analysis (using original data) of 65 000 workers and over 1000 lung cancer deaths. Lung cancer rates increased with increased cumulative exposure in internal categorical analyses. Odds ratios by quintiles of cumulative exposure were 1.0, 1.0 (0.9–1.3), 1.3 (1.1–1.7), 1.5 (1.2–1.9), 1.6 (1.3–2.1), using cutoffpoints if <0.4, 0.4–2.0, 2.0–5.4, 5.4–12.8, >12.8 mg/m³ years. A number of these studies controlled indirectly for smoking, which had little impact on results. These exposure–response data, based on almost all cohort studies with quantified exposure data, showing a significant positive trend between silica exposure and lung cancer, strengthen the case that silica is a human lung carcinogen.

Four other exposure–response analyses have been published based on data not included in the IARC pooled analysis. Two of these showed significant positive exposure–response trends.18,22 Yu et al.23 studied a cohort of silicotic workers in Hong Kong and did not see a positive exposure–response trend, but since all silicotics have generally had high exposure, it may be difficult to detect exposure–response trends within this cohort with relatively small exposure variation. Brown and Rushton24 published an analysis of silica sand workers in England and failed to find a positive exposure response, but the exposure levels in this study were very low, and hence this study might not be expected to result in positive exposure–response trends.25

Overall, the data suggest that silica is a relatively weak carcinogen compared with other classic lung carcinogens. Figure 80.1 shows the exposure response for silica compared with several metals. This low relative potency is one of the reasons why the lung carcinogenicity of silica has been somewhat controversial and difficult to establish.

It has been speculated that the risk of lung cancer among the silica-exposed is restricted to those who develop silicosis, or that silicosis is a risk factor for lung cancer independent of exposure.26 Silicosis is a marker of high exposure, and it is therefore logical (under the assumption that silica per se increases lung cancer risk) that silicotics would have higher risk than non-silicotics, even without any independent role for silicosis. However, existing epidemiologic data are not, and probably never will be, sufficient to disentangle this issue.20 One would need very good longitudinal data on exposure and silicosis throughout the follow-up period in a large cohort, i.e. very good exposure assessment of silica levels and repeated chest x-rays. 

Figure 80.1 Lung cancer relative risk by mg/mm³, five agents; n = lung cancers. RR, relative risk.

Existing data to date have not been sufficient to answer this question. In the UK scheme for Industrial Injuries Disability Benefit, lung cancer with silica exposure is only recognized for benefits in individuals who have silicosis.27

A common method of expressing risk of lung cancer in a silica-exposed population consists of calculating an excess risk of death from lung cancer by the age of 75, above the already existing background risk for the non-exposed. Based on the spline model from Steenland et al.’s exposure–response analysis,21 the excess lifetime risk of lung cancer (to age 75) after a 45-year exposure at current standard (0.1 mg/m³) is 1.7 per cent (0.2–3.6 per cent), above a background risk of lung cancer death of 7.5 per cent (in a non-exposed population, including smokers and non-smokers).

By way of comparison, to get some feeling for the magnitude of these excess risks, consider never smokers and...
current smokers. Never smokers have a background risk of dying of lung cancer by age 75 of about 1 per cent, while current smokers (assuming a rate ratio of 15 for current smokers versus never smokers) have an excess risk of about 9 per cent (or an absolute risk of about 10 per cent), of dying of lung cancer by age 75, after taking into account competing causes of death.

KIDNEY DISEASE

In the last 10–15 years, several studies have linked crystalline silica with renal disease (particularly glomerulonephritis). Five occupational cohort studies (three mortality studies, two incidence studies) and one proportional mortality ratio (PMR) study have shown two- to three-fold excesses of renal disease among those with silica exposure, based on relatively small numbers.28–33 Two population-based case–control studies of incident renal disease34,35 have shown odds ratios of two or more for silica exposure. One study of silicotics found an increased risk of high creatinine compared with controls without silica exposure.36 Another report from England found a higher incidence of renal disease, particularly glomerulonephritis, among those living in mining areas.37 Overall, the evidence is too sparse to be conclusive, but it seems likely that silica causes kidney disease.

Again, exposure–response studies can provide additional evidence in support of causality. Cohort studies of rare diseases often suffer from small numbers of cases, but on the other hand, exposure is usually better defined and measured than in case–control studies, where past exposure is self-reported and difficult to quantify. For renal disease and silica, there are three cohort studies with sufficient numbers to evaluate exposure response, two of which have been positive and one negative. In a cohort incidence study of 4620 industrial sand workers with good historical exposure information and relatively high silica exposure, Steenland et al.29 found significantly elevated risk of mortality for chronic renal disease (SMR 2.22 for underlying cause, 10 deaths; SMR 1.61 for any mention on the death certificate, 36 deaths). These authors then matched their cohort to a US national end-stage renal disease (ESRD) registry, which covered a more limited time period than the mortality follow up. They found 23 ESRD incident cases versus 11.7 expected (standardized incidence ratio (SIR) 1.97 (1.25–2.96). Exposure–response analyses revealed a strong positive exposure–response trend; rate ratios were 1.00, 3.09, 5.33 and 7.79 for categories of cumulative exposure (0–0.10, 0.10–0.51, 0.51–1.28 and 1.28+ mg/m³ years). In a pooled study of three silica-exposed cohorts which examined mortality \( n = 13000 \), Steenland et al.38 found 51 deaths from kidney disease as an underlying cause, and 151 deaths considering any mention on the death certificate (multiple cause). The overall comparison of the exposed workers to the US population yielded an SMR of 1.41 (1.05–1.85) for underlying cause, and 1.28 (1.10–1.47) for multiple cause. These authors found significant positive trends in exposure–response analyses for both underlying and multiple causes. On the other hand, McDonald et al.28 studied 2670 industrial sand workers and, while finding a significantly elevated SMR of 2.39 based on 19 cases, found a negative trend in mortality risk with increased cumulative exposure.

Under the assumption that using incident cases is preferable to using mortality data and relying on the exposure–response found for ESRD in Steenland et al.,29 the estimated excess risk of ESRD incidence after a 45-year working lifetime under the current OSHA silica standard \((0.1 \text{ mg/m³})\), as of age 75 for males, is a high 5.1 per cent \((3.3–7.3 \text{ per cent})\), above a background risk of 2 per cent. However, the data are too sparse and contradictory at this point to consider this figure as anything more than suggestive.

Silica damage to the kidney can result from direct toxicity of silica particles reaching the kidney, deposition in the kidney of immune complexes (IgA) following inflammation, or an autoimmune mechanism.39 Silica-exposed patients often have high levels of antibodies (IgA, IgG) and immune complexes have been seen in the glomerulus. Others have anti-nuclear antibodies (ANA) and anti-neutrophil cytoplasmic antibodies (ANCA), suggesting an autoimmune mechanism.35

AUTOIMMUNE DISEASE

There is increasing evidence that silica can cause autoimmune disease, particularly rheumatoid arthritis, systemic lupus erythematosus (SLE) and scleroderma (see reviews in Parks et al.,40 Cooper et al.,41 Cooper and Parks,42 Pernis43 and Parks and Cooper44). It is possible that the strong immune response to silica in the lung, which has immune effects outside the lung, can trigger an autoimmune reaction.41 There are mice models showing increased autoantibodies and other indices of an autoimmune process after silica exposure.45–47

The majority of epidemiology in this regard, and perhaps the strongest evidence, has been for rheumatoid arthritis. Khuder et al.48 reviewed 15 studies published from 1986 to 2001 in a meta-analysis, and found a combined relative risk for rheumatoid arthritis (RA) with silica exposure of 3.43 (2.25–5.22). Cooper et al.41 also provide an overview of the literature, citing five occupational cohort studies with a relative risk of three or more. Several of these studies were based on disability claims among members of exposed cohorts, while others were based on mortality, and one was based on a medical record review of patients with silicosis. However, not all studies have reported positive associations with RA. Turner and Cherry49 found no relation between cumulative silica exposure and RA (58 cases) among 8300 workers under medical surveillance in the pottery industry in England. Limitations of this study included its restriction to currently employed
workers, relatively low levels of silica insufficient to result in silicosis and matching of cases to controls on age of employment tending to decrease variation in cumulative exposure. Since the two 2002 reviews mentioned above, there have been three new reports. In one of the largest and most thorough studies to date, Stolt et al.\textsuperscript{50} conducted a population-based case–control study of RA in males in Sweden from 1996 to 2001 (276 cases, 276 controls). Men working in jobs with presumed exposure to silica (rock drilling, stone crushing, exposure to stone dust) had an odds ratio of 2.2 (1.2–3.9). Calvert et al.\textsuperscript{51} analysed US death certificate data and found a significant association between RA and work in jobs assumed to have silica exposure. Finally, Cooper et al.\textsuperscript{52} measured anti-nuclear antibodies in the general population and found a significant two-fold increased risk of high titer antibodies for those with a past history of occupational silica exposure.

Increasingly strong evidence also links SLE to silica exposure. This evidence has been summarized recently by Parks and Cooper,\textsuperscript{44} who cite six studies of various designs and quality, all of which show some evidence linking silica exposure to SLE. Perhaps the strongest evidence comes from a population-based large case–control study by Cooper et al.\textsuperscript{53} These authors compared 265 incident SLE cases from rheumatology practices in southeastern United States with 355 controls. Nineteen per cent of SLE cases from rheumatology practices in southeastern United States with 355 controls. Nineteen per cent of SLE cases reported occupational silica exposure compared with 8 per cent of controls, and the odds ratio for SLE for medium versus no silica exposure was 2.1 (1.1–4.3) and for high versus no silica exposure the odds ratio was 4.6 (1.4–15.4). A newer report by Finckh et al.\textsuperscript{54} described a case–control study of 115 SLE cases, which showed a significant four-fold increased risk with occupational silica exposure, as ascertained via a job–exposure matrix (4 per cent exposure prevalence among controls).

Evidence linking scleroderma and systemic sclerosis to silica was reviewed by Cooper et al.\textsuperscript{41} Four occupational cohort studies showed a three-fold increased risk, while five population-based case–control studies had mixed results. Since this 2002 review, there are three new studies. Magnant et al.\textsuperscript{55} reported that in a case series of 39 silica-exposed and 66 non-exposed patients with systemic sclerosis, severe disease was significantly more common among the silica-exposed. Bovenzi et al.\textsuperscript{56} and Diot et al.\textsuperscript{57} both conducted relatively small case–control studies of systemic sclerosis, the former finding a statistically non-significant excess risk with silica exposure, and the latter finding a significant positive association with silica exposure.

A fourth autoimmune disease associated with silica is ANCA-associated vasculitis. Vasculitis, an inflammation of the blood vessels, may occur by itself, but is also often a feature of RA or SLE. Vasculitis can arise from infection or from immune complexes which form after infection. A third type is associated with an autoimmune process, characterized by the presence in the blood of ANCA. ANCA-associated vasculitis has been associated with silica exposure in several studies (for example, see Hogan et al.,\textsuperscript{58} Beaudreuil et al.\textsuperscript{59} and Lane et al.\textsuperscript{60})

### COMPARATIVE RISKS

Silica has now joined a handful of other toxic exposures which cause multiple serious diseases, such as tobacco smoke, dioxin and asbestos. Table 80.2 presents a summary of the excess (or absolute) risk due to a 45-year lifetime of exposure to silica at the current standard (0.1 mg/m\textsuperscript{3}) as of age 75, for silicosis, lung cancer and kidney disease. The risk estimates for lung cancer, silicosis mortality and end-stage renal disease incidence, and kidney disease mortality are based, respectively, on exposure–response data from Steenland et al.,\textsuperscript{21} t’Mannetje et al.,\textsuperscript{11} Steenland et al.\textsuperscript{29} and Steenland et al.,\textsuperscript{38} while the risk estimates for silicosis morbidity are based on the broad assumption that lifetime cumulative risk at the current standard is somewhere between 0.47 and 0.77 (Table 80.1). These risk estimates should be considered tentative, especially for silicosis morbidity where studies have given heterogeneous results, and for end-stage renal disease where there is only one incidence study with large enough

\textsuperscript{5}Usual Occupational Safety and Health Administration (OSHA) permissible excess (or absolute) risk, 0.1%.
numbers. Furthermore, no risk estimates for rheumatoid arthritis, lupus or scleroderma/systemic sclerosis are presented, as detailed exposure–response data are generally not available for these diseases.

Also presented in Table 80.2 are the corresponding risks at levels a tenth of the current standard (0.01 mg/m³), as well as the corresponding background risks for the non-exposed population. These absolute risks and excess risks are calculated solely for men, because there were negligible numbers of women in the cohorts which were studied.

Keeping in mind that the usual acceptable excess risk of serious disease or death for workers for US OSHA is 0.1 per cent, it is clear from Table 80.2 that the current standard is far from sufficiently protective of worker’s health. Lowering the standard to a tenth of the current one still results in risks that are above the usual US OSHA permitted excess (or absolute) risk. Nonetheless, it seems unlikely that it is currently feasible to lower the standard to this level, both because it would be quite difficult to lower actual exposure levels in many work sites to this level, and because of increased measurement difficulties. However, the perfect is the enemy of the good: any significant lowering of the standard would be an important step forward in light of the evidence.

Key points

- Crystalline silica has long been known to cause silicosis. A large number of epidemiologic studies are now available to estimate exposure–response relationships. These studies suggest that the common standard in many countries of 0.1 mg/m³ needs to be lowered by at least half and probably more to protect exposed workers from a lifetime risk in excess of 1 per 1000.
- The epidemiologic data linking silica to lung cancer have increased over recent years and there are increasing numbers of studies with exposure–response data. The studies are rather consistent in showing that silica is a human lung carcinogen. However, it appears to be a weaker one per unit dose than many classic lung carcinogens, which has led to controversy and a slower acceptance of silica’s carcinogenicity than other lung carcinogens.
- The epidemiologic data linking silica to non-malignant kidney disease have also increased in recent years. Although not as conclusive as the data for silicosis and lung cancer, the data are reasonably consistent and point in the direction of causality.
- There are also epidemiologic data linking silica with a variety of autoimmune diseases, such as lupus, scleroderma and rheumatoid arthritis. Again, these data have not reached the point where causality can be reasonably assumed, but they point in that direction.
- Silica is linked to many diseases. Exposure–response data sufficient for risk assessment are available for silicosis, lung cancer and non-malignant kidney disease. Of these, the lifetime risk of silicosis and non-malignant renal disease is greater than the lifetime risk of lung cancer at the existing occupational standard of 0.1 mg/m³, but all three outcomes point towards the need for a substantial reduction of that standard.

Other non-fibrous mineral dusts

ANNE COCKCROFT

INTRODUCTION

Most of the other non-fibrous mineral dusts leading to occupational lung diseases are mixed dusts containing quartz. Much of their toxicity is related to their quartz content, but modified according to the other components of the dust and the form of the quartz.

COALWORKERS’ PNEUMOCONIOSIS

Coal mining and dust exposure

Coal mining as an occupation is historically important; coal was the fuel that supported the Industrial Revolution. The British coal mines at one time employed nearly a million men. While there is now little coal mining in the United Kingdom, there are still many men with lung disease resulting from their exposure as coalworkers. Coal mining remains an important industry worldwide, and many countries continue to rely on coal as a main energy source. The top five producers of hard coal are China, the United States, India, Australia and South Africa. Some 60 per cent of world coal production comes from underground mining; some countries, such as Australia, have most of their production from surface (opencast) mining.

Workers in the coal mining industry, particularly those who work in underground coal mines, are exposed to a variety of mineral dusts besides coal. To open up or extend and maintain a coal mine, shafts and roadways must be driven though other strata which may contain hard rock with 75 per cent or more of quartz. This quartz exposure can lead to silicosis (see Chapter 79, Silica and silica-related diseases). This work may be done by specialized teams or by men who also work on the coalface itself. When the coal seams are two metres or more thick, the rock above and below the seam is left undisturbed. One of the reasons that most mines in the UK became uneconomic is because the coal seams are thin and frequently faulted, so the rock must be cut above and below to allow the men and machines access to the coal (hard heading). All underground workers are exposed to some extent to this rock dust, which may contain high proportions of quartz.

Coal was formed when forests were crushed under the weight of sedimentary rock. It therefore includes stones from the forest floor and from above. This is a source of rock dust exposure to surface and transport workers, as well as those down the mine.

The proportions of quartz and other mineral dusts vary from mine to mine and from job to job within a coalfield and even more between different coalfields. The greatest differences in dust exposure, however, are between countries where the work practices and the regulations controlling exposure are different. This can have profound effects on the prevalence and characteristics of the occupational lung disease among coalworkers in different places.

The exposure to dust in opencast mining is much lower than in underground mining. However, there is evidence that some workers in opencast coal mines develop radiological changes of pneumoconiosis, perhaps contributed to by the quartz content of the dust.1
Simple coalworkers' pneumoconiosis

This condition develops after relatively high cumulative exposures to underground coal mine dust, usually over a period of more than 20 years (see below). It has been a source of continuing controversy in the UK and internationally, with some people arguing that it is not associated with any respiratory disability unless the relatively rare complicated form of the disease is present. Others have presented convincing evidence of a loss of lung function related to cumulative dust exposure in coalworkers and ex-coalworkers without complicated pneumoconiosis, which can be severely disabling in some men as a result of the associated chronic airflow limitation (mainly emphysema). During the last three decades, much evidence has accumulated in favour of the proposition that coal dust exposure can produce serious respiratory disability in the absence of complicated coalworkers' pneumoconiosis, and this is now generally accepted.5

The features of simple coalworkers' pneumoconiosis result from accumulation of dust in the lung parenchyma and the tissue reaction to that dust. Typically, the chest radiograph shows small, rounded opacities scattered through the lung fields (see Chapter 68, Imaging in occupational lung disease, Figure 68.3). In the early stages, there is little or no impairment of lung function. Pathologically, there are simple coal macules: collections of dust-laden macrophages around the terminal bronchioles in the centre of the acinus, with a little surrounding centrilobular emphysema ('focal' emphysema).

If men are removed from dust exposure at this stage, very few will progress to complicated pneumoconiosis and most will not suffer respiratory impairment. However, even without further dust exposure, some men have a progression of disease. The opacities on the chest radiograph tend to become more irregular in shape, an obstructive pattern of lung function loss occurs and the lungs pathologically show increasing emphysema and fibrosis around the centrilobular collections of dust-laden cells. The picture is often complicated by the effects of cigarette smoking, but severe pathological emphysema can occur even in non-smoking coalworkers (or, more usually, retired coalworkers) with heavy dust exposure.7 There is good evidence of an excess of pathological emphysema, including severe degrees, in coalworkers compared with non-coalworkers, taking smoking into account.8 Studies from the Institute of Occupational Medicine in Edinburgh demonstrated a dose–response relationship between pathological emphysema and dust exposure in coalworkers9 and showed there could be important loss of lung function associated with coal dust exposure in non-smoking coalworkers.10

Research on the relationship between radiographic appearances, pathology and lung function in coalworkers has shown that small irregular opacities are better associated with emphysema and loss of lung function than small rounded opacities.11 Research in South Wales demonstrated an association between years of coalwork and small irregular opacities6 and evidence from the Pneumoconiosis Field Research scheme set up by British Coal confirmed a relationship between small irregular opacities, as well as small rounded opacities, and cumulative dust exposure.12

The main cause of lung function loss and disability in men with simple coalworkers’ pneumoconiosis is emphysema, sometimes with associated fibrosis. Cases of interstitial fibrosis, with or without changes of simple coalworkers’ pneumoconiosis, have been reported in coalworkers,13 but there is no evidence that interstitial fibrosis is more common among coalworkers than non-coalworkers. Until relatively recently, the prevalent belief, in the UK at least, was that emphysema in men with simple coalworkers’ pneumoconiosis was due to other factors, mainly cigarette smoking, and not related to the pneumoconiosis process. However, in 1993, emphysema and chronic bronchitis became prescribed diseases in coalworkers under the UK Industrial Injuries Disablement Benefit (IIDB) scheme (see under Disability benefit for coalworkers’ pneumoconiosis and Chapter 8, Compensation schemes). Coggon et al.14 found that the mortality from coalworkers’ pneumoconiosis varied greatly between coalfields in the UK, whereas the mortality from chronic bronchitis and emphysema varied less and did not correlate with the pneumoconiosis mortality, and suggested that this indicated the two conditions were related to different features of the coal dust. Another approach is to consider both conditions as part of the overall picture of the lung reaction to accumulated dust, with variation according to features of the dust itself and to individual susceptibility factors.

Complicated coalworkers’ pneumoconiosis

This describes cases in which simple pneumoconiosis is complicated by additional (related) pathology. As a group, coalworkers do not have an increased risk of tuberculosis or lung cancer. However, coalworkers with high exposure to hard rock dust and with features of silicosis are at increased risk of tuberculosis, and possibly also lung cancer (see Chapter 80, Epidemiology of silica-related disease). The pneumoconiosis 'complication' usually takes the form of large masses of solid tissue within the parenchyma, and is disabling. There are three main causes: coal mine dust itself, quartz encountered in coal mines, and dust plus rheumatoid disease.

PROGRESSIVE MASSIVE FIBROSIS

The most frequent type of mass occurring in the lungs of coalworkers with heavy dust exposure is circumscribed, smooth in outline and a uniform black or dark grey. It is usually in the upper or middle zone, oval in shape, with the long axis parallel to the pleura and the outer surface initially 2 or 3 cm from the pleura. It is convex, the inner
surface can be flattened or slightly concave and is clearly separate from the hilum (Figure 81.1). Size ranges from around 3 cm to over 10 cm long. The masses may appear singly or one in each lung and others may appear some years later. They may be missed (except in retrospect) for several years because each first shows as a faint but clearly defined area of increased density which becomes denser and slightly smaller as the years go by. Due to emphysematous change in the lung between the mass and the pleura, they appear to move towards the hilum over time. They are not detectable on physical examination, but are associated with a definite loss of lung function. The lung function loss is mainly obstructive, partly because the lesions distort and produce scar emphysema in the surrounding lung and partly because they usually occur on a background of heavy simple pneumoconiosis with associated emphysema. Some loss of lung volume can occur due to the space occupied by large progressive massive fibrosis (PMF) masses.

After many years, these masses may cavitate and yield, once or repeatedly, large quantities of material like black ink (so-called ‘melanoptysis’), which is necrotic tissue and dust. Death may occur from aspiration of the black material or from associated haemoptysis, but this is uncommon. The cavity may shrink and cause no further trouble or become infected with fungi (to form a mycetoma) or with opportunistic mycobacteria. Both can be life-shortening in spite of treatment and are indications for surgery if lung function permits. Infection with Mycobacterium tuberculosis is not a feature of straightforward PMF and the lesions are not prone to malignant change.

Pathologically, before they cavitate, the lesions are firm and rubbery with no definite capsule. On microscopic examination, there is a great deal of amorphous ground substance mixed with the dust and the ghosts of macrophages, but no collagen. At the periphery, there are living macrophages and other mononuclear cells set in a reticulin network. The blood vessels within the mass show a low-grade inflammatory change leading to obliteration. The sitting and shape of the mass suggests that the vascular occlusions are secondary. Immunoreactive cells and immune complexes are present in the lesions, especially around the periphery. PMF may result at least in part from an immune reaction to dust in the hilar lymph nodes, with passage of activated material back into the lung parenchyma by invasion of bronchi or branches of the pulmonary artery.

The attack rate of PMF among coalworkers is strongly influenced by the cumulative dust exposure and the radiographic category of simple pneumoconiosis. Development of PMF is unlikely in men with less than category 2/2 simple pneumoconiosis. However, it can occasionally occur at low profusions of simple pneumoconiosis. A few men may develop it long after they have stopped being exposed to dust. Reported rates of PMF...
have varied considerably over time and between coalfields. PMF was especially common in South Wales from the 1930s to the 1960s: in the 1950s, 30 per cent or more of coalworkers with category 3 simple pneumoconiosis developed PMF over an eight-year follow up. In individual men, the risk of PMF is also related to the amount of quartz in the dust, and to tuberculosis. Studies of genetic markers involved in inflammatory and fibrotic processes have so far failed to identify specific genetic variations related to the risk of developing PMF.

SILICOSIS IN COALWORKERS

The lesions of subacute or chronic silicosis may be seen in coalworkers. They can usually be traced to exposure to quartz in work on shafts and drivages, or to coalface dust with an exceptionally high quartz content (more than 10–15 per cent) due to hard heading or to working rock-contaminated coal. Coalworkers with these exposures may show larger, rounded (‘r’) opacities in the lung fields, subsequently leading to confluent irregular massive shadows in the upper zones with pleural thickening, hilar enlargement, calcification of the parenchymal shadows and eggshell calcification of the hilar nodes (see Chapter 79, Silica and silica-related diseases). More commonly, coalworkers with relatively high quartz exposure have the features of coalworkers’ pneumoconiosis, with or without typical PMF lesions, mixed with some features of silicosis, or they may have a few typical silicotic nodules found in the lung or hilar nodes at autopsy.

RHEUMATOID PNEUMOCONIOSIS

At the peak of the surge in PMF cases in the mid-twentieth century, Caplan, working in South Wales, noticed atypical shadows on the radiograph of coalworkers who also had rheumatoid arthritis. The shadows could appear at any level of dust exposure, being relatively common in young miners with little or no simple coalworkers’ pneumoconiosis and with short exposure.

The lesions were round, 1–4 cm in diameter, and usually about 2 cm in from the pleura (Chapter 68, Imaging in occupational lung disease, Figure 68.4). There was no definite change in the surrounding lung so that they looked like secondary cancer deposits. They often remained the same size for months or years and then enlarged by perhaps 0.5 cm, sometimes at the same time as new lesions appeared. Clinical arthritis often developed later than the lung lesions and was relatively mild, but the men were seropositive for rheumatoid factor. After perhaps five or ten years, the lesions sometimes cavitated (with a brief flu-like illness followed by the coughing up of inky sputum often with haemoptysis, which could be severe). The cavities that formed often closed and the lesions recavitated at intervals. As they enlarged, lesions lying close together often used to form large lumpy masses which were difficult to distinguish from PMF or confluent silicosis. The distinction could only be made histologically. It is not known whether the treatments given for rheumatoid arthritis affected the course of the lung lesions. The prognosis in the absence of further dust exposure depended on whether the rheumatoid disease became inactive, but the risk of cavitation remained.

The histology of the early lung lesions showed the same regular arrangement of subacute inflammatory cells as rheumatoid nodules in other tissues. Older lesions showed central necrosis with new concentric layers of inflammatory reaction surrounding it. This layered pattern is so characteristic that rheumatoid lesions causing massive shadows or adding to the lesions produced by coal dust or quartz could be identified easily. Rheumatoid pneumoconiosis was not necessarily associated with the other lung lesions of rheumatoid arthritis. Between 100 and 200 cases of this syndrome were identified in South Wales. In the rest of the United Kingdom, and indeed the rest of the world, only isolated cases have been reported. It seems to have been a characteristic of South Wales at that time and few new cases from the area have been reported since. Rheumatoid pneumoconiosis has also been reported rarely in men with silicosis or asbestosis.

Disability benefit for coalworkers’ pneumoconiosis

Coalworkers’ pneumoconiosis is covered by occupational disability benefit schemes in countries that have such schemes. In the UK, it is a prescribed disease and attracts benefit under the Industrial Injuries Disability Benefit scheme. Prior to 1993, Industrial Disability Benefit was payable to coalworkers with simple pneumoconiosis if their chest radiograph showed at least category 2/2 profusion of small rounded opacities. The level of benefit was low since it was argued that the simple pneumoconiosis itself did not lead to disability. Sometimes, a small amount of additional benefit was granted for concomitant emphysema and chronic bronchitis, but only if the radiograph showed the qualifying changes (category 2/2 rounded opacities). Severely disabled men were generally considered to be suffering the effects of cigarette smoking and men who claimed to smoke little or not at all were usually not believed.

In 1992, the UK Industrial Injuries Advisory Council (IIAC) recommended prescription of chronic bronchitis and emphysema in coalworkers with 20 years’ underground exposure, a loss of lung function (FEV₁) of at least 1 litre below the predicted value, and evidence of dust retention (category 1/1 changes on the chest radiograph). In 1996, IIAC recommended removing the requirement for evidence of dust retention on the chest radiograph. The new system was criticized on the grounds that the radiograph is a better index of actual exposure and dust retention in the lungs than the length of time underground.
SLATE WORKERS' PNEUMOCONIOSIS

Exposure to slate dust

The slate quarries and mines in North Wales supplied most of the slate for the roofing of factories and houses in the United Kingdom during the nineteenth century, and produced slate for export in large quantity. Because explosives and machines tended to shatter the slate and make it unsuitable for roofing or cladding, most of the work had to be done by hand. At its peak at the end of the nineteenth century, the industry employed about 100,000 people in many small businesses. The industry subsequently dwindled because it could not compete with synthetic roofing and cladding material made close to the point of use.

Slate is formed by the sedimentation of a mixture of finely divided mineral particles in layers on to a flat surface. The mixture varies from layer to layer and site to site. The North Wales slate contains mica, feldspar and anything from 15 to 35 per cent crystalline quartz (other deposits may contain over 60 per cent crystalline quartz).

When splitting slate by hand, a little puff of respirable dust is released every time the rock is split along the plane of cleavage (Figure 81.2). The pneumoconiosis among slate workers was recognized over 100 years ago when ‘silicosis’ was diagnosed and attributed to the use of mechanical saws to cut slabs dry and the dry engraving of tombstones. That work was often done in sheds and was very dusty. The introduction of wet working (Figure 81.3) some 100 years ago was thought to have solved the problem of lung disease in slate workers.

The disease

Up to the 1950s, the high rate of chest disease in the slate-working areas of North Wales was attributed to tuberculosis. However, a subsequent study, which included men who had left the slate industry, found evidence of radiographic change and loss of lung function related to time spent in slate work. The jobs with most exposure were ‘getting’ of slate underground (as opposed to open quarrying) and ‘dressing’ of roof slates indoors.

The radiographic changes in slate pneumoconiosis are somewhat different from silicosis seen in other industries. The findings in North Wales were as follows: Against a clear background or a low profusion of smaller rounded opacities (‘q’ or ‘p’), ‘r’ shadows appeared in the upper zones in the older men. These sometimes remained static and calcified and sometimes coalesced to form irregular massive shadows. The massive shadows were difficult to distinguish during life from cavitating tuberculosis because the associated emphysema looked like cavitation. There was sometimes patchy pleural thickening overlaying the irregular coalescent masses in the upper zone or evidence of more extensive pleurisy. However, the most unusual feature was the amount of bilateral hilar gland enlargement with eggshell calcification which was found even in some men with no radiological evidence of parenchymal disease. The lung dust burden at autopsy is high, perhaps 100 g per lung, and the proportion of quartz higher than in the inspired dust. The radiographic changes and pathology were those of a mixed dust pneumoconiosis with only part of the abnormality in the lung and the hilar nodes in the form of silicotic nodules.

The risk of tuberculosis in men with radiological slate pneumoconiosis in North Wales seems to have been at least as high as that reported by Westerholm in patients with silicosis in Sweden. Many of the cases were treated with conventional courses of chemotherapy.

Despite the reduced exposure to dust in the North Wales slate industry, a 24-year cohort mortality study (1975–98) found an excess of deaths among slate workers compared with controls, mainly due to respiratory disease and pneumoconiosis. Dust measurements in the slate industry in Norway found up to 41 per cent quartz in the respirable dust and levels of quartz exposure often above the Norwegian limit value, leading to concern about development of silicosis among the exposed workers. Silicosis has been reported in small-scale slate pencil manufacture in India, where the workers, often teenagers,
sawed pencils from blocks of slate containing up to 60 per cent quartz. Gross disease and early deaths resulted.

**KAOLIN PNEUMOCONIOSIS**

Kaolin (china clay) is formed by the action of water on granite. In Cornwall, in the United Kingdom, the deposits of clay are still in the cone-shaped holes in the granite where they formed. They are associated with silica sand, mica, fluorspar and undegraded granite (china stone). In other parts of the world, such as in the southern United States, the clay was washed out of the granite and sedimented into layers of pure clay millions of years ago. Such pure deposits are sufficiently free of parent minerals that clay can be dug out, dried and sold without purification. However, in the main Cornish industry, the clay is extracted with high pressure hoses and the contaminating mica and silica sand removed by sedimentation before drying and marketing as a fine powder. The level of contamination of the product by quartz and mica depends both upon the nature of the original deposit and the method of extraction. The exposure in one country may be quite different from that in others. Whereas, by the time it is handled dry, Cornish kaolin seldom contains as much as 1 per cent of quartz (with up to 7 per cent fluorspar and 6 per cent mica), some of the ‘ball clays’ which are dried directly may contain up to 20 per cent quartz.

The kaolin itself (kaolinite) is a multilayered particle made up of alternating plates of aluminium hydroxide and silicon oxide and is a powerful adsorbent. Nowadays, more is used as a filler for paper than for making crockery. It is also used as a thickener for paints, as an ingredient of special plasters and as a medication for treating diarrhoea. In Cornwall, a byproduct of the industry was ‘china stone’. Lumps of quartz-containing stone in the kaolin deposit were either shipped unground to the potteries for milling or were milled locally and added to the kaolin before it was sent to the potteries.

In the pottery industry, any hazard from kaolin was swamped by the effect of silica. In Cornwall, most of the workers lived well beyond retiring age so that the occasional case of serious chest disease was attributed to tuberculosis, to silicosis from working in the tin mines or from milling ‘china stone’. Early animal studies compared the effect of inhaled kaolin with inhaled quartz. The kaolin effect was described as minor with a reticulin reaction, but no true fibrosis. As a result, kaolin was classified as a nuisance dust (nuisance dusts are low toxicity dusts regulated in the UK to 4 mg/m³ respirable).

**The disease**

An early survey by Sheers described changes on the radiograph in men working with kaolin who had not had any obvious exposure to quartz. Kaolin workers develop an exposure-related simple pneumoconiosis similar to that seen in British coal miners. Even though the dust appears to have contained considerably less than 1 per cent quartz, the simple rounded opacity change appeared earlier than for coalworkers. Men who had worked a lifetime in the dustiest jobs could reach category 2/2 change by retiring age. Although some coalescence is seen, calcification and hilar gland changes are rare. Progressive massive fibrosis is not now seen in working and recently retired men, but has
been found in men seeking compensation after leaving the industry in the past. The massive shadows tend to be smooth outlined, resembling those seen in coalworkers’ pneumoconiosis rather than those seen in silicosis.

Further detailed surveys of ventilatory capacity, respiratory symptoms, radiographic changes and exposure to kaolin, confirmed radiographic changes and a small loss of lung function related to exposure.\textsuperscript{35,36} They confirmed that the effects seen were mainly due to earlier, higher dust exposures and that men employed after 1971 in the Cornish china clay industry were unlikely to develop radiographic changes or lung function loss after a full working life in the industry.

In a post-mortem study of china clay workers, some of whom had ground china stone, three types of pathological change were noted: (1) nodular fibrosis similar to that seen in silicosis, related to high amounts of quartz in the lung dust; (2) diffuse or interstitial fibrosis similar to that resulting from mica exposure; and (3) massive lesions similar to those seen in coalworkers and not showing the histological characteristics of either silicosis or rheumatoid pneumoconiosis.\textsuperscript{37}

Adherence to the exposure limit for nuisance dust (4 mg/m\textsuperscript{3} respirable dust) greatly reduced the risk of kaolin pneumoconiosis in the china clay industry. More recently, in view of the evidence for an exposure–response effect, a somewhat lower, specific occupational exposure standard was set for kaolin (2 mg/m\textsuperscript{3} respirable). Concerns have been raised about the possibility of an excess lung cancer risk among kaolin workers because of the quartz content of the dust, but there is no evidence of such an excess of lung cancer, which would be expected to be small if any.

TALC

Talc is a form of magnesium silicate that has crystallized into thin plates which readily split and slide over each other. Powdered talc is used as a lubricant and parting medium in industrial processes varying from the moulding of tyres to the making of chocolate-coated toffee bars. It is also used as a filler in heat-resistant ceramics, refractories and insulators. It is perhaps best known as the fine white powder (talcum powder) used for powdering babies (and others) after bathing.

The disease

The quarrying and mining of talc and its subsequent milling to a powder have been known to be risky occupations for over a hundred years. Early reports described a disabling disease affecting a high proportion of the workers with heavy dust exposure. Talc deposits are often contaminated with other minerals and at first it was assumed that the disease was really silicosis due to quartz in the ore, but radiographs showed a fine nodular pneumoconiosis with either rounded (‘p’ and ‘q’) or irregular opacities (‘s’ and ‘t’), unlike those usually seen in silicosis. The histology also showed a more diffuse granulomatous lesion with more interstitial fibrosis and few if any of the typical silicotic nodules.

Talc was the traditional coating for surgeons’ gloves to prevent them sticking together during autoclaving. Unless carefully washed off at the beginning of an operation, some was left in the wound. Granulomas filled with talc were recognized as the cause of intra-abdominal adhesions and similar late complications of operation. In the 1950s, talc was replaced by starch powder for surgical gloves. More recently still, latex surgical gloves without any powder are recommended to reduce the risk of occupational asthma (see Chapter 72, Occupational asthma).

In 1949, McLaughlin \textit{et al.}\textsuperscript{38} described fibrous particles and coated fibres resembling asbestos bodies in a case of talc pneumoconiosis arising in the motor tyre industry. In the early 1960s, when the full extent of the risks of asbestos was being explored, the situation with regard to talc was reviewed because some ore deposits contain fibrous forms of calcium and magnesium silicates (tremolite, actinolite and anthophyllite), which are really forms of asbestos. Regulations were introduced in the United Kingdom to restrict the importation of talc for cosmetic use to material completely free of fibres. No such controls, however, were applied to talc for industrial purposes.

Epidemiological work in the United States clarified the situation. Talc from Montana, Texas and North Carolina is almost free from fibres and contains very little quartz. Heavily exposed workers showed a simple rounded opacity pneumoconiosis without significant loss of lung function, although some develop disabling pleural changes. There was no increase in cancer.\textsuperscript{39} Talc is also produced in New England where the deposits vary in their tremolite content. In exposed workers, there was a variable incidence of disabling interstitial fibrosis leading to right heart failure in some workers and a simple non-disabling pneumoconiosis in others.\textsuperscript{40} The evidence suggests that the severe disease is associated with fibre (tremolite, actinolite or anthophyllite) contamination; exposed workers also have an increased risk of lung cancer and mesothelioma (see Chapter 77, Epidemiology of asbestos-related diseases).

Tremolite falls into the group of asbestos minerals with no safe limits of exposure. Therefore, talc deposits containing respirable tremolite fibres should not be worked and the use of talc from such deposits in industry is banned in developed countries. On the other hand, there appear to be adequate deposits of fibre-free talc and there is no reason why talc from these sources should not continue to be used for industrial and cosmetic purposes.

THE MICAS AND VERMICULITE

This family of silicates shares the same crystal structure (monoclinic with basal cleavage) which forms flat sheets like talc but often on a much larger scale. They are aluminium
and potassium silicates with varying amounts of magnesium, iron, lithium and sodium, and have a number of geological names such as muscovite, biotite and phlogopite.

The large transparent sheet material (mostly mined in India) was used as window glass in stoves and furnaces because of its heat resistance. Other sheet material was used as an insulator in the electrical industry and the waste material was ground and used instead of talc. Synthetic materials have replaced mica for most purposes, except perhaps as a filler in iridescent paints and in those countries where mica is produced, such as India and South America.

A benign simple pneumoconiosis has been reported in men mining and milling mica,\(^4^1\) as well as the occasional more serious case.\(^4^2\) Animal experiments have not given a clear answer about whether pure mica is fibrogenic; it is likely that the pneumoconiosis in humans exposed to mica dust is usually due to contaminating minerals, including quartz.\(^4^3\)

### Vermiculite

Vermiculite is a poorly compacted form of mica which exfoliates to occupy more than ten times its original volume when heated. It is then used as an insulator for roof spaces, domestic stoves, etc., and in lightweight materials which combine fire resistance with insulation. Like the other micas, pure vermiculite does not appear to be a significant risk.

Amandus and colleagues\(^4^4\) described a cluster of mesotheliomas around a commercial deposit of vermiculite in Montana. Although the recent product does not contain easily detectable quantities of tremolite, apparently sufficient tremolite fibre was released in the past to have caused primary lung cancers and mesotheliomas. Not all vermiculite deposits are contaminated with fibrous tremolite.

### Diatomite (Kieselgahr)

Diatomite, or diatomaceous earth, is a soft rock or clay resulting from the dust deposition of dead plankton (diatoms) on the floors of lakes and shallow seas. It is of geologically recent origin, so that the skeletons of the diatoms are still easily seen under the microscope. The main constituent is amorphous silica with some calcium, magnesium and aluminium silicates. Depending on how dry the deposit is, the extraction may or may not be dusty. Heat processing is carried out in two stages: (1) drying and burning off the residual organic content; then (2) treatment at about 1200°C (calcining) which converts the amorphous silica to cristobalite (see below).

Diatomite is milled and marketed as a fine powder after either stage 1 or 2. The stage 1 material is used in face powder, as an improver for heavy soils, as a filter aid and to clarify soft drinks. The stage 2 material can be used (dry) for polishing or in special plasters and cements and ceramics.

Serious progressive pneumoconiosis leading to respiratory failure and with a high risk of tuberculosis has occurred with exposure to diatomite.\(^4^5\) Histology showed silicotic nodules in some cases, but a more diffuse cellular reaction (similar to that found with talc) in others.

Epidemiological investigations indicate that the serious risk comes from the calcined product, which contains cristobalite. There may be a risk after stage 1 if this process is carried out at too high a temperature (above 600°C). In a follow-up study of diatomite mine and mill workers in California, radiographic abnormalities were rare and definite pneumoconiosis was not found in workers with less than 25 years of service, despite the fact that the processing included flux-calcination with opportunity for exposure to cristobalite.\(^4^6\) More recent studies in workers in the diatomaceous earth industry have demonstrated radiographic evidence of silicosis related to the exposure of respirable crystalline silica (in the form of cristobalite)\(^4^7\) and a dose–response relationship between exposure to cristobalite and risk of lung cancer, even in the absence of silicosis.\(^4^8\)

### OTHER NON-FIBROUS CLAYS

#### Bentonites, montmorillonite and Fuller’s earth

This ill-defined group comprises mixtures of poorly crystallized and amorphous silicates of sodium, potassium, aluminium and magnesium. Bentonites are versatile clays consisting predominantly of montmorillonite, a clay mineral of the smectite group, and are almost always contaminated in their raw state with crystalline silica. Extensive deposits are linked to large volcanic eruptions. Bentonite rocks form mainly from the devitrification of volcanic glass in pyroclastic and/or volcaniclastic rocks subject to hydrothermal activity or other aqueous environments, such as alkaline lakes, marine sediments or by percolating groundwater.

Today, bentonite is a key raw material in the production of energy and metal castings, and other applications of great importance to the world economy. These clays are used in many building materials and as drilling muds, for example in oil exploration and mining. They also have adsorbent qualities and were traditionally used since Roman times in cleaning raw wool (fulling). They are used in treating patients who have swallowed poisons or have diarrhoea, as a vehicle for pesticides, to prevent workers slipping on oil spills and as cat litter. They are nearly always processed and marketed according to the uses they are designed for. High-end products containing contaminant-free bentonite include paint, ink, cosmetics and pharmaceuticals.

Epidemiological data are scarce. Some operations seem to cause a simple pneumoconiosis,\(^4^9\) but more aggressive disease has been reported.\(^5^0\) It is not clear whether the disease reported is due to the clay itself, to the contaminating crystalline materials or to the products of calcining. Overall, the limited data available suggest that the toxicity of bentonite particles in the lung is low.\(^5^1\)
Gypsum, plaster of Paris

Gypsum is a hydrated calcium sulphate in microcrystalline form that is used in the building industry, especially in plaster board. Careful heating will drive off part of the water to produce ‘plaster of Paris’ which sets when mixed with sufficient water to return it to the fully hydrated state. Gypsum is found in many places and varies from rock (alabaster and selenite) to soft clay. Some deposits are contaminated with quartz and others contain elongated crystals (needles) that might resemble fibres. Long crystals also form when gypsum is processed to make plaster board. Gypsum is mined, dried and sometimes ‘calcined’ before being milled and marketed in powder form. The mines may be opencast or deep; the level of dust exposure and the quartz contamination vary considerably.

Gypsum is classified as a nuisance dust because workers survive many years of exposure without serious respiratory difficulty and animal studies using pure gypsum have failed to produce lung fibrosis. However, study of two English deposits reported that pneumoconiosis can occur.52 A simple pneumoconiosis with radiological changes up to category 2/1 was seen with only minor loss of lung function; disability occurred in the most heavily exposed. Disease was more frequent in the area where the quartz content of the dust was higher.

Gypsum needles are unlikely to be pathogenic in the lungs because of their short half-life (estimated at minutes) as a result of their high solubility.53,54 Epidemiological studies of workers exposed to pure-phase gypsum dust have not found evidence of lung fibrosis or pneumoconiosis (see, for example, Refs 55 and 56). In tests on rat and guinea pig lungs, aerosols of calcium sulphate fibres were quickly cleared via dissolution and mechanisms of particle clearance.57 In a chronic inhalation study, Schepers et al.58 found that calcined gypsum dust produced minor effects in the lungs of guinea pigs.

Carbon black is produced by the incomplete combustion of heavy petroleum products, and a small amount from vegetable oil. It is a form of amorphous carbon with a high surface area to volume ratio, although its surface area to volume ratio is low compared with activated carbon. It differs from soot because of its much higher surface area to volume ratio and significantly less (negligible and non-bioavailable) polynuclear aromatic hydrocarbons (PAH) content. Carbon black is used as a pigment and as reinforcement in rubber and plastic products. Its main use is in tyres.

Studies of lung cancer among carbon black manufacturing workers have been inconclusive. The International Agency for Research on Cancer classifies carbon black as possibly carcinogenic to humans.59 Studies of workers in European carbon black production plants have found symptoms of chronic bronchitis, small lung function reductions and small opacities on the chest radiograph associated with measures of current and cumulative dust exposure.60 There is evidence that the radiographic abnormalities may be reversible after reduction or cessation of exposure.61

Key points

- Coal dust exposure, usually over ten years or more, leads to both simple coalworkers’ pneumoconiosis and to chronic bronchitis and emphysema; serious disability can result, mostly due to the emphysema.
- Radiographically, the small rounded opacities of simple coalworkers’ pneumoconiosis relate to the dust exposure but not to lung function loss, while small irregular opacities relate to exposure, lung function loss and degree of emphysema.
- The development of progressive massive fibrosis is mainly related to cumulative dust exposure; immune mechanisms are also involved, and high quartz content of the dust and tuberculosis increase the risk.
- In rheumatoid pneumoconiosis (Caplan’s syndrome), rheumatoid nodules, which may cavitate, develop in the lungs of coalworkers with rheumatoid diathesis. The syndrome may also occur rarely in silicosis and asbestosis.
- Slate workers’ pneumoconiosis is related to the quartz content of the dust; serious disease can occur with heavy exposure to slate dust.
- Kaolin pneumoconiosis is similar to simple coalworkers’ pneumoconiosis; the quartz exposure is generally low and there is no evidence of an increased risk of lung cancer in china clay workers.
- Talc pneumoconiosis is a mild condition, but some talc deposits are contaminated with asbestos and this exposure can lead to interstitial fibrosis and lung cancer.
- Exposure to carbon black may lead to a mild pneumoconiosis; studies of lung cancer have been inconclusive, but carbon black is classified by IARC as possibly carcinogenic to humans.

INTRODUCTION

The subject of metal-induced lung diseases is complex, not only because there are so many different agents to be considered, but also because the conditions caused are quite diverse. Pulmonary diseases caused by occupational exposures to metals involve more than 'pneumoconioses'; they encompass almost the entire spectrum of respiratory conditions, ranging from acute inhalation injury to lung cancer, from airway disease to parenchymal disorders. The clinical experience and epidemiological understanding of metal-induced pulmonary disease is much less extensive than for silicosis, coal pneumoconiosis or asbestos-related disease. This section is an update of the same section in the previous edition, which was itself an updated summary of an older review article containing specific references to the older literature.1

The toxicity of a metallic compound is heavily dependent on its physicochemical form, also called 'metal speciation'. Inhalation of metallic compounds does not necessarily lead to significant pulmonary damage. Lung disorders in workers occupationally exposed to metals (or metal-containing ores) are not always due to these metals, but may be due to cigarette smoking, concomitant exposure to silica (particularly in mining), asbestos, irritant gases (as in welding), organic chemicals (such as degreasing solvents, or isocyanates) or microorganisms (such as fungi or mycobacteria in metal working fluids).2 Exposure to metals is not confined to metal mining or metallurgy, but may take place in almost every sector of industry, for example as paint pigments, as catalysts in chemical processes, as well as in the general or domestic environment.

It is customary to divide metals and their alloys into ferrous metals (iron and various types of steels) and non-ferrous metals. The first category is the most widely encountered and does not pose much specific respiratory hazard, whereas non-ferrous metals can cause a number of specific respiratory conditions.

ACUTE TOXIC EFFECTS

Metal fume fever

Metal fume fever (see Chapter 44, Welding) is a non-allergic, influenza-like reaction following a single exposure to high concentrations of metal fumes. The syndrome consists of fever, chills, muscle pains and malaise, generally with relatively mild respiratory symptoms, and classically little or no radiographic or functional abnormalities, although this is not always the case. The symptoms usually begin a few hours after a heavy exposure to metal oxides and they subside spontaneously after 24 hours or a night's sleep. Peripheral leukocytosis is present during the acute illness, and studies using bronchoalveolar lavage have showed marked neutrophil infiltration and cytokine release in the lungs.3

Although metal fume fever is said to occur after exposure to the fumes of many different sorts of metals, it has been documented mainly following exposure to fumes of zinc (i.e. zinc oxide, ZnO) and to a lesser extent copper. Zinc fume fever commonly occurs, for example, after the smelting or thermal spraying of zinc without adequate exhaust, or after welding or flame cutting galvanized steel in a confined space. Workers at risk of metal fume fever are usually quite familiar with the condition; however, few cases come to the attention of physicians. No specific treatment is required, except preventive hygiene measures.
Metal fume fever is said not to lead to sequelae, but this has not been adequately investigated.

**Acute inhalation injury**

As indicated in Table 82.1, the inhalation of various metallic compounds can cause severe inhalation injury, involving the upper and/or lower respiratory tract. Depending on the agent and the intensity of exposure, the injury may manifest itself as rhinitis, laryngitis, tracheobronchitis or chemical pneumonitis and non-cardiogenic pulmonary oedema. Symptoms will, therefore, possibly include lacrimation, nose irritation with sneezing and bleeding, sore throat, hoarseness, cough, wheezing, chest pain or tightness, and dyspnoea. In severe cases, the clinical picture may be that of the adult respiratory distress syndrome. When the deep lung is involved, respiratory distress is often delayed for several hours (without any alarming symptoms) until severe non-cardiogenic pulmonary oedema develops.

**METAL OXIDES**

Exposure to metal oxides (see Chapter 12, Metals) may result from the smelting, welding, flame-cutting or thermal spraying of pure metals or alloys, but sometimes also through direct exposure to dust particles (e.g. V$_2$O$_5$, MnO) or vapours (e.g. Os$_2$O$_3$). Inhalation injury may occur with new technologies, such as those involving the thermal spraying of metals, as shown by a fatal case caused by spraying nickel.

**CADMIUM**

The best documented metallic agent causing toxic pneumonitis is cadmium. Cadmium is a byproduct of the zinc and lead industry; it is used in metal plating and in special alloys; it is also used in the production of batteries, pigments and plastic stabilizers. Cadmium oxides may be liberated, often unknown to the worker, from the welding or burning of cadmium-containing alloys and cadmium-plated metal, from the use of hard solders, or from the smelting of zinc or lead (or scrap metal), which often contain significant levels of contaminating cadmium. It is important to distinguish acute toxic pneumonitis from simple metal fume fever.

**MERCURY**

Acute pneumonitis after the inhalation of high quantities of mercury vapours has been described as a consequence of the refining of gold or silver (using amalgams) in confined spaces, which is often the case in the cottage industry, and after accidents involving (large quantities of) mercury lamps. However, there is no risk of acute lung injury after exposure to the small quantities of mercury (about 4 mg) – compared with 500 mg in a mercury thermometer – that may be released when a single energy-efficient compact fluorescent lamp (CFL) is broken.

**VANADIUM**

Vanadium pentoxide (V$_2$O$_5$) may be present in significant quantities in slags from the steel industry (ferrovanadium) and, because some fuel oils contain high quantities of vanadium, in furnace residues from oil refineries or in soot from oil-fired boilers. Dust containing V$_2$O$_5$ may cause upper and lower airway irritation: rhinitis with sneezing and nose bleeds, pharyngitis, acute tracheobronchitis, with cough, wheeze and (possibly) airway hyper-reactivity (‘boilermaker’s bronchitis’), as well as possibly bronchopneumonia.

**ZINC**

Cases of adult respiratory distress syndrome, some with a protracted course, have been reported in military or civilian personnel accidentally exposed to smoke bombs which liberate zinc chloride (ZnCl$_2$).

**OTHER METALLIC AGENTS**

Accidental exposure, for example as a result of explosions, burst pipes or leaks in chemical plants, to antimony trichloride (SbCl$_3$) and pentachloride (SbCl$_5$), zirconium tetrachloride (ZrCl$_4$), titanium tetrachloride (TiCl$_4$) and uranium hexafluoride (UF$_6$) may also lead to inhalation injury. Nickel carbonyl [Ni(CO)$_4$] is a volatile liquid of very high toxicity for the lungs and brain. Acute inhalation may cause haemorrhagic pulmonary oedema.

Lithium hydride (LiH), phosphine (hydrogen phosphide, PH$_3$, used as a doping agent for the manufacture of silicon crystals, or released from aluminum phosphide grain fumigants or zinc phosphide rodenticides), hydrogen selenide (SeH$_3$) and diborane (B$_2$H$_6$, used as high energy fuel) have also been reported to cause acute inhalation injury with, possibly, pulmonary oedema.

---

**Table 82.1** Non-exhaustive list of metallic agents described as possible causes of acute lung injury.

| Oxides of cadmium (Cd), manganese (Mn), nickel (Ni), osmium (Os), vanadium (V), cobalt (Co), beryllium (Be) |
| Mercury (Hg) vapours |
| Zinc chloride (ZnCl$_2$) and other metal chlorides (TiCl$_4$, SbCl$_3$, SbCl$_5$, ZrCl$_4$, UF$_6$) |
| Nickel carbonyl [Ni(CO)$_4$] |
| Hydrides (B$_2$H$_6$ or diborane, LiH, PH$_3$, AsH$_3$, SbH$_3$, ...) |

See also specific metals under Part two, Diseases associated with chemical agents, Section two, Metals.
Inhalation of the hydrogenated forms of arsenic (arsine, \( \text{AsH}_3 \)) or antimony (stibine, \( \text{SbH}_3 \)) can also be lethal as a result of fulminant haemolysis, which may sometimes manifest itself initially as dyspnoea, abdominal and lumbar pain, and haemoglobinuria.

**Chronic obstructive lung disease**

Occupational exposures may have a significant impact on the incidence of chronic obstructive pulmonary disease (COPD), independently of or in synergy with cigarette smoking. In general, epidemiological studies have concerned workers exposed to mine dust or to poorly specified mineral dusts. The overall conclusions of these studies are that the population attributable risk of COPD caused by occupational exposures is around 15 per cent (at least in industrially developed countries).11–13

There is good evidence that exposure to high concentrations of cadmium may cause pulmonary emphysema. This was demonstrated in a study of a group of 101 workers and ex-workers from a cadmium alloy factory in England, in which a clear excess of functional and radiological signs of emphysema were found compared with appropriate controls.14 The study found evidence of a dose–response relationship, with dose being estimated both by past hygiene measurements and by the internal (liver) cadmium burden. Other studies have found an increased mortality from non-malignant respiratory disease in cadmium-exposed workers.15

There have been many surveys of the prevalence of chronic obstructive lung disease in workers from the iron and steel industry, as well as among metal welders (see Chapter 44, Welding and Chapter 74, Extrinsic allergic alveolitis). Although exposure in the iron and steel industry is mainly to iron dust, many other metallic and non-metallic particulates (including silica and asbestos), as well as gases, may be inhaled. During welding, even of steel, the plume is not so much composed of the metals being welded together, but of the materials which make up the electrode, the filler wire and the fluxes used. Despite the generally consistent finding of an increase in the prevalence of chronic bronchitis, as defined by questionnaire, among welders and steelworkers, the results regarding ventilatory function have been largely negative, inconclusive or showing only small effects.16,17 However, because of differences in total dust, in concomitant exposure to other compounds, or in population characteristics and study designs. The absence of demonstrable effects does not exclude the existence of a preventable health risk.

**Bronchial asthma**

Several metals are known to be capable of causing bronchial asthma.23 Metal-induced asthma is a particular case of an occupational asthma caused by agents of low molecular weight, a topic which is covered elsewhere in this book (see Chapter 72, Occupational asthma). In essence, the clinical characteristics of metal-induced asthma are similar to those of occupational asthma caused by other agents. With some metals (as in fact with some organic molecules), alveolitis and asthma may coexist, as has been described with cobalt. Other forms of metal-related occupational asthma are more likely to belong to the category of non-immunologic asthma, i.e. ‘irritant-induced asthma’ or ‘occupational asthma without latency’.

The best known cause of metal-induced occupational asthma is that caused by complex platinum salts, which has mainly been described in workers from precious metal refineries. However, significant exposure to platinum may also occur in the manufacture of catalysts,24 in photographic applications and in electroplating. Platinum salts are extremely potent sensitizers and are generally considered to do so via IgE-mediated pathway. Palladium25 and rhodium salts26 are other precious metal salts that may occasionally cause occupational asthma (see Chapter 12, Metals).

Nickel, chromium and cobalt are also potential causes of occupational asthma, although the number of reported cases is not high, certainly compared with the high prevalence of allergic sensitization of the skin caused by these metals. This may be partly due to differences in mechanisms of immunological sensitization, but there is probably also some degree of underdiagnosis. Patients with asthma caused by nickel or chromium often also have urticaria or allergic contact dermatitis.27 Significant exposure to hexavalent chromium
occurs mainly in chromate production industries, in chrome plating, during stainless steel welding, but also in the building industry because cement often contains small amounts of chromates, which is not only a frequent source of allergic contact dermatitis, but occasionally also an unsuspected cause of occupational asthma.28

Most cases of cobalt asthma have been described in relation to the manufacture or grinding of sintered hard metal, in which cobalt is used as a binder for tungsten carbide.29,30 Coolants used in wet grinding of hard metal tools may contain a high concentration of dissolved (i.e. ionized) cobalt, thus leading to the paradox that wet grinding may be more 'harmful' than dry grinding.31 Cobalt asthma has also been found in relation to the production of cobalt,32 the manufacture or use of cobalt pigments or additives, and in diamond polishers. It is possible that cobalt asthma is but an ‘airway variant’ of hard metal disease (see Hard metal lung disease – ‘cobalt lung’, p. 1045) and there are occasional subjects who exhibit both asthmatic reactions and parenchymal involvement.

Pot room asthma is a particular form of occupational asthma described in aluminium smelters (see Chapter 13, Aluminium), who are exposed to the fumes evolving from the ‘pots’ in which aluminium ore is molten after the addition of fluoride salts. Several clinical and epidemiological studies carried out mainly in the Norwegian aluminium industry,33 but also elsewhere,34 have described ‘pot room asthma’. The exact causal agent of this form of asthma is not known and it probably does not involve allergic mechanisms. It seems more likely that pot room asthma is a form of irritant-induced asthma, with the irritants being most probably the fluorides present in the fumes. Occupational asthma has also been reported as a result of exposure to aluminium fluoride salts.

There are rare reports35 of asthma in subjects welding galvanized metal, with sensitization to zinc being postulated on the grounds of a positive bronchial challenge. Similarly, occupational asthma due to soldering fluxes containing zinc chloride has been described.36 However, no immunological support for sensitization to zinc has been provided. It is conceivable that (some) individuals with non-specific bronchial hyperreactivity exhibit asthmatic reactions when they have a bout of metal fume fever. The possible presence of metals other than zinc should also be considered in such instances.

Exposure to vanadium, usually as vanadium pentoxide (V₂O₅), has been reported as a possible cause of occupational asthma. This exposure has been described in workers who maintain, clean or dismantle oil-fired boilers, because the fly ash produced by some types of fuel oil may be very rich in vanadium (see Chapter 37, Vanadium). From the available evidence it appears that this form of asthma essentially results from the strong irritation produced by V₂O₅ which may cause nasal ulceration and acute bronchitis, with more or less lasting non-specific bronchial hyper-reactivity as a result.

In addition to the specific causes of occupational asthma described above, steel welding is often mentioned as a cause of occupational asthma or as a risk factor of asthma.37–41 It is not clear whether these are cases of asthma from metal sensitization, ‘irritant-induced’ asthma due to irritant gases, or work-related asthmas (see Chapter 44, Welding). A study from Finland described a series of 34 workers (welders, fitters, plumbers and others) with a history of occupational asthma occurring after many years (22 years on average) of being exposed to stainless steel welding fumes, and whose occupational asthma was confirmed by challenge tests with fumes from stainless steel welding; none of these subjects had positive skin prick tests to metal salts.42

**Lung cancer**

Several metallic compounds are proven lung carcinogens in humans and include radioactive metals (and their decay products) and non-radioactive metals (see Chapter 85, Occupational cancer: Epidemiology, biological mechanisms and biomarkers). The increased incidence of lung cancer observed in uranium miners has been causally linked with the inhalation of radon daughters.43 However, the underground mining of other compounds may also be associated with significant exposure to radioactivity, if there is insufficient ventilation of the radon which leaks from igneous rocks.44 This factor has been implicated in the higher incidence of lung cancer seen in various groups of mine workers, such as Swedish iron ore miners,45 although it does not seem to play a role in the similarly increased lung cancer incidence of French iron ore miners.46 Domestic radon gas exposure is also implicated in the causation of bronchial cancer.

The epidemiologic evidence of the relation between exposure to specific metallic agents and lung cancer has been reviewed in detail by Wild et al.47 Epidemiological and experimental studies have clearly established the carcinogenic risk of exposure to arsenic, chromates and nickel, at least to some of their chemical forms. Thus, the relationship of arsenic to increased lung cancer risk in copper smelting workers is unequivocal. This is also the case for other occupational exposures to arsenic, such as the manufacture or spraying of arsenical pesticides. A greatly increased risk of lung cancer has also been demonstrated for workers in the primary chromate production and in the chromate pigment industry. Epidemiological studies of the carcinogenic risk of exposure to chromium during metal plating or during stainless steel welding have been inconclusive. Occupational exposure to nickel compounds in nickel smelters and refineries is clearly associated with an increase in cancer of the lung and the nasal sinuses. Cadmium and beryllium are also considered as human lung carcinogens. A re-evaluation of the carcinogenicity of cobalt compounds by the IARC concluded that occupational exposure to cobalt with tungsten carbide is possibly carcinogenic for humans (group 2A),48 mainly based on
epidemiological studies showing increased lung cancer risks in workers from the hard metal industry.\(^{45,50}\)

Moreover, in many epidemiological studies, occupations involving exposure to (less well specified) metallic agents appear to be associated with increased risks of lung cancer.\(^{51–54}\) Studies of iron and steel foundry workers have consistently found an increased risk of lung cancer, but this may be due to other agents, such as silica or asbestos, or to polycyclic aromatic hydrocarbons emitted as pyrolysis products of organic materials used.

**PNEUMOCONIOSES AND SPECIFIC INTERSTITIAL LUNG DISORDERS CAUSED BY METALS**

Some epidemiological surveys have revealed that subjects with ‘idiopathic’ lung fibrosis are more likely than controls to have been occupationally exposed to metals (and also to wood).\(^{55,56}\) This means either that many patients receive a diagnosis of idiopathic lung disease because no good occupational and environmental history has been taken, or that some metals may play a hitherto unrecognized role in the causation of interstitial lung disease. Both explanations are probably valid to some extent.

Documentation of exposure to metals may be obtained from the analysis of metal concentrations in blood or urine (or even hair or nails) taken for biological monitoring. In addition, elemental analysis may be carried out on bronchoalveolar lavage fluid, on biopsy tissue or on autopsy material. Both macroanalytical (or bulk) and microanalytical techniques may be applied. The former are destructive techniques which allow the detection, quantitation and/or characterization of the crystalline structure of inorganic elements. The latter techniques allow in situ analysis of individual cells and particles. Several sophisticated microanalytical techniques, coupled with scanning or transmission electron microscopy, exist: energy dispersive x-ray analysis (EDXA), particle-induced x-ray emission (PIXE), electron energy loss spectrometry (EELS) and laser microprobe mass analysis (LAMMA). These techniques have been successfully applied in both bronchoalveolar lavage (BAL) fluid and lung biopsies, and databases of ‘normal’ values of inorganic particles are available.\(^{57,58}\) Of course, the presence of a particular element, even in abnormally high quantities, does not in itself constitute proof that it is causally involved in the disease, but it may reveal unsuspected past exposures or confirm such exposures.

**Siderosis**

Of the metallic pneumoconioses, the most frequent and best (although still poorly) studied is siderosis, which is caused by the inhalation of iron compounds. More than 90 per cent of the total world production of metallic materials is in the form of steels and cast irons, and occupational exposure to iron is, therefore, extremely widespread. It occurs during iron (hematite) mining and related operations, during iron refining and at various stages in steelmaking, during welding, cutting and abrading of iron-containing materials, as well as during the manufacture or use of iron-containing abrasives (such as emery). Despite the large number of workers who are exposed to iron-containing dust, little research has been carried out in recent years regarding the pulmonary effects of occupational exposure to iron dust. Yet, in the past decade there has been considerable interest in the possible role of iron in pulmonary diseases, because ferrous/ferric ions catalyze the Fenton reaction, whereby the very toxic hydroxyl radical (OH\(^{-}\)) is produced. It is noteworthy that workers exposed to iron have a higher risk of (lobar) pneumonia.\(^{18,19}\)

There is a widespread belief that siderosis is only a ‘radiological disorder’ which manifests itself by the presence of small, very radiodense opacities with uniform distribution throughout the lungs, without coalescence. With cessation of exposure, the radiographic opacities may gradually disappear. Pure siderosis is not associated with respiratory symptoms or functional impairment, and does not predispose to tuberculosis. However, exposure to silica or asbestos is not uncommon in many jobs that involve exposure to iron, thus giving rise to mixed dust fibrosis (‘siderosilicosis’) or to asbestosis, with their associated morbidity. The view that the symptomatic interstitial fibrosis which is sometimes found in welders (‘welder’s pneumoconiosis’), is simply siderosis with coexisting silicosis has been challenged on the grounds that the pulmonary silicon content of such cases did not differ from that of control lungs.\(^{59}\) There are case reports of siderosis with significant fibrosis in welders.\(^{16}\)

**Aluminium lung**

The existence of ‘aluminium lung’ has been the subject of some controversy. Indeed in view of the extensive industrial use of aluminium, parenchymal lung disease caused by exposure to this metal appears to be very uncommon, both at the stage of its production and during its use. On the basis of animal experimental data showing that aluminium counteracts the toxic effects of silica, inhalation of aluminium was proposed and even implemented (without real success, but also without apparent pulmonary adverse effects) for the prevention of silicosis and even for its therapy. Dinman\(^{60}\) concluded that fibrosis only occurred in workers who were heavily exposed to submicron-sized aluminium plates during the production of fireworks and explosives and in workers involved in the smelting of bauxite for the production of Al\(_2\)O\(_3\) (corundum) abrasive (Shaver’s disease). The second group was perhaps also exposed to crystalline silica. An extensive review also concluded that pulmonary fibrosis was not a significant problem in aluminium smelter workers.\(^{34}\) The conclusion is that exposure to aluminium dust does not pose an important risk of interstitial lung disease.
Nevertheless, there is still a risk. Severe interstitial fibrosis was described in three workers (out of a workforce of about 1000 workers) who had been heavily exposed for 19–33 years mainly, but not exclusively, to Al₂O₃ in the production of abrasives.⁶¹ There are reports of isolated cases of granulomatous lung disease, fibrosis and alveolar proteinosis in aluminium welders or polishers. The physical characteristics of the aluminium particles, not only their surface area, or even their possibly fibrous nature, have been suggested as important determinants of their bioreactivity and hence fibrogenicity.

**Other metal pneumoconioses**

Other rare ‘benign’ pneumoconioses include those caused by tin (stannosis), barium (baritosis) and antimony (antimoniosis). These pneumoconioses were described many years ago and few recent clinical and epidemiological data are available.

‘Dental technician’s pneumoconiosis’ is an interstitial fibrosis of many potential origins, including silica and beryllium, but possibly also vitallium, an alloy consisting of chromium, cobalt and molybdenum. The synthetic abrasive silicon carbide (SiC) or carborundum is not actually a metallic compound – in contrast to some other abrasives such as corundum (Al₂O₃) or emery (corundum with iron oxides). Respiratory disease, including pneumoconiosis with fibrosis, has been associated with exposure to silicon carbide, during its manufacture or use.⁷¹,⁷²

Recently, cases of interstitial pulmonary disease have been described in workers exposed to ‘indium tin oxide’ (ITO), a sintered material consisting mainly of indium oxide (In₂O₃, 90 per cent) doped with tin oxide (SnO₂, 10 per cent) which is used for making flat panel and liquid crystal displays. Cases of serious interstitial lung disease, with features of pulmonary alveolar proteinosis, have been reported from Japan⁷³,⁷⁴ and the United States.⁷⁵ Experimental studies⁷⁶ and epidemiologic surveys⁷⁷,⁷⁸ confirm the pneumotoxic potential of this new material.

Although no instances of pneumoconioses or interstitial lung disease caused by engineered nanomaterials have been reported as yet, the development, manufacture and use of various types of (insoluble) metal oxides as nanoparticles represent a potential threat of occupational lung disease for researchers, production and maintenance workers, if exposure to such novel materials becomes significant (see Chapter 70, Health effects of ultrafine/nanoparticles).

**Interstitial lung disease with granuloma formation**

Granulomatous lung disease has been attributed, mainly in case reports, to exposure to zirconium (Zr), during the manufacture of ceramic tiles,⁷⁹ the welding of nuclear fuel rods,⁸⁰ or lens grinding.⁸¹ Exposure to titanium,⁸² and aluminium⁸³ are also said to have led to sarcoid-like lung granulomatosis. Beryllium lung is discussed separately in Chapter 83, Berylliosis.

Exposure to rare earth metals (or lanthanides), of which cerium (Ce) is the most abundant element, has also been associated with interstitial fibrosis in a small number of subjects.⁸⁴,⁸⁵ Rare earths are essential components of carbon arc lamps used for photoengraving, and the majority of cases of this pneumoconiosis have been described in photoengravers. Deposits of rare earths have also been found, without radiologic abnormalities, in the lung of a movie projectionist.⁸⁶ Rare earths are also used in the fabrication and polishing of glass, where they have been associated with pneumoconiosis.⁸⁵,⁸⁷ The presence of granulomatous interstitial alterations is mentioned occasionally, but this is not the case in most available pathologic descriptions of cerium pneumoconiosis.

**Hard metal lung disease – ‘cobalt lung’**

Hard metal (lung) disease (sometimes also called hard metal pneumoconiosis) is a specific form of interstitial lung disease, which may occur in workers as a result of exposure to cobalt-containing dusts during the manufacture or use of hard metal or diamond tools.⁸⁸,⁸⁹ Hard metal-induced bronchial asthma, which may coexist with interstitial disease in the same patient, is sometimes included in the clinical entity of hard metal lung disease, but usually the term ‘hard metal lung disease’ is restricted to the parenchymal form of the disease.

Hard metal is a composite material composed mainly of tungsten carbide and varying amounts (5–25 per cent) of cobalt, which functions as a binder. Besides tungsten carbide, other carbides (e.g. with tantalum, titanium, niobium) may also be used and small amounts of other metals (e.g. nickel, chromium) may also be present. Hard metals are also designated as sintered carbides or cemented carbides. Sintering refers to a process by which a powder compact is converted into a solid polycrystalline material by pressing under specific conditions of temperature and pressure. Hard metals are mainly utilized in tools used for drilling, sawing, cutting, grinding or polishing various materials, such as stones, concrete, metals, wood, etc. In recent years, diamonds have also been increasingly used to make grinding tools or saw blades and here too, the binder used for the microdiamond powder is cobalt, which makes up to 90 per cent of the grinding surface. Although these diamond tools are not composed of ‘hard metal’, they pose a similar hazard (see Chapter 19, Cobalt).⁹⁰

The highest exposures to cobalt dust take place during the various stages of the manufacture of hard metal or diamond tools. However, hazardous exposure to cobalt may also occur during the filing and resharping of hard metal tools, particularly during wet grinding, as well as during the polishing of diamonds with diamond-cobalt disks. Coating with hard metal by the detonation gun process and related operations may also give rise to significant
exposure. All these activities often take place in small- or medium-sized factories with poor hygiene conditions, and even in large plants, tool-sharpening is often not recognized as a significant health risk.

Hard metal lung disease shares many clinical features with hypersensitivity pneumonitis: the presentation may be that of a subacute alveolitis with fever, cough, dyspnoea and a clear exposure-related clinical course, while in other instances a more insidious course with progressive diffuse fibrosis may be found. Overt disease only occurs in a minority of exposed workers and those affected may be young subjects with only a short exposure. These features clearly point to a condition caused mainly by a specific, perhaps immunological, susceptibility, as opposed to a simple process of chronic accumulation of dust in the lungs, as in the classical mineral pneumoconioses. On the other hand, hard metal lung disease also exhibits characteristics which make it distinct from hypersensitivity pneumonitis caused by organic antigens. Thus, no precipitating antibodies are found in the serum and the lung pathology and cellular findings in the bronchoalveolar lavage fluid generally differ from those of hypersensitivity pneumonitis.

The most characteristic finding in the lungs, as well as in bronchoalveolar lavage, is the presence of numerous so-called ‘bizarre’ giant multinucleated cells with ‘cell in cell’ or ‘cannibalistic’ features. The latter feature, i.e. giant cell interstitial pneumonitis, is pathognomonic for hard-metal disease. However, these giant cells may be absent and histology may exhibit desquamation of numerous cells in the alveoli (desquamative interstitial pneumonitis), lymphoplasmocyte infiltration, and varying degrees of interstitial, mainly centrilobular fibrosis. Except for the possible presence of giant cells, bronchoalveolar lavage fluid findings are non-specific, with all cell types – macrophages, lymphocytes, neutrophils or eosinophils, and even mast cells – being possibly increased. The finding of the constituents of hard metal (usually only tungsten) in the bronchoalveolar lavage fluid or lung tissue is a useful indicator of (past) exposure, but there is no quantitative relation with disease.

The evolution of hard metal lung disease is variable, but cessation of exposure usually results in clinical improvement and good recovery, but some patients progress to end-stage fibrosis. Although corticosteroids have been given, their benefit has not been established.

While the role of cobalt in the causation of interstitial lung disease in hard metal workers and diamond polishers is undisputed, exposure to cobalt alone does not appear to be sufficient to lead to parenchymal disease and fibrosis. Thus, occupational exposure to even high levels of ‘pure’ cobalt dust is apparently not associated with interstitial lung disease (although pure cobalt and cobalt salts may cause asthma).

The mechanisms for the pulmonary toxicity of cobalt have not yet been entirely elucidated. The relative rarity of the condition and the fact that it may arise after short and apparently low exposures plead for an important role of individual susceptibility. The known dermal and respiratory sensitizing properties of cobalt and some of the clinical features of the disease, including the recurrence of giant cell interstitial pneumonitis in a transplanted lung despite cessation of exposure, favour immunological sensitization as a possible mechanism. However, unlike the situation with beryllium, no hard evidence for immunological sensitization to cobalt as a cause for ‘cobalt lung’ is available. Experimental data and the observation that oxygen administration may be detrimental in ‘cobalt lung’ suggest that poor defence against oxidants may also be involved.

---

**Key points**

- Although exposure to zinc fumes leads to a generally mild condition (‘metal fume fever’), exposure to some metallic fumes, most notably cadmium fumes, can lead to severe, potentially fatal lung injury (chemical pneumonitis).
- Occupational asthma may be caused by sensitization to complex platinum salts, as well as by cobalt, nickel and chromium.
- Working in the iron and steel industry is a risk factor for pneumonia, chronic airways disease, lung cancer and, rarely, pneumoconiosis (siderosis).
- Some metals, most notably beryllium, may cause granulomatous lung disease that is clinically similar to sarcoidosis.
- Exposure to dust from hard metal (sintered tungsten carbide with cobalt) or diamond-cobalt tools may lead to interstitial lung disease, characterized by cannibalistic multinucleated giant cells in the alveoli (‘giant cell interstitial pneumonitis’).

INTRODUCTION

Beryllium has chemical and physical properties that make it an excellent material for highly technological applications. Unfortunately, it continues to cause a significant burden of illness among those who work with the metal and its alloys. Exposure occurs during the extraction and the processing of beryllium into metal alloys and ceramic raw materials, as well as during the production of beryllium-containing products that may involve heating and machining operations, and the recycling of beryllium-containing products. The spreading use of beryllium in modern industries has created a serious public health problem worldwide.1

EPIDEMIOLOGY

Berylliosis takes two principal forms: acute and chronic. The major, persisting problem in modern industry is with chronic beryllium disease (CBD) which was first described in the United States in the 1940s, when fluorescent lamp workers presented with pulmonary granulomatous disease.2 A large, but imprecisely known number of workers internationally have been exposed to beryllium, with estimates exceeding 800 000.1 A recent review placed a low end estimate for current US workers at 134 000.3,4 The prevalence of CBD, from epidemiologic studies, has been variously estimated at 1 per cent to greater than 15 per cent of exposed workers, depending on the group of workers studied. On average, CBD develops six to ten years after exposure, but has been reported to occur with a latency up to 40 years and as early as three months after initial exposure. Beryllium sensitization precedes CBD and affects approximately 1–5 per cent of exposed workers.5–24 The rate of progression from sensitization to CBD is estimated at 6–8 per cent per year.25

While the precise exposure–response relationship for CBD is not linear, certain beryllium industrial processes and job tasks with high beryllium exposures carry a higher risk.6–10,12,14,16,22,24 CBD has been detected in workers with evidence of only very low levels and short duration of exposure, with sensitization being seen at levels as low as 0.02 μg/m³ lifetime-weighted exposure.1,7,8,15–17,22,24,26–28

MECHANISMS OF DISEASE

Beryllium induces immunologic reactions in exposed and sensitized individuals, by triggering an adaptive immune response to beryllium antigen in T lymphocytes.29–31 In the presence of beryllium salts in vitro, both blood and bronchoalveolar lavage lymphocytes proliferate, forming the basis of the beryllium lymphocyte proliferation test (BeLPT), the preferred diagnostic and screening test. This response is specific for beryllium and is not induced by other metals.30,32

Lung mononuclear cell inflammation and granuloma formation is maintained by the accumulation in the lung of CD4⁺ memory T cells specific for beryllium, presented to those cells by human leukocyte antigen (HLA) molecules found on antigen-presenting cells.33

The progression from exposure to sensitization to CBD hinges partly on genetic susceptibility. Research has demonstrated that HLA-DPB1 with a glutamic acid residue at position 69 (E69) is associated with beryllium sensitization and CBD.34–42 Regardless of an individual’s genetics, CBD does not occur unless a worker has been exposed to beryllium.
CLINICAL DISEASE

Acute disease

Although acute disease is rare, exposure to elevated concentrations of beryllium can result in nasopharyngitis, tracheobronchitis and a lymphocyte-predominant acute pneumonia. Signs and symptoms are non-specific and include cough, occasionally productive of blood-tinged sputum, dyspnoea and chest discomfort. Examination may reveal airway hyperaemia, as well as rales or rhonchi. The chest radiograph may show increased bronchovascular markings, diffuse bilateral alveolar infiltrates or severe bilateral pulmonary oedema. Management is mainly supportive for acute upper airway disease and should include removal from exposure. Corticosteroids, oxygen, rest and even ventilatory support may be part of the treatment regimen, although no controlled clinical trials have been published of their efficacy.

Skin disease

Beryllium can induce a number of dermatologic conditions, depending on the form of beryllium and severity of exposure. Contact dermatitis can occur on exposed areas of skin. It generally resolves with cessation of exposure and recrudescences with re-exposure. If the contact dermatitis involves the face, conjunctivitis, periorbital oedema and upper respiratory tract involvement may occur concomitantly. Ulceration or granulomatous nodular skin lesions may occur after accidental beryllium inoculation. These persist until the beryllium material is excised and the lesion debrided.

Lung cancer

A number of large epidemiologic studies have shown an increased risk of lung cancer among beryllium-exposed workers and among workers with acute beryllium disease. The International Agency for Research on Cancer (IARC) classifies beryllium as a class I human carcinogen.

Chronic beryllium disease

Chronic beryllium disease may be asymptomatic and detected through medical surveillance, including testing for immune response in the BeLPT. Such cases typically have normal chest radiographs and resting pulmonary function, but often have abnormal gas exchange with exercise.

CBD shares many clinical and histopathological features with pulmonary sarcoidosis. It is estimated that up to 6 per cent of patients diagnosed with sarcoidosis may actually have CBD. CBD typically has a gradual course and insidious onset of non-specific respiratory and systemic symptoms, with most patients presenting with some combination of fatigue, non-productive cough, and gradually progressive shortness of breath, especially upon exertion. Anorexia, weight loss, fevers, night sweats, chest pains and arthralgias are fairly common. Dry bibasilar rales, cyanosis, clubbing, lymphadenopathy and skin changes may be present on examination, with other findings depending on the severity. With advancing disease, symptoms associated with pulmonary hypertension, cor pulmonale or respiratory failure develop.

PULMONARY PHYSIOLOGY

The pulmonary function abnormalities seen in CBD are typical of many interstitial lung diseases. A restrictive pattern with decreased lung volumes occurs in advanced disease; however, normal volumes with a mild obstructive pattern is common early in CBD. The diffusing capacity for carbon monoxide (D_{LCO}) is reduced in more advanced disease. Common abnormalities noted on exercise testing include reduced exercise tolerance, decreased oxygen consumption (VO_{2}), an abnormal fall in oxygen saturation, and widening alveolar–arterial gradient. Reduced oxygenation at rest and during exercise is a sensitive indicator of physiologic impairment.

IMAGING FINDINGS

The chest radiograph may be normal or show hilar adenopathy with reticulonodular opacification especially in mid- and upper lung zones. Thin-section computed tomography (CT) is more sensitive than chest radiography in identifying parenchymal nodules, septal lines, ground glass opacities and hilar or mediastinal adenopathy. Pleural thickening can be observed adjacent to areas of dense subpleural parenchymal nodules.

BRONCHOALVEOLAR LAVAGE AND TRANSBRONCHIAL BIOPSY

In CBD, bronchoalveolar lavage (BAL) shows increased total white cells with CD4+ T lymphocyte predominance. The extent of BAL cellularity, lymphocytosis, and BAL BeLPT response correlates with disease severity, suggesting that the magnitude of the inflammatory and antigenic response in the lung may help predict disease progression.

PATHOLOGY

The non-caseating granuloma is a hallmark of CBD, but is histologically indistinguishable from the granulomas found in sarcoidosis. Other pathologic abnormalities commonly found include a mononuclear cell interstitial infiltrate and varying degrees of fibrosis. The absence of granulomas on either transbronchial biopsy or thoracoscopic lung biopsy does not exclude CBD.
presence of multinucleated giant cells and mononuclear cell interstitial infiltrates is also consistent with CBD.

**DIAGNOSTIC EVALUATION**

The diagnosis of CBD is confirmed by demonstrating a beryllium-specific immune response, through the BeLPT on blood or, preferably, on BAL fluid, together with finding pathologic changes consistent with CBD on transbronchial biopsy. Bronchoscopy is not essential for diagnosis; the presence of a beryllium-specific immune response in the blood, together with a chest radiograph or CT scan showing changes consistent with CBD provide sufficient evidence. Patients who demonstrate a beryllium-specific immune response with normal lungs are considered to have beryllium sensitization without CBD.

**TREATMENT AND FOLLOW UP**

There is no known cure for CBD. The goals of treatment are to inhibit inflammation and slow disease progression. Removal from exposure is important. Corticosteroids are the first-line therapy for CBD, reducing symptoms and improving lung function. Indications for treatment include (1) severe symptoms, such as debilitating cough or dyspnoea; (2) abnormal gas exchange, diminished exercise tolerance or abnormal pulmonary physiology; (3) progressive decline in these tests of impairment; or (4) evidence of pulmonary hypertension or cor pulmonale. Initial therapy includes oral prednisone at a dose of approximately 20–40 mg either daily or on alternate days. After three to six months, the response to therapy should be reassessed and the prednisone dose tapered gradually to the minimum dose required to sustain symptomatic improvement. Therapy is usually required lifelong, because relapses occur after steroid withdrawal. More severe cases may require additional supportive measures, such as supplemental oxygen, to improve hypoxaemia and treat pulmonary hypertension and cor pulmonale, or diuretics for right heart failure. Obstructive ventilatory defects and cough may respond to inhaled bronchodilators and steroids. In patients who fail to respond to corticosteroids or who experience severe side effects, other immunosuppressive agents such as methotrexate (up to 20 mg orally per week) may prove effective.

Less severe cases not requiring steroid therapy should be examined and tested annually to monitor for disease progression. Patients who are beryllium sensitized without granulomatous disease should be checked for evidence of CBD, perhaps every two years, because of the risk of progression to clinical disease.

**PREVENTION**

The current US Occupational Safety and Health Administration (OSHA) exposure limit for beryllium is not protective. Industries have minimized exposure by using safer metals, improving ventilation systems, implementing administrative controls, requiring personal protection equipment, educating workers concerning the hazards and offering medical monitoring using the BeLPT. As dermal exposure might also contribute to risk, measures should also be taken to protect the skin.

**FUTURE RESEARCH**

Current and future research efforts are focused on identifying additional non-invasive tests to confirm a diagnosis of CBD, as well as seeking new treatments. Tumour necrosis factor-alpha blockers appear to be promising therapeutic agents, but no clinical trials of this approach have been completed to date.

---

**Key points**

- Broader use of beryllium in modern industry has created an increasing public health problem globally, affecting 1–15 per cent of exposed workers.
- Chronic and acute forms of berylliosis continue to occur as a result of immunologic recognition of beryllium antigen.
- Beryllium sensitization and chronic beryllium disease can be detected in workplace surveillance programmes and can be distinguished from other granulomatous disorders using the beryllium lymphocyte proliferation test.
- Chronic beryllium disease is a latent disorder preferentially affecting the lungs and immune system, as well as other organs.
- Exposure to beryllium at levels below current permissible exposure limits results in disease, necessitating strict attention to ventilation, use of personal protective equipment, administrative controls, exposure monitoring and substitution of beryllium with safer materials whenever possible.

INTRODUCTION

The history of modern occupational dermatology begins in 1915 with the first edition of Prosser White’s classic text, followed in 1939 with publications by Poul Bonnevie and Schwartz, Tulipan and Peck (and later Birmingham). Since the Second World War, the major impetus came first from Europe (and, in particular, from Sigfrid Fregert, Foussereau and Zschunke). Adams in the United States and Kanerva et al. have since produced further major texts.

There is no universally accepted definition of an occupational skin disease (or dermatosis). A broad definition is a dermatosis due wholly or partially to the patient’s occupation. Occupation must be a major factor in stricter definitions, and essential to causation in still stricter definitions.

EPIDEMIOLOGY

Dermatoses are perceived as following musculoskeletal and psychiatric conditions in the ranking of their frequency among occupational disorders. A 1995 self-reported survey in the United Kingdom led to an estimate of over 50 000 work-related conditions involving the skin. Reports to EPIDERM and OPRA (Occupational Physicians Reporting Activity) surveillance schemes in the UK between 1996 and 2001, suggested an annual rate of 720 new cases of occupational dermatoses per million at risk, according to reports to the scheme by dermatologists and occupational physicians. Reports between 2002 and 2005 suggest overall rates of 406 per million workers. These rates probably represent only the tip of the iceberg, with most cases going unreported. Data on the economic impact of occupational skin disease are limited, but the annual costs of occupational dermatoses in the United States have been estimated at up to 1000 million dollars. A study of occupational dermatitis claims in Oregon has shown an average claim cost of $3552. Financial costs will vary greatly from country to country depending on the social security systems in place, and also how the figures are estimated. The cost to the working community is a human as well as a financial one, with the disablement from an occupational dermatosis sometimes approaching that from loss of a limb. Many high-risk occupations have been identified in which the prevalence of occupational dermatoses rises as high as 15 per cent.
While 90–95 per cent\(^1\) of occupational dermatoses are contact dermatitis, their clinical spectrum also includes contact urticaria, oil folliculitis, chloracne, leukoderma, scleroderma, ulcerations and neoplasia. Many substances that cause occupational dermatoses are also capable of causing respiratory and other disorders, for example rosin (colophony), chromium, formaldehyde, (meth)acrylates and isocyanates.\(^1\) Psoriasis may be aggravated, or even initiated for the first time on the hands, by physical or chemical occupational irritants (Figure 84.1) and contact dermatitis may koebnerize into psoriasis. Scabies, though rarely occupational, may mimic contact dermatitis (Figure 84.2).

CONTACT DERMATITIS

Contact dermatitis is dermatitis caused by skin contact with external substances (Figure 84.3). It is distinguished from endogenous (constitutional) dermatitis not by morphology or histopathology, but only by aetiology. The term ‘dermatitis’, as used above, is synonymous with the term ‘eczema’, although the latter term might best be reserved for endogenous or constitutional dermatitis. Not only must dermatitis be divided into endogenous or contact (that is, exogenous), or a mixture of the two, but it must carefully be distinguished from clinically similar dermatoses, such as psoriasis and tinea. Practical experience is essential, but can usefully be supplemented by reference to well-illustrated textbooks\(^1\) and other helpful publications.\(^2\)

To cause contact dermatitis a substance must first be capable of penetrating the superficial layers of the epidermis, known as the barrier layer. This is the most superficial layer of the skin and is a paper-thin lipoprotein membrane, remarkably resistant to penetration, although vulnerable to substances of molecular weight below 1000. If a substance does penetrate to the living tissues beneath, it may then cause contact dermatitis by one of two mechanisms, contact irritation and contact sensitization (or contact allergy), which may go on to provoke irritant contact dermatitis and allergic contact dermatitis, respectively. Both forms of contact dermatitis may be morphologically indistinguishable from each other, as well as from endogenous dermatitis. Because of their predominance as the site of occupational contact, the hands are involved in as many as 90 per cent of cases of occupational contact dermatitis.\(^3\)

IRRITANT CONTACT DERMATITIS

A contact irritant is a chemical (or physical) agent capable of causing cell damage (cytotoxicity) if applied to the skin for sufficient time and in sufficient concentration. The precise mechanisms of cytotoxicity are still not yet well
defined, although they are already known to differ from one irritant to another.22

Due to the increasing use of protective gloves, acute (or strong) irritants are becoming a less common cause of irritant contact dermatitis and chemical burns.24 Occupational irritant contact dermatitis is caused most frequently by chronic (weak, mild or marginal) irritants, the damage from which is insidious and insensible, but cumulative with time.23 Chronic irritant contact dermatitis is often the result of more than one occupational irritant (multifactorial), with common factors being wet work and the use of soaps and cleansers.14

Individual susceptibility to chronic irritant contact dermatitis varies very widely, though still largely unpredictably.23 One high-risk group that has been identified are subjects with a previous history of severe childhood eczema, particularly if this involved the hands.24,25 Susceptibility to one irritant, however, does not necessarily imply susceptibility to another.23 Variation in susceptibility to weak irritants results in chronic irritant contact dermatitis involving only a certain proportion of an exposed workforce, which rarely rises in practice above a third.18

Age of onset varies from one occupation to another, sometimes showing a bimodal curve, with those at both ends of working life seeming to be at higher risk than those in mid-career,20 and other times increasing with age (or sometimes even apparently decreasing). One example of this is the apprentice hairdresser or the student nurse who presents with occupational irritant contact dermatitis (ICD) of the hands due to more frequent wet work (washing hair, cleaning, etc.) involved in the personal care of patients. Individuals susceptible to ICD may often present early under these circumstances. Conversely, motor mechanics often present later in their occupational life, when 20–30 years of exposure to irritants (solvents and friction, etc.) lead to chronic hand eczema. Similarly, length of exposure prior to onset varies widely, depending both on the irritant and the degree of contact with it, but sometimes being years rather than, more commonly, months. Any apparent difference in susceptibility between the sexes arises from the different type of work that they do, rather than from any inherently increased susceptibility in either sex.23

The principal occupational irritants18,23,26 may be grouped broadly into soaps and detergents, alkalis and acids, metalworking fluids (cutting oils), organic solvents, other petroleum products, oxidizing agents, reducing agents, animal and plant products, and physical factors, such as friction and low relative humidity, as well as desiccant powders. The more frequent wearing of occlusive gloves results in increased sweating of the hands, in itself a cause of irritation. German wet work regulations now legislate for those at increased risk of occupational dermatitis due to wet work (described as over two hours’ exposure of the hands to water, wearing of occlusive gloves for over two hours/day or frequent hand washing). Individuals at risk need to undergo annual surveillance for occupational dermatitis.27 Common high-risk occupations for chronic irritant contact dermatitis18,23,26 are catering, cleaning, construction, hairdressing, horticulture and floristry, metalworking, nursing, painting, printing, and vehicle maintenance and repair.

**ALLERGIC CONTACT DERMATITIS**

Although probably not as common as occupational irritant contact dermatitis, occupational allergic contact dermatitis is often less amenable to subsequent prevention, because of the much smaller quantities of allergen that may sustain a contact dermatitis in a sensitized individual, compared with the quantities required of irritants. It may therefore become much more difficult to manage than irritant contact dermatitis. Conversely, if the allergen can be identified and removed from the workplace, then prognosis may be excellent.

A contact allergen (or contact sensitizer), after penetrating the barrier layer of the skin, is chemically reactive
enough to provoke delayed, cell-mediated or type IV allergy. The first stage of this process is termed 'induction' and, once initiated, takes around seven days to be completed. After such time, further skin contact with that particular allergen results in the second stage of the process, called 'elicitation', that results in allergic contact dermatitis within a few hours to a day or two of the subsequent exposure, depending on both degree of contact and degree of sensitivity. Allergic contact dermatitis is usually morphologically indistinguishable from irritant contact dermatitis.

Sensitization may be induced after only one contact, or after many contacts over a prolonged period. occupationally, it is often induced after a few months of repeated contact, although sometimes it can occur after many years of well-tolerated contact, as with chromate sensitization in bricklayers. There is a very wide individual variation in susceptibility to contact sensitization, and susceptibility to one allergen does not necessarily imply any general susceptibility to contact sensitization. Age and sex are not significant influences.

Knowledge of the mechanism of type IV hypersensitivity has accumulated in the last three decades to a fascinating degree. Allergic contact dermatitis depends primarily on the activation of specifically sensitized T cells, an untoward side effect of a well-functioning immune system. Induction of contact sensitization begins with the binding of allergen to major histocompatibility complex (MHC) class II molecules on the surface of allergen-presenting cells. These MHC class II molecules are present on Langerhans' cells within the epidermis, which migrate via the lymphatics to the paracortical areas of the regional lymph nodes. Here, T cells specifically recognize the allergen-class II molecule complexes and are activated to proliferate within the node, subsequently to be released into the circulation and enter the skin. The process of induction is then complete, having taken around seven days.

Elicitation of allergic contact dermatitis then depends on allergen-presenting cells and specific T cells subsequently meeting in the skin and leading there to cytokine production. Release of such mediators results in the arrival of more T cells, thus further amplifying local mediator release. This leads to a dermatitic reaction, peaking after one to two days.

Several thousand contact allergens are now recognized. Rubber accelerators, epoxy resins and hardeners, (meth)acrylates, formaldehyde and formaldehyde-releasers, other biocides (preservatives), and plants and woods are common occupational examples. High-risk occupations include chemical and pharmaceutical manufacture (Figure 84.4), construction, dyeing, electronics, hairdressing and tanning. Chromium (in cement) used to be a common cause of occupational allergic contact dermatitis (ACD) in construction workers, but rates are now falling, as legislation in Europe and elsewhere has led to the addition of ferrous sulphate to cement powder to reduce the amount of free hexavalent chromate present.

Establishing the occupational causation of contact dermatitis can be far from straightforward. The foundation remains a thorough dermatological and occupational history, coupled with a close examination of the whole skin. There are certain essential facts that form the basis of every such history.

The time of onset of the earliest signs

The shorter the history, the more likely is the diagnosis of contact dermatitis. However, there is an important proviso to this general statement. Patients initially tend to underestimate the length of history, remembering the exacerbation that finally led them to seek medical advice rather than the original onset of the earliest signs. Many patients do not seek medical advice until they have had milder degrees of contact dermatitis for considerable periods (Figure 84.5). In Fregert’s study, 22 per cent of cases of occupational contact dermatitis had a history of less than one month, yet 29 per cent had a history of more than one year.

The primary site of onset

In occupational cases, this is usually the hands. In a few cases, the wrists, forearms, lower legs or face are the primary site. The covered areas of the trunk or feet are rare primary sites.

The route and timing of any secondary spread

Spread from one hand to the other and from the hands to the forearms is common, even in the absence of contact
with the causal agent at such secondary sites. Distant spread from the hands to the feet or to the face is more common in allergic contact dermatitis rather than irritant. Photocontact dermatitis is rarely occupational, but primarily involves the face and backs of the hands.

**Atopy**

Those with a history of severe childhood eczema, particularly if this involved the hands, are at higher risk as a group, of developing occupational irritant, though not allergic, contact dermatitis (Figure 84.6).

**Occupation**

The essential questions that need to be asked of the patient are their occupational title, length of time in this job and precisely what work tasks are involved. As exact a picture as possible must be acquired of the degree of skin contact, as well as simply the substances involved. Personally visiting the workplace and actually looking at the work being done can increase the understanding of a dermatitis problem.

**Work-relatedness**

The question as to whether the dermatitis improves away from work and worsens on return to work is clearly fundamental, but can usefully be refined a little further. Primarily endogenous eczema may also show such a pattern, but occupational allergic contact dermatitis usually shows greater and more consistent work-relatedness. Occupational allergic contact dermatitis tends to relapse more rapidly on return to work than does irritant contact dermatitis, and allergic may sometimes be slower than irritant to improve away from work. As occupational contact dermatitis of either type becomes chronic, its initial work-relatedness tends to become increasingly less clear-cut.

**Preventive measures**

Attempts to prevent or remove skin contamination and the use of personal protective equipment should be enquired about, as well as the amount of success achieved by such methods. Occupational contact dermatitis may sometimes be aggravated further by the irritancy of skin cleansers or allergy to protective gloves.

**Fellow workers**

The involvement of a substantial proportion of working colleagues is more suggestive of irritant than allergic contact dermatitis. Patients’ own assessments of the similarity of their workmates’ dermatoses are, understandably, often unreliable, and a personal examination of any such additional cases is always to be recommended.

**Diagnosis**

Mathias has previously described criteria for diagnosing occupational contact dermatitis (Box 84.1).

**PATCH TESTING**

While there is no routine skin test to confirm the diagnosis of irritant contact dermatitis, patch testing is the only way of confirming the diagnosis of allergic contact dermatitis. The principle of patch testing is relatively straightforward, yet its reliability is highly dependent on the abilities of the person(s) carrying it out.

Patch testing is based on the dilution of potential contact allergens to below their threshold for either induction
of contact sensitivity or for contact irritancy under the conditions of the test, down to a level at which they nevertheless remain capable of an elicitation reaction in an already sensitized patient. The appropriate dilution for patch testing varies widely from substance to substance. Its selection is crucial to the reliability of the test. Underdilution may result in a positive reaction in the absence of contact allergy (false-positive reaction), whereas overdilution may result in a negative reaction in the presence of contact allergy (false-negative reaction).

A set of between 30 and 45 common allergens (standard series) and some additional series directed towards specific occupations are available commercially, but in occupational cases these will frequently need to be supplemented by patch tests to a patient’s own contactants. It is here that dilutional errors are easily made. Reference sources are a guide to correct patch test dilution, but there is no substitute for training and experience; even commercial patch test preparations may occasionally give false-positive or false-negative reactions. The value of testing to patients’ own samples has recently been shown. It is essential, when taking the history, to identify as many of the chemicals as possible to which a worker is exposed. Ideally, small quantities of each substance are obtained, with the relevant material safety data sheet, and these are used to decide how to dilute and test to the substance. Some substances are not tested because of their known irritancy.

Appropriate dilutions are occluded against the skin (Figure 84.7), usually in shallow aluminium chambers and usually on the back, for either one or (more usually) two days. Readings are made of any reactions that are present after removal of the tests and, preferably, again at between three and seven days after application. The interpretation of such reactions requires trained skills. Positive reactions also require further informed assessment of their relevance to the current dermatitis, which may involve substantial investigation of potential occupational sources (Figure 84.8). A positive patch test only indicates allergy to the substance. It is then necessary to show its relevance to the workplace and the worker’s contact dermatitis.

OTHER INVESTIGATIONS

As well as patch testing, other special investigations may be required in order to make an accurate diagnosis. Radioallergosorbent testing (RAST) or prick testing (Figure 84.9) may be indicated in contact urticaria and protein contact dermatitis (see under Contact urticaria, p. 1069 and Protein contact dermatitis, p. 1069). Skin biopsy may be needed in certain other non-eczematous dermatoses. Skin scrapes may be used to exclude tinea infection (fungal infection).
Simple chemical tests for the identification of specific allergens, more advanced chemical analytical techniques and methods for measuring the degree of skin contamination are reviewed.\textsuperscript{18,33} Such chemical elucidation has considerably advanced our understanding of contact sensitization by such occupational allergens as chromate, epoxy resin, phenol-formaldehyde resin and colophony.

In recent years, non-invasive measurement techniques have come to play an increasing role in contact dermatitis research,\textsuperscript{29} including transepidermal water loss, skin reflectance and conductance, and laser Doppler flowmetry. As yet, these have no routine applications in clinical dermatology.

\textit{In vitro} tests for sensitization, such as the migration inhibition and lymphocyte transformation tests, are described,\textsuperscript{29} but have not yet reached the level of reliability required to replace patch testing.

\section*{TREATMENT}

The treatment of occupational contact dermatitis rests on the foundation of accurate diagnosis combined with partial or complete separation of the patient from the cause.

\textbf{Acute contact dermatitis} may sometimes require a period away from work, everything possible being done to minimize the length of any such period. Dermatological treatment is essentially the same as for any other acute eczema.\textsuperscript{32,44} Hospital clinicians and general practitioners should be aware of the demoralization that can be produced by periods off work – even if only for a few weeks.

\textbf{Chronic contact dermatitis}, with certain exceptions indicated below, can usually be treated while the patient continues to work, even if this is in a temporary alternative location. Again, dermatological therapy is as for other chronic eczemas.\textsuperscript{42,44}

Isolated uncomplicated allergic contact dermatitis may, however, respond so well to a permanent change of occupation that, if substitution of an allergen cannot be achieved,\textsuperscript{45} this may become the best advice. Also, atopic individuals who find themselves with dermatitis from unavoidable irritants, such as in metalworking, hairdressing, catering and healthcare work may be best advised to look for a permanent alternative.

\textbf{Irritant contact dermatitis} may often respond better to the regular use of emollients (moisturizers) than to potent topical corticosteroids, the latter being more likely to be needed in \textbf{allergic contact dermatitis}. In either type of contact dermatitis, secondary bacterial infection may require additional treatment with topical or systemic antibiotics.

\section*{PREVENTION}

The prevention of occupational contact dermatitis\textsuperscript{18} is based on the same hierarchy of measures as for other occupational diseases, usefully considered under the headings of reduction of exposure, reduction of the effects of exposure and reduction of the effects of disease.

While substitution will always remain the ideal exposure control,\textsuperscript{45} clinicians will more often find themselves involved in advising on personal protective equipment, and this largely in the form of gloves. Awareness is required here, both because in some jobs gloves are either unsafe or impracticable, as well as the fact that the choice of glove material can be crucial for certain substances.\textsuperscript{18}

The effectiveness of ‘barrier’ creams remains controversial, but data are beginning to accumulate on their role in preventing at least some of the effects of skin contact, particularly from irritants.\textsuperscript{46} The benefit of emollient (moisturizer) application following skin cleansing is also beginning to receive some experimental support, again particularly with respect to irritants.\textsuperscript{45}

The preventive role of pre-employment assessment\textsuperscript{24} remains limited by our lack of reliable indicators of susceptibility, although a partial exception to this is that subjects with a history of severe childhood eczema are, as a group, more susceptible to skin irritation.\textsuperscript{24,25} Such susceptibility does not appear to extend, however, to those with a history of only mucosal atopy (hay fever and asthma).

The primary objective in reducing the long-term effects of occupational contact dermatitis is to enable the patient to remain at work.\textsuperscript{11} Clinicians should therefore strive to reduce periods of work absence to a minimum, with any unavoidable breaks in work being regularly monitored. Delay in diagnosis is a prime contributor to dermatological disability.\textsuperscript{48} One exception to this is when a period off work (taken as sick leave or annual leave) can be used to assess the work-relatedness of a skin condition. Occupational contact dermatitis would be expected to improve with a period of time away from work, at least in its early stages. Evidence-based skin care recommendations have been published (summarized in Box 84.2).\textsuperscript{49} If improvements are made to the working conditions by intensified preventative measures, then this is likely to lead to a reduction in cases of occupational contact dermatitis.\textsuperscript{50,51} It is also important to assess and give relevant advice on factors in the home, where there may be additional sources of ICD or exposure to relevant allergens.

\end{figure}
PROGNOSIS

In his pioneering questionnaire study, Fregert found that only 25 per cent of his patients diagnosed as having occupational contact dermatitis had completely healed two to three years later: 50 per cent still had intermittent symptoms, while as many as 25 per cent still had continuous symptoms. Although 40 per cent had changed their occupation, the change had not improved their prognosis. These considerations applied to irritant as much as to allergic contact dermatitis.

Wall and Gebauer refined this study by increasing the number of patients followed up, examining the majority of these, and establishing more precisely what their change of job had entailed. More than half their patients still had their dermatitis to some degree. Again, around 40 per cent had changed their jobs, but of these more than 25 per cent had chosen new jobs in which the work environment further aggravated their skin. Of the 57 per cent who were either in the same job or deemed to be still in the same type of occupation, as many as 68 per cent were still symptomatic, whereas of the 43 per cent who had changed to an entirely different work environment, from the dermatological point of view, only 37 per cent were still symptomatic. Overall, 11.5 per cent of the patients had an ongoing skin disease for which there was no identifiable present cause: this the authors termed ‘persistent post-occupational dermatitis’.

Rosen and Freeman took such studies still further by documenting improvement as well as complete healing, establishing improvement in 82 per cent of those who changed duties within the same industry, 76 per cent of those who changed industry altogether, and 61 per cent of those who remained with the same duties in the same industry.

The main findings of all three of these major studies can be summarized as follows. The prognosis of occupational contact dermatitis severe enough to be referred to a dermatologist (known to have a special interest in occupational dermatoses) is one of persistence in more than half, although with improvement in around half of these. This applies to irritant as much as to allergic contact dermatitis. Appropriate occupational changes improve the prognosis for most, but around 10 per cent of patients overall develop persistent post-occupational dermatitis. Chromate was the major allergen in all studies causing persistent post-occupational dermatitis (Figure 84.10), allergic contact dermatitis from plastics and resins having the best prognosis.

Questionnaire studies of cutting fluid dermatitis (mainly irritant) have shown varying results. In a small study in Birmingham, UK, clearance was found in 45 per cent of patients followed for up to 2.5 years after diagnosis: only one of 40 patients had been obliged to change their job. In a similar larger study in London, of those who continued to work with water-based metalworking fluids, 78 per cent had not healed after two years, and of those who had stopped working with soluble oils, 70 per cent had still not healed two years after discontinuing contact; a generally poor prognosis was found whether or not such patients continued in their work.

The prognosis for catering workers studied by Cronin was also poor. Of 32 such patients followed up for around two years, 12 had been obliged to give up their work because of their contact dermatitis. Of the 19 who remained in catering, only four healed completely; of the 13 who left, only four healed.

Box 84.2 Basic workplace skin care principles

- Luke-warm water for washing
- Use correct gloves before exposure for the shortest time
- Remove rings
- Cotton liners underneath protective gloves
- Avoid disinfectant hand cleansers
- Apply emollient hand creams
- Protect hands at home
- Workforce education

Figure 84.10 Persistent (allergic) contact dermatitis from chromium in cement (for colour image, see www.hodderplus.com/hunters).
The reasons for this generally poor prognosis, which applies to irritant as much as to allergic contact dermatitis, remained debatable. However, many less severe cases than those having to be referred to specialist dermatologists have a much better prognosis, as occupational physicians will be well aware. Also, even in such severe cases, dermatitis may become significantly more manageable after adequate investigation and treatment.

**NON-ECZEMATOUS OCCUPATIONAL DERMATOSES**

There are a number of non-eczematous skin disorders that, even together, constitute only a minority of occupational dermatoses. Nevertheless, some have serious implications that demand their accurate diagnosis.

**CONTACT URTICARIA**

This is a wheal-and-flare reaction usually within 20–30 minutes of contact between certain substances and the skin surface (Figure 84.9). It may be of immunological (allergic), non-immunological (irritant), or uncertain aetiology. The most frequent occupational cause currently is immunological (type I) contact urticaria from natural rubber latex, the main at-risk group being healthcare professionals who wear rubber gloves. Clinical symptoms of type I allergy to natural rubber latex may extend from contact urticaria, conjunctivitis and rhinitis, to asthma and anaphylaxis. Two major latex allergens have been identified, the important one for healthcare professionals being a soluble protein, hevein. Cross-reacting proteins are present in many fruits and vegetables, including avocado, banana, sweet pepper, potato, kiwi fruit and tomato. Atopics are at greater risk. Latex allergens are adsorbed on to cornstarch glove powder, thus increasing airborne exposure: powdered natural rubber latex gloves should therefore no longer be used. Guidance is increasingly available as to how to control this problem, particularly in the healthcare setting. This has led to a tailing off of the latex allergy epidemic seen in the 1990s.

The most common other causes of occupational contact urticaria are cow dander and foodstuffs, which are considered below under Protein contact dermatitis. Confirmation of the diagnosis of immunological contact urticaria may be obtained by use tests, prick tests or RASTs, guided by clinical assessment of the extent and severity of symptoms. Prick testing should never be conducted without appropriate resuscitation equipment to hand.

**PROTEIN CONTACT DERMATITIS**

Food handlers and those working closely with animals may have hand dermatitis, either as well as or rather than contact urticaria, yet show positive prick tests or RASTs, rather than positive patch tests, to foodstuffs or animal products, a phenomenon first termed ‘protein contact dermatitis’ in 1976, where it was described in a cohort of sandwich makers. The underlying allergic mechanism may depend on specific immunoglobulin-E being bound on the surface of epidermal Langerhans’ cells. Testing for type I as well as type IV allergy may therefore be required in chefs, animal laboratory technicians, farmers and veterinarians with hand dermatitis, as well as in the natural rubber latex glove wearers.

**OIL FOLLICULITIS (OIL ACNE)**

Petroleum oils exert a localized irritant effect on hair follicles, which causes a folliculitis of the hair-bearing skin of the backs of the hands, arms, thighs (Figure 84.11), abdomen, face and neck. The primary lesions are open comedones (‘blackheads’), causing mechanical blockage of the follicular openings. Second, inflammatory papules and pustules may develop. Metalworking machine operatives are the prime at-risk group, although adequate industrial and personal hygiene should nowadays make it rare. Those with previous cystic acne are more susceptible.

**CHLORACNE**

This is both clinically and aetiologically distinct from oil acne. It might better be termed ‘halogenacne’, in that, as well as polychlorinated aromatic hydrocarbons of a highly specific molecular structure, brominated, iodinated and fluorinated homologues are also causal. These uncommon chemicals, of which the dibenzodioxins are an example (see Chapter 43, Pesticides and other agrochemicals), may be encountered in pesticide manufacture, chemical disposal plants and, sporadically, in other chemical and pharmaceutical work. Chloracne may be differentiated...
from other causes of chemical acne. Lesions are distributed typically over the temples, behind the ears and on the male genitals, and may spread to the trunk and limbs (Figure 84.12). The primary lesions are open comedones and pale-yellow cysts (Figure 84.13). In more severe cases, inflammatory lesions are also seen. The condition is notoriously chronic, even after complete removal of the cause, and may be extremely resistant to treatment. Chloracne is always a symptom of systemic absorption and may be associated with systemic morbidity. Many substances causing chloracne may also cause hepatotoxicity. The most potent chloracnegenic agent known is 2,3,7,8-tetrachlorodibenzo-p-dioxin. Exposure to relevant chemicals and the pattern of comedogenic acne is important in making the diagnosis.

**LEUKODERMA**

Chemical depigmentation of the skin can arise occupationally from exposure either to various chemicals themselves or to their residues in products, such as adhesives (Figure 84.14). The chemicals responsible include phenols, catechols and hydroquinones. Because of systemic absorption, white patches may appear well beyond sites of direct skin contact, thus closely mimicking idiopathic vitiligo. There are several possible explanations for the effects of such chemicals on the pigmentary system, their structures being very similar to melanin precursors. Death of melanocytes results in depigmentation usually being permanent. Associated changes in liver function tests of uncertain significance have been reported. Occupational leukoderma is a prescribed disease in its own right (see Chapter 8, Compensation schemes).

**PSORIASIS**

Psoriasis can koebnerize in areas of skin inflammation — that is to say that any inflamed skin can develop into psoriasis in a predisposed individual. In patients with, for example, hand or fingertip psoriasis, it may be prudent to patch test to potential allergens in the workplace and home to exclude an ACD koebnerizing into psoriasis. In the same way, an ICD of the hands, including one with frictional features, could also koebnerize into psoriasis.

**SCLERODERMA-LIKE DISEASES**

Vinyl chloride monomer, silica dust, organic solvents and epoxy resins have all been reported as associated with scleroderma-like conditions. Exposure to vinyl chloride monomer has also caused acro-osteolysis and angiosarcoma of the liver in polymerization vessel cleaners, and
miners exposed to silica dust may have associated silicosis. A patient was reported with a sclerodermatous syndrome following occupational exposure to herbicides. The mechanism remains obscure. In a recent study of 82 cases of scleroderma in France, up to 10 per cent were found to be potentially work related, with relevant occupational exposures present. No clear diagnostic criteria were given.

**ULCERATIONS**

There are two main occupational causes of ulcerations, hexavalent chromium compounds and wet cement, in both cases the cause being toxic (irritant) rather than allergic. Chrome ulcers are mainly seen on the hands in those exposed to chromic acid in electroplating, although regulation has generally made them rarer, and may occur from other sources, such as porcelain enamel paints. Nasal septal ulceration, proceeding to perforation, may be associated.

Cement ulcers (or cement burns) are a rapid effect of wet cement trapped against the skin, for example by kneeling in it or by it entering footwear. Symptoms may appear within an hour or two, the resulting ulceration then inexorably progressing and often requiring skin grafting. Precautions to avoid the occlusion of wet cement against the skin should be preventive, but inexperienced, amateur or heavily exposed professional cement users may still be affected.

**SKIN CARCINOMAS**

Although now largely of historical interest, except in outdoor workers from sun exposure, cancerous and precancerous skin lesions can still present, for example in elderly machine operatives exposed to cutting oils in the 1950s and 1960s, as well as sporadically from previously unsuspected causes. The characteristic skin lesions are keratoses (‘oil warts’) and squamous cell carcinomata. They affect particularly the scrotum in machine operatives, and also commonly the hands and forearms, but rarely the face and neck. The carcinogens in mineral oils have been identified as polycyclic aromatic hydrocarbons. Solvent refining is considered to have reduced these to an adequately safe level, which epidemiological analysis of new cases has since begun to reflect. Those occupationally exposed to polycyclic aromatic hydrocarbons in coal tar pitch may be similarly affected.

The risk of skin lesions that could turn cancerous due to occupational solar exposure is becoming increasingly recognized. In some parts of the world, sunscreen is routinely available to outdoor workers. Proving work-relatedness is often difficult, due to the long delay between solar exposure and the development of skin cancer (basal cell carcinoma (BCC), squamous cell carcinoma (SCC) and melanoma). A recent Bavarian study showed increased rates of BCC and SCC in outdoor workers than indoor workers, although there was no difference in rates for melanoma.

**COLD URTICARIA**

Cold urticaria is an uncommon occupational skin disease. In general, patients with cold urticaria are advised to avoid exposure to the cold in their work.

**PSEUDO–EPIDEMICS**

It is not uncommon for pseudo–epidemics of skin problems to present in a workplace or factory. The presentation of a few cases of actual work-related skin problems often leads to increased reporting of common skin problems unrelated to occupation among work colleagues. It is essential for a dermatologist to assess all workers with skin complaints to confirm the diagnoses. Where multiple patients are involved, it may be necessary to patch test the most severely affected to screen for ACD, and then widen the testing to include the others if positives are found.

**MAJOR OCCUPATIONS CAUSING DERMATOSES**

**Agriculture**

Irritant contact dermatitis can arise from disinfectants and cleansers for milking equipment, and from diesel oil powering machinery. Allergic contact dermatitis is seen mainly from rubber chemicals, including N-isopropyl-N’-phenyl-p-phenylenediamine (IPPD), in gloves, boots and milking equipment; plants, including Compositae (Asteraceae) such as the common weeds dandelion and thistle; pesticides; antibiotics in animal feeds and veterinary use; cobalt in fertilizers and animal feeds; other animal feed additives such as ethoxyquin and quinoxaline derivatives; and chromate in cement. Contact urticaria or protein contact dermatitis may be caused by animal hair and dander. Zoonoses include cattle ringworm and orf in sheep.

**Catering**

Detergents, as well as fish, meat, fruit and vegetable juices, and dough, can all cause irritant contact dermatitis. Allergic contact dermatitis is caused mainly by onion and garlic, spices, formaldehyde and other preservatives, and rubber chemicals in gloves. Contact urticaria or protein contact dermatitis is common from fish, shellfish, meat, fruit, vegetables, flour and flour improvers, and natural rubber latex in gloves. Candidal paronychia and viral warts also occur.
Chemical and pharmaceutical

Irritants and sensitizers are specific to each process. Sensitization is often more common during research and development than in later full-scale production. Halogenated chemical intermediates are potent allergens. Inadvertent synthesis of new chloracnegens may result in sporadic outbreaks of chloracne.

Cleaning

Detergents and cleansers containing organic solvents, acids or alkalis are irritant. Rubber chemicals in gloves, formaldehyde and other preservatives, and fragrance chemicals cause allergic contact dermatitis. Contact urticaria and protein contact dermatitis arise mainly from natural rubber latex in gloves. Candidal paronychia is also a problem.

Construction

Cement, fibreglass and wood preservatives can all cause irritant contact dermatitis, as well as mould oil in brick-making. Cement burns are caused by wet cement trapped against the skin. Chromate (and cobalt) in cement, epoxy resin in special cements, softwoods and hardwoods, and rubber chemicals in boots and sealing strips are the main allergens. Leptospirosis is an infectious hazard of open watercourses. A European Union directive (2003/53/EC) requires ferrous sulphate to be added to cement to reduce chromium (VI) to less soluble (therefore less allergenic) chromium (III). The incidence of chromium allergy in construction workers should fall over the next few years as it has done so in Scandinavian countries, since ferrous sulphate has been added to cement in Scandinavian countries for many years.

Electronics

Soldering fluxes are a cause of irritancy, sensitization and contact urticaria. Warm dry air causes itchy dry skin. Epoxy resin and anaerobic acrylic sealants are other important sensitizers.

Fishing

Irritant contact dermatitis arises from wet work, especially in the cold, friction, oils and fuels, and fish juice itself. The major sensitizers, apart from rubber chemicals in boots, are marine organisms, such as those responsible for Dogger Bank itch, and plants. Dogger Bank itch is an allergic contact dermatitis to the (2-hydroxyethyl) dimethyl-sulphoxonium ion, a metabolite produced by the marine Bryozoan alcyonidium diaphanum. This marine organism is commonly found off the waters of the United Kingdom and despite the reduction in the size of the local fishing fleet, is likely to cause significant ongoing problems in fishermen and trawlermen.

Contact urticaria and protein contact dermatitis can also be caused by fish, marine organisms and plants.

Hairdressing

Shampoos, permanent-wave solutions and bleaches are all irritant. The principal allergens are p-phenylenediamine (PPD) in hair dyes, glycercyl thioglycolate (GTG) in acid/pH-balanced permanent-wave solutions, and formaldehyde or isothiazolinones as preservatives in hair gels and mousses. Contact urticaria or protein contact dermatitis can arise from ammonium persulphate in bleaches, as well as natural rubber latex in gloves and even PPD.

Apprentice hairdressers are at particular risk of developing hand eczema due to their relatively greater exposure to washing clients hair, etc. Studies have shown poor knowledge within the workforce of the potential skin hazards.

Health care

The main irritants are skin cleansers, disinfectants and prolonged wearing of occlusive gloves. Warm dry air in hospitals causes itchy skin dryness. Rubber gloves cause allergic contact dermatitis from their chemical content (rubber accelerators and natural rubber latex), contact urticaria or protein contact dermatitis from their natural rubber latex and potentially irritant contact dermatitis from prolonged wearing and subsequent sweating in occlusive gloves. Hand cleansers are potential sources of allergens. There has been a recent increase in the use of alcohol-based hand rubs. While many workers complain of stinging and soreness when using these, one study has shown low rates of cutaneous adverse reactions to these products. In general, occupational dermatologists feel that these products are less drying than frequent hand washing. The stinging and soreness tends only to occur when they are used on already broken skin. Dentistry sensitizes to local anaesthetics, resins and catalysts. Orthopaedic surgeons run the risk of sensitization from acrylic cement. The cold sterilant glutaraldehyde has been a sensitization hazard in, for example, endoscopy units. Propacetamol (a prodrug of paracetamol given in i.v. formulation, often in post-operative patients) is the latest in a long line of drugs to sensitize their handlers.

The presence of dermatitis affecting the hands in healthcare workers provides potential sources of entry for pathogens and for increased colonization of the skin. Rapid assessment and treatment is therefore recommended in healthcare workers presenting with hand dermatitis.
It is important to bear in mind that in many patients the hand eczema may be multifactorial, with ICD, ACD, possibly contact urticaria and constitutional eczema all playing a role. There has been a recent increase in the use of vinyl medical examination gloves – these do not provide adequate protection for blood-borne infections and their use should be reserved for low-risk exposures.

**Horticulture and floristry**

Irritant contact dermatitis arises from wet work, friction from manipulating wire, handling bulbs and certain plants, such as *Dieffenbachia*, daffodils and spurge. Many other plants and flowers are sensitizers: *Primula obconica*, chrysanthemum, other Compositae (including common weeds), tulip and alstroemeria. Daffodils (and narcissi) may also sensitize. Dermatitis provoked by exposure to sunlight following contact with plants (phytophotodermatitis) occasionally occurs occupationally.110 In the United Kingdom, the two main families of plants responsible are the Apiaceae (Umbelliferae), including celery, parsley, parsnip and carrot, as well as giant Russian hogweed; and the Rutaceae, including rue. In hotter climates, the Moraceae (figs) and Leguminosae (pea) may also be causal. The level of phototoxic furocoumarins (psoralens) is increased in response to fungal disease. Tending plants in aquaria may result in *Mycobacterium marinum* infection. Rubber gloves may cause the same problems as in other occupations. Contact urticaria and protein contact dermatitis may also be caused by plants such as *Schlumbergera* cacti.

**Metalworkers**

So-called ‘soluble oils’ are the major irritants, as well as organic solvents and aggressive skin cleansers. The irritancy of soluble oils may be increased by the overaddition of alkaline biocides. Both soluble oils and neat cutting oils also contain potential sensitizers, such as biocides (including formaldehyde-releasers) and tall-oil-based emulsifiers (which cross-react with colophony in the patch test standard series) in the former and epoxides in the latter. The usually trace amounts of nickel, cobalt and chromate in cutting oils rarely sensitize.

**Mining**

Mineral dusts, oils and hydraulic fluids, and cement can all cause irritant contact dermatitis. Rubber chemicals in boots and chromate (and cobalt) in cement sensitize. Tinea pedis tends to be endemic, because of shared washing facilities at the surface, and may spread to the hands, among other areas. Scleroderma-like disease has been documented in miners in Eastern Europe and South Africa.

**Office workers**

Low relative humidity may dry out the skin in air-conditioned offices, leading to intense pruritus and astreatic eczema. Allergic contact dermatitis may arise from nickel (paper clips and staplers), rubber chemicals (rubber bands, thimbles and sponges) and colophony (used in paper sizing, where modified rosins are added to paper to alter the wear and durability characteristics of the paper).

**Painting**

Thinners (especially when used for skin cleansing), emulsion paints and wallpaper adhesives are irritant. Organotin compounds in anti-fouling paints for ships are highly irritant. Turpentine is now a sensitizer only in arts and crafts painters (e.g. porcelain). Other sensitizers include D-limonene (the ‘citrus solvent’), organocobalt paint driers, epoxy, acrylic and polyurethane resins, preservatives, such as chlorothalonil in water-based paints, and triglycidyl isocyanurate (TGIC) in polyester powder paints.

**Photographic processing**

Photographic processing chemicals include many sensitizers, such as metol (p-aminophenol) in black-and-white processing, and substituted para-phenylenediamines in colour developing (sometimes causing lichenoid eruptions). Rubber gloves cause the same problems as in other occupations. However, with the advent of universal high quality video and digital photography sensitization to photographic chemicals is an increasingly rare occurrence.

**Printing**

Irritant contact dermatitis arises from organic solvents and multifunctional acrylates in ultraviolet curing inks, lacquers and printing plates. Colophony is a sensitizer in paper size (see under Office workers, p. 1073), rubber chemicals in offset printing roller blankets, formaldehyde or isothiazolinones as preservatives in gum arabic and fountain solutions, and multifunctional acrylates in the ultraviolet-curing products already discussed. Rubber gloves are also a source of sensitization.

**Tanning**

Acids, alkalis, reducing and oxidizing agents are all irritant, while chromate, formaldehyde, glutaraldehyde, vegetable tannins, dyes and resins are potential allergens. Formaldehyde may also be a source of contact urticaria, in addition to rubber gloves. Anthrax remains a risk from hides from endemic areas.
Veterinary care\textsuperscript{119}

Disinfectants may irritate. Rubber gloves, antibiotics and antinfectives, glutaraldehyde and preservatives in rectal lubricants may all sensitize. Sources of contact urticaria and protein contact dermatitis include animal hair and dander, obstetric fluids and animal tissues, as well as rubber gloves. Zoonoses are clearly also a risk (see under Agriculture, p. 1071).

Woodworking\textsuperscript{120,121}

Irritation may arise from certain hardwoods, wood preservatives and formaldehyde resins in fibreboard and chipboard. Other woods (both soft and hard) are sensitizers, as may also be formaldehyde resins, and frullania and lichens may in addition sensitize forestry workers.

Key points

- Irritant contact dermatitis is the commonest occupational skin health problem.
- The prognosis of allergic contact dermatitis is not always good.
- The morphology of allergic and irritant contact dermatitis is indistinguishable.
- Irritant contact dermatitis is treated with exposure reduction and allergic contact dermatitis with elimination.
- Atopy is a major risk factor for developing occupational contact dermatitis but there are other as yet not defined (genetic) factors.
- Non-eczematous dermatoses are important but very rare.

SECTION TWO

Occupational cancers
This page intentionally left blank
Introduction

Occupational carcinogens have an important role in the identification and prevention of cancer. They were the first human carcinogens to be identified and a large proportion of the carcinogens currently identified originate in the workplace. In England in 1771, Percival Pott, in his work Chirurgical works, described a higher frequency of cancer in the scrotum among chimney sweeps and associated the disease with exposure to soot. Bladder cancer, which is among the major cancers attributed to occupational exposures, occupies an important place in the history of occupational cancer epidemiology since the highest cumulative incidence of any cancer ever reported is for bladder cancer among workers in the dye industry. In addition, studies on occupational cancer have been among the first to develop methods for the conduct of historical cohort studies applying the concept of person-years through the pioneering work of Bradford Hill in 1948 and Richard Doll in 1952. Occupational cancers should be considered as preventable and this makes their identification even more necessary. The benefits of prevention go beyond occupational settings since the general population is also exposed to several of these compounds, for example asbestos, benzene, diesel exhaust and formaldehyde.

On the basis of the evaluations made by the International Agency for Research on Cancer (IARC), about 400 agents can be considered as carcinogens and about 150 occur in the workplace. In addition, employment in 18 industries or occupations has been identified as conveying an increased risk for cancer.

In industrialized countries, about a quarter of all deaths are due to cancer. Nowadays, the tumour sites more frequently associated with occupational exposure are lung, urinary bladder, nasal cavity, liver (angiosarcoma), mesothelioma, leukaemia and non-melanocytic skin cancer. Associations between industrial exposures and many other cancer sites, such as the pancreas, brain, pharynx, prostate, colon, breast, kidney, soft tissue sarcomas, lymphomas, multiple myeloma and others, have also been described, although the evidence is not always conclusive, or alternatively the proportion of cancers attributed to occupational exposures is low.

There is some controversy in relation to the percentage of all cancers attributable to occupational exposures. Most of the researchers and evaluating agencies consider that around 5 per cent of all cancer is attributable to exposures considered in the occupational setting, but there are also other (higher and lower) estimates. In most countries, occupational diseases are not regularly and completely identified. In industrialized countries it has been estimated that more than 80 per cent of occupational diseases, including cancer, are not recognized as such. This is despite the identification of numerous carcinogenic exposures in the workplace. The EU includes, for example, 15 agents related to cancer: asbestos, aromatic amines, arsenic and its derivatives, benzene, beryllium, bis-(chloro-methyl) ether, cadmium, vinyl chloride, chromium IV and
chromium VI compounds, polycyclic aromatic hydrocarbons (PAHs) and products of distillation of coal, nickel and nickel compounds, wood dust, silica, radon and ionizing radiation. Despite this list, the number of cancers notified as occupational is very low, in most countries being less than 1 per cent or even less than 0.1 per cent of all cancers.

Epidemiological research on occupational cancer has traditionally focused on men, although it has been decades since women entered the labour market on a massive scale. In the past, there were relatively few extensive studies focused on occupational cancer in women. The dramatic changes in work conditions of the last decades have also resulted in a reshaping and widening of epidemiological research on occupational health and recent studies have also focused on the work environment of women. The effects of shift work on breast cancer incidence have been among the most important recent findings in relation to women’s work.

In this chapter, we will review the evidence on occupational cancer and specifically refer to the major exposures and the main cancers caused by occupational exposures, present estimates of cancers attributable to occupational exposures, discuss the main issues related to epidemiological cancer research and, finally, extensively discuss mechanisms of disease and the use of biomarkers in studies on occupational cancer.

**OCCUPATIONAL CARCINOGENS AND EXPOSURE TO OCCUPATIONAL CARCINOGENS**

**IARC classification of carcinogens**

The IARC monograph series is the most well-known reference source for carcinogens, including carcinogens in the workplace. National health agencies extensively use this information as scientific support for their actions to prevent exposure to potential carcinogens. The monograph series of the IARC (available from www.iarc.fr) has been functioning since 1971 and has the objective of identifying environmental factors that can increase the risk of human cancer. Evaluations of the epidemiological and experimental evidence of the carcinogenicity are performed for chemicals, complex mixtures, occupational exposures, physical and biological agents, and lifestyle factors. Agents are selected by the IARC to be evaluated if there is evidence that exposure occurs in humans, and also if there is suspicion that the agent could cause cancer. The evidence used in the IARC monographs is based on exposure data, epidemiological studies, studies in experimental animals and also data on mechanisms of action (e.g. kinetics, mutagenicity). The IARC groups agents into five categories (Table 85.1). From 1972 to 2009, the IARC has published 100 volumes and has evaluated approximately 1000 agents, mixtures or exposure circumstances. Until January 2009, 108 have been classified into group 1 (carcinogenic to humans), 66 in group 2A (probably carcinogenic to humans), and 248 in group 2B (possibly carcinogenic to humans).

The IARC does not categorize the carcinogens evaluated as for the source of exposure and therefore does not indicate which should be considered as occupational. To identify which carcinogens could be classified as occupational, it is necessary to review the text of the monographs and then apply ad hoc criteria. The identification and listing of exposures that could be defined as occupational can be complex. Many occupational exposures also occur in the general environment and, vice versa, many predominantly environmental exposures occur in the occupational environment. For example, asbestos exposure is considered predominantly occupational but undoubtedly also occurs in the environment and numerous cases of mesothelioma have been reported among residents close to asbestos mines and asbestos-cement plants. Exposure to medical drugs is another example of agents to which most people are not exposed as a consequence of their work environment, but those working in the health sector may be exposed. Another issue refers to the evaluation of exposures among workers in an occupation or industry with a known increased risk. On most occasions, a specific exposure can be identified, for example benzene provokes a higher risk of leukaemia in shoe workers. However, although an increased risk of cancer can be identified for an occupation, e.g. lung cancer in painters, the specific exposures associated with this increased risk cannot be confidently identified.

In recent reviews, Siemiatycki et al. and Rousseau et al. categorized the IARC carcinogens in relation to whether they could be identified as occupational. They used various criteria, but the most important was whether this exposure occurs in the work environment among more than 10,000 workers in the world or 1000 workers in any specific country. Due to difficulties in undertaking an accurate estimation, they excluded exposures to medical drugs and to biological agents such as HIV or the hepatitis B and C.
viruses, although it is proven that healthcare workers may be exposed to these agents in their work environment. Using these criteria, they identified as occupational carcinogens (lists modified using more recent evidence):

- 34 definitive human carcinogens (group 1 of IARC; Table 85.2, modified from original publication);
- 21 probable carcinogens (group 2A of IARC; Table 85.3, modified from original publication);
- 114 possible carcinogens (group 2B of IARC);
- 16 occupations or industries where an increased cancer risk has been identified among workers but no specific agent could be identified (Table 85.4, modified from original publication).

### Table 85.2
Substances and mixtures that have been evaluated by IARC as definite (group 1) human carcinogens and that are occupational exposures (data from Ref. 4).

Prevalence of exposure to occupational carcinogens: CAREX estimates

Effective prevention of occupational cancer requires knowledge on the occurrence of exposure, but information on the numbers of workers exposed is seldom available. An information system called CAREX (carcinogen exposure) has been constructed for EU countries for the estimation of the numbers of workers exposed to established and suspected human carcinogens. CAREX includes data on agents evaluated by the IARC (all agents in groups 1 and 2A and selected agents in group 2B) and on ionizing radiation, displayed across 55 industrial classes. CAREX provides selected exposure data and documented estimates of the number of workers exposed to carcinogens by country, carcinogen and industry. It was estimated that in the 1990s about 32 million workers (23 per cent of those employed) in the EU were exposed to agents covered by CAREX. At least 22 million workers were exposed to IARC group 1 carcinogens. The most common exposures (Figure 85.1) were solar radiation (9.1 million workers exposed at least 75 per cent of working time), environmental tobacco smoke (ETS, 7.5 million workers exposed at least 75 per cent of working time), crystalline silica (3.2 million exposed), diesel exhaust (3.0 million), radon (2.7 million) and wood dust (2.6 million). Exposure to ETS has been drastically reduced in recent years in many countries, since the CAREX estimates were done prior to the establishment of legislation limiting workplace exposure to ETS.

Since the original publication which included 15 EU countries, CAREX has been updated and applied in other countries, including some developing countries. In Costa Rica, CAREX was adapted for 27 carcinogens and seven groups of pesticides. Widespread workplace carcinogens in the 1.3 million workforce of Costa Rica are similar to those in industrialized countries, including solar radiation (333 000 workers) and diesel engine exhaust (278 000) as the most common exposures. Among pesticides, the most common exposures were to paraquat and diquat (175 000) and mancozeb, maneb and zineb (49 000). Among women, formaldehyde, radon and methylene chloride were the most common exposures.

OCCUPATIONAL CANCERS

Lung

Among men, lung cancer is the most important tumour to present to the clinician. In many industrialized countries, it has also become among the most common tumours in women. Its association with tobacco consumption requires no further emphasis. It is important to note, however, that certain workplace exposures that cause respiratory tumours may act additively or even synergistically with cigarette exposure (see under Issues in design and analysis, p. 1107). In particular, asbestos and cigarette consumption is, perhaps, the best known example of interaction in occupational health, as the two agents have a possible multiplicative effect on the risk of developing lung cancer. Mortality rates in workers exposed to smoking and asbestos are shown in Table 85.5. Those exposed to asbestos but who are non-smokers have around five times the risk of non-smokers/non-asbestos exposed. Smokers/non-asbestos exposed have around ten times higher risk, while smokers who are exposed have around 60 times higher risk.

Although the clinician might seem to be looking for a needle in a haystack when contemplating occupational factors for yet another lung cancer case, it is worth noting that estimates for occupational attributability vary between 0.6 and 40 per cent, depending on the place and the time. The most generally accepted estimates indicate that around 15 per cent of all lung cancers in men are due to occupational exposures, while a lower percentage has been
estimated in women. In many countries, exposure to asbestos fibres has been the occupational exposure causing most lung cancers in the population.

For the clinician, the presenting features of lung cancer are all too well known and the confirmatory investigations usually demonstrate extensive and often inoperable spread at the time of diagnosis. The prognosis is frequently poor. Histopathologically, 90 per cent of all lung cancers are covered by four main categories: squamous, small cell, large cell and adenocarcinoma. Attempts to tease out a relationship between histopathology and putative lung carcinogens have not proved particularly successful. For example, adenocarcinoma or small cell carcinoma predominate in beryllium-exposed cases, while small cell types are in excess in uranium miners and in patients with exposure to bis(chloromethyl) ether, but this biological specificity is the exception rather than the rule.

There are many proven causes of lung cancer. Table 85.6 shows substances, mixtures, occupations and industries associated with lung cancer (IARC group 1 and 2A).

Data from Siemiatycki et al.4

manufacturing certain pesticides. As for nickel, it is in nickel refining that the excess risk of lung (and nasal sinus) cancer has been observed. The precise compound has not been fully elucidated, but the available evidence points to the carcinogenicity of nickel sulphate and of the combination of nickel sulphides and oxides encountered in the
The interest in the carcinogenicity of the chloromethyl ethers (which are of importance in the production of ion exchange resins) is out of proportion to their incidence. These chemicals seem to be particularly potent lung carcinogens, producing symptomatic neoplastic change in as short a latency period as 10–15 years, and with relative risks for heavily exposed workers as high as 20-fold. Their apparent association with small cell carcinoma has already been noted.

Polycyclic aromatic hydrocarbons are well-known lung (and skin) carcinogens and their presence in soot, tar, pitch and petroleum product exhaust fumes provides a potential opportunity for a wide variety of workplace exposures. The relevant worksites include gas retort and coke oven processes, the steel industry, the printing industry, aluminium refining sites, iron and steel foundries, as well as the motor vehicle transport industry and possibly the rubber industry. Chimney sweeping has re-emerged as an occupation at risk of cancer, as recent studies in Sweden and Denmark have shown a lung cancer excess in chimney sweeps. Welders are potentially exposed to a wide variety of gases and fumes, including nickel, chromium (VI) and nitrogen oxides.

The evidence for beryllium being a lung carcinogen rests, to some extent, on the excess risk associated with relatively short (one to five years) exposure and a latency period of two decades. Some authorities doubted the biological relevance of such short exposures, but it appears that these exposures were short because the affected individuals developed acute berylliosis. The exposures would therefore have been high and the inhaled dose, if not readily removed, could have lain there long enough to induce neoplastic change.

There is extensive epidemiological evidence associating exposure to silica with lung cancer. The IARC has evaluated crystalline silica as a group I human carcinogen, based on lung cancer findings across a large number of existing occupational studies and positive animal studies. In many studies, the excess seems to be found in silicotics, but not in silica-exposed workers without silicosis. Whether this simply reflects an average higher exposure to silica among the silicotics, the role of fibrosis or itself as an intermediate stage in the causation of cancer remains unclear. Although evidence is not entirely consistent, it appears that lung cancer occurs only after considerable exposure to silica and this may not necessarily have to follow a diagnosis of silicosis. The most informative study evaluating dose–response is a pooled analysis of ten large silica-exposed cohorts with around 65,000 workers and 1000 lung cancer deaths. This multicentric study found a significant positive exposure–response trend with cumulative silica exposure (Figure 85.2), but the lung cancer rate ratios did not increase in categorical analyses until after a cumulative exposure of 2 mg/m³-years. Overall, there are still many inconsistencies in findings of different cohorts. For example, a recent study from the United Kingdom did not identify an increased risk among workers in the industrial sand industry. These inconsistencies probably are due to several factors, including differences in the specific mineralogical properties of the silica that might result in varying levels of toxicity, and also may be due to differences in exposure levels. This is particularly so since exposure–response analysis showed that silica is not a strong lung carcinogen compared with the classic occupational carcinogens, such as nickel, arsenic and asbestos and that risk increases only after considerable exposure occurs.

The first modern description of pathology (fibrosis) associated with exposure to the naturally occurring crystalline fibres of asbestos, in its different varieties, goes back to the beginning of the twentieth century, soon after the start of the mining and the exploitation of asbestos on an industrial scale. In 1931, this led to the Asbestos Industry Regulations to control exposure to asbestos dust. The first cases of pulmonary carcinomas superimposed on asbestosis were reported in the mid-1930s. The first clear epidemiological evidence of an increased risk of lung
cancer from exposure to asbestos in a textile industry came, in the early 1950s, from a historical cohort study in a British factory, where 11 cases of lung cancer against an expectation of less than one were observed. This seminal paper by Sir Richard Doll,19 confirmed by numerous other studies,20 studied asbestos insulation workers in New Jersey and found a seven-fold excess of lung cancer. By the end of the 1960s, it had been shown that the lung cancer excess, in many circumstances of exposure to asbestos fibres, reflected an interactive effect of asbestos and tobacco smoking. Although asbestos use has been banned in many industrialized countries there remains a risk of exposure to unrecognized residual asbestos. An evaluation of exposure to carcinogens in Europe through the CAREX system11 identified that those working in the construction industry were the primary occupations exposed in Europe. However, of even more concern is the exposure to asbestos in developing countries.21 Precise estimates are not available of the number of workers in developing countries who are exposed to occupational carcinogens. Official statistics of the number of workers in specific industries are not fully reliable, since they may not cover major sections of the workforce, such as artisans, small-scale industrial production and illegal and migrant workers. At present, asbestos production is mainly done outside Western Europe, Australia and the United States,22 with Russia, Brazil and Kazakhstan being among the largest producers (Table 85.7). Among industrialized countries, only Canada has been producing asbestos on a large scale and has mostly been exporting this production to developing countries.

Mention must be made of the controversy surrounding the carcinogenic potential of the asbestos substitute products, such as synthetic mineral fibres. For the clinician, it may well emerge that a worker with a history of using the newer insulation material was, in a previous job, using the older insulation products – namely, asbestos. This may even apply to those engaged in manufacture rather than use. Early cohort studies have found an elevated risk of lung cancer among rock and slag wool production workers.23 However, retrospective analyses including nested case–control studies indicate that exposure to man-made mineral fibres is not associated with lung cancer risk.

A nested case–control study within the IARC multicentric study included 133 lung cancer cases and 513 matched controls in seven plants in Denmark, Norway, Sweden and Germany. After adjusting for smoking, there was no association with level of exposure to rock and slag wool fibres.24

Many of the above assertions on occupations are disputed and the arguments revolve around the quality of the human epidemiological studies. Nevertheless, the clinician has plenty of occupational aetiologies to consider even when contemplating the cause of a common tumour predominantly associated with cigarette smoking.

### Urinary bladder

The occupational exposures classified by the IARC as being associated with a higher risk of bladder cancer are listed in Table 85.8. Aromatic amines, PAHs and diesel engine exhaust are the exposures most consistently found to

</table>
increase the risk. Occupational exposures had been identified in the past as the second most important risk factor for bladder cancer after smoking.\textsuperscript{25,26} Studies in the 1980s and 1990s suggest that certain high-risk occupations may be responsible for 4–10 per cent of bladder cancer cases in men\textsuperscript{27} and a lower percentage in women.\textsuperscript{28}

Aromatic amines are among the first identified occupational carcinogens. In 1954, a study among dyestuff-manufacturing workers in the United Kingdom was the first large occupational epidemiology study directly examining aromatic amines.\textsuperscript{29} Exposure to b-naphthylamine entailed a 90-fold and to benzidine a 14-fold excess risk of bladder cancer. Numerous other studies of dyestuff-manufacturing workers confirmed these findings\textsuperscript{30} and provided analyses of the exposure–response patterns for these chemicals. Among workers manufacturing aromatic amines, including b-naphthylamine, benzidine, 4-aminobiphenyl and 4-o-toluidine, relative risks ranging from 6 to 70 have been found. Findings for users of dyes are less consistent.\textsuperscript{31} An excess risk of bladder cancer identified in the rubber industry in the early 1950s\textsuperscript{32} was associated with the use of an antioxidant containing b-naphthylamine (Figure 85.3). The withdrawal of this compound in the rubber industry led to a reduction of bladder cancer risk among rubber workers, although an excess risk in the order of 50 per cent (Figure 85.4) appears to persist.\textsuperscript{33} Aromatic amines are present in lower quantities in many other occupations, including aluminium production, hairdressing, painting, printing and shoemaking.

A moderately increased risk of bladder cancer has been associated with heavy exposure to PAHs, particularly from coal tars and pitches, and to diesel exhaust,\textsuperscript{34} although the evidence is not entirely consistent. Exposure to PAH is high for workers in several industries, such as the pot rooms in aluminium production, coal gasification, roofing, road paving and the transport industry. Many case–control studies provided evidence of excess risk among transport workers exposed to engine exhausts, including diesel exhausts.\textsuperscript{35} Cohort studies among workers exposed to diesel engine exhaust, such as taxi and truck drivers and operators of heavy equipment, however, have not confirmed a positive relationship between exposure to PAHs or diesel exhausts and bladder cancer risk.

Employment in several occupations has been identified as entailing an increased bladder cancer risk. Among the most consistent findings are those for painters, machinists, mechanics, workers in the metal industry such as sheet metal work and blacksmiths, workers in the textile industry, leather work and shoemaking, hairdressing, dry cleaning and transport work. These occupational relationships reflect, in part, past exposure to chemicals not currently used, such as benzidine or b-naphthylamine, but also more current exposures, possibly to aromatic amines, PAHs, cutting oils and solvents. Among the most consistent findings are those for painters.\textsuperscript{10} A recent meta-analysis,\textsuperscript{36} which included more than 2900 incident cases or deaths from bladder cancer among painters reported in 41 studies, identified a summary relative risk for bladder cancer in painters of 1.25 (95 per cent confidence interval (CI) 1.2–1.3; 41 studies) overall and 1.28 (95 per cent CI, 1.2–1.4; 27 studies) when including only estimates that were adjusted for smoking. Exposure–response analyses suggested that the risk increased with duration of employment. Metal workers are exposed to a heterogeneous group of potential carcinogens, including cutting oils (a category including numerous agents), PAHs, metal fumes and dusts, as well as combustion gases and vapours. In European Union countries, metal workers appear to be the largest occupational group associated with increased bladder cancer risk.\textsuperscript{27} An excess risk associated with men working, although only moderately high, is among the most consistent epidemiologic findings. An elevated risk of bladder cancer has frequently been found among aluminium smelter workers, blacksmiths, foundry workers, furnace operators, machinists, welders and others.\textsuperscript{37,38}

Various studies have also observed excess risks in white-collar occupations, such as sales workers, even after adjusting for potential confounding variables, an observation

compatible with the socioeconomic pattern of this disease. These excess risks are difficult to attribute directly to exposures in the workplace and may be more likely related to general lifestyle factors. Less consistent are the findings for people in numerous other occupations, such as construction workers, electrical fitters, engine drivers, food processors and preservers, garage workers, plumbers and welders, railway workers, slaughterers and meat processors, cooks and waiters.

An open question is whether occupational exposures in industries identified in the past as high risk can still be linked to an excess risk of bladder cancer. In a pooled analysis, attributable risks were higher for subjects first employed in a high-risk occupation before the 1950s than for those employed later. The attributable risk was also related to age, with higher estimates for people younger than 50 years.

### Mesothelioma

Mesothelioma of the peritoneum and pleura has been shown to occur following both environmental and occupational (mining) exposure to crocidolite in South Africa and was subsequently shown to occur also after exposure to other varieties of asbestos. Although the risk of both lung cancer and mesothelioma have been documented for all main varieties of asbestos (chrysotile – the most widely used variety – amosite and crocidolite), several issues still remain open. For example, data are inadequate for quantitative comparisons on a fibre by fibre basis, and on a mass basis, between the potency of different fibres in respect of lung cancer and mesothelioma.

An estimation from an International Expert Meeting on Asbestos, Asbestosis and Cancer in 1997 indicated that around 10 000 cases of mesothelioma in Western Europe,
North America, Japan and Australia could be attributed to asbestos exposure. Mesothelioma is strongly related to exposure to asbestos fibres and mortality from mesothelioma can be taken as an indicator of past exposure to mesothelioma. An international ecological analysis (Figure 85.5) of mesothelioma mortality in men in 32 countries showed a very close correlation with historical consumption of asbestos with an $R^2$ of 0.74 and $p$ value <0.0001.

Some salient features emerge from the long epidemiological history of asbestos in the working environment. First, there was a substantial lag between the first clinical case reports of cancers (in the mid-1930s) and the epidemiological evidence (mid-1950s), which led to an even longer delay in taking cancer into account when establishing hygiene standards. Second, the large volume of studies on a variety of exposed workers – such as miners and millers, textile workers, shipyard workers, including replicated cohort studies in several countries, which have contributed substantive evidence on the carcinogenic role of asbestos (and mineral fibres in general) – prompted methodological developments in occupational epidemiology and played a central role in demonstrating the need to prevent occupational cancers, as well as the effectiveness of exposure controls. Third, and notwithstanding this mass of data, there is a residual substantial uncertainty in the quantitative exposure–response relationships, which is in part likely to persist for ever, as in any case the information accruing from a longer follow up of worker cohorts is limited by the mediocre quality of past exposure measurements (while today exposure levels have been lowered and should, hopefully, produce no detectable effects). Finally, although asbestos has now been banned in most industrialized countries, there is still an observed increase in deaths from mesothelioma, due to the long latency period between exposure and occurrence of mesothelioma. An analysis of time trends in mesothelioma mortality in Britain in 1995 resulted in a prediction that the peak of deaths from mesothelioma would occur around 2020 (Figure 85.6).

**Figure 85.5** Ecological relations between current mortality rates from mesothelioma in men (deaths per million persons per year) and historical asbestos consumption weighted by the size of sex-specific national populations in 32 countries. Haematopoietic system

Tumours of the blood-forming organs make up a complex group in which frequent changes in the nomenclature add to the complexity. Ionizing radiation is associated with non-lymphocytic leukaemia, multiple myeloma and non-Hodgkin’s lymphoma. Non-Hodgkin’s lymphoma has been associated with exposure phenoxy acid herbicides and dioxins, benzene and some chlorinated organic compounds, such as trichloroethylene, tetrachloroethylene and polychlorinated biphenyls. The main occupational exposures with any degree of certainty of neoplastic effect are, however, associated with leukaemia.

LEUKAEMIAS

Leukaemias are a heterogeneous group of diseases. Epidemiological studies tended to group all leukaemias in one category. Recently, the use of new molecular techniques has resulted in new classifications and leukaemias are evaluated separately for the myeloid and lymphoid lineage. It is noteworthy that chronic lymphocytic leukaemia (CLL) is currently classified as a B-cell lymphoma.

Occupational ionizing radiation has been consistently associated with myeloid leukaemia through studies on radiologists and x-ray technicians working in the first half of the twentieth century. A recent combined analysis of approximately half a million nuclear workers indicated a small excess for myeloid leukaemia. Of special interest is the consistent finding of an increased risk of leukaemia associated with ‘electrical’ occupations. While electricians, telephone, radio and telegraphic staff are potentially exposed to a number of volatile solvents and resins, much interest has now centred on the possible role of electromagnetic field exposure in the leukaemogenic process. Improved exposure assessments and control of confounding factors has enhanced the quality of the latest studies. The best available studies indicate that there is no evidence that exposure to non-ionizing radiation and specifically extremely low frequency electromagnetic fields is associated with myeloid leukaemia (see Chapter 55, Extremely low frequency electric and magnetic fields).

Benzene has been the first chemical agent identified to cause leukaemia and specifically acute myeloid leukaemia. Numerous case reports and series have suggested a relationship between exposure to benzene and the occurrence of various types of leukaemia. Early studies in Finland and more widely known studies in Turkey identified increased leukaemia risks among shoe and other workers exposed to benzene. These studies were confirmed with both cohort and case–control studies, including the key pliofilm cohort which has been extensively used for benzene risk assessment. Numerous studies in the last 20 years which have followed earlier or new cohorts with quantitative data on benzene exposure show fairly consistent dose–response relationship between exposure to benzene and risk of acute myeloid leukaemia. Recent mechanistic studies have provided convincing evidence on the haematotoxicity of benzene at low exposure levels.

Workplace exposures identified as being associated with a leukaemia risk – at least in the past – include much of the petrochemical industry. Apart from the chemical industry and exposure to benzene, there are several other occupations and industries with increased risks of leukaemia including painters, those working in the rubber industry and those working with formaldehyde. A variety of other chemicals have been implicated as possible leukaemogens. Apart from the antineoplastic drugs, the most frequently cited chemicals are styrene, butadiene, epichlorhydrin and ethylene oxide. The source studies are often small, however, or the workplace exposures are confounded by benzene. An increased risk among farm workers has been identified in many countries, but the evidence is not consistent. The potential exposures among farmers include pesticides or exposure to biological agents.

Chronic lymphocytic leukaemia is currently classified together with lymphomas (B-cell lymphoma). CLL is not associated with ionizing radiation. There is little evidence that CLL is associated with chemical exposures. Recently, the IARC evaluated that there is limited evidence that benzene is associated with CLL. There is some evidence of an increased risk associated with exposure to styrene and also limited evidence that CLL is associated with exposure to ethylene oxide from studies in nurses or other exposed workers.

Acute lymphocytic leukaemia (ALL) is more common in young ages. There exists some evidence that ALL in children may be associated with parental exposure to pesticides and solvents. The IARC recently evaluated that there is limited evidence that exposure to benzene in the workplace is associated with ALL. However, this evidence is based on studies in adults with relatively small number of cases.

The investigation of a possible occupational etiology for the leukaemia patient can frequently be a difficult one. In our experience, while the disease is in no doubt, the exclusion of cytotoxic drug exposure, as well as benzene and ionizing radiation, provides little opportunity for further progress. Nevertheless, the patients are frequently younger than many with occupationally associated cancers and the failure to identify a causative agent is frustrating for the physician and harrowing for the patient.

Non-melanocytic skin cancer

There are three major forms of skin cancer, basal cell carcinoma (BCC), squamous cell carcinoma (SCC) and melanoma. Skin cancer has been historically one of the first cancers related to occupation, with the description by Percival Pott in the late eighteenth century of a higher incidence of cancer in the scrotum among chimney sweeps due to their exposure to soot. Sunlight exposure is the main risk factor for these cancers and many occupations currently at high risk for skin cancer are those with high
There are no reliable data worldwide on the incidence of keratinocyte cancers of the skin (BCC and SCC). In the United States, it has been estimated that about one million cancers occur annually. The highest incidence rates are observed among white-skinned populations. In this chapter, we will focus on BCC and SCC since the link of melanoma with occupational exposures is still uncertain.

Apart for solar radiation, BCC and SCC have been associated with several other occupational exposures, including mineral oils and coal-tar containing products, although risks nowadays tend to be relatively low in industrialized countries. The agents or mixtures classified by the IARC as carcinogens (group 1) or probable carcinogens (group 2A) associated with non-melanocytic skin cancer are shown in Table 85.9.

Cancers of the sinuses and nasal cavity are rare neoplasms with an incidence of around one per 100,000 per year and are strongly associated with occupational exposures. Classical early studies in the 1950s identified a higher risk among nickel refiners who had worked at the Clydach plant in South Wales before certain process changes occurred in the late 1920s. An early study also identified a high risk of ethmoid

identified high risks for non-melanocytic skin cancer (NMSC) among miners and quarrymen, secondary education teachers and masons (Table 85.10). Railway engine drivers and firemen, specialized farmers and salesmen were associated with BCC only. Occupations with a high risk for SCC only were those involving direct contact with livestock, masons and others. In a study from the United States, elevated risks of both BCC and SCC in men were found among groundskeepers and gardeners, except farm and for garage and service station-related occupations for BCC only. Women in health service occupations had elevated risks for both tumours, and administrative support occupations were related only to BCC risk. Only one study provided measurements of ultraviolet (UV) radiation and estimated cumulative dose, while the remaining studies base the evaluation of exposure on questionnaires. A recent evaluation of occupational cancer in the United Kingdom identified occupational exposure to solar radiation, mineral oils and coal tars/pitches as the main occupational causes of skin cancer.

**Other cancers**

**CANCERS OF THE SINUSES AND NASAL CAVITY**

Cancers of the sinuses and nasal cavity are rare neoplasms with an incidence of around one per 100,000 per year and are strongly associated with occupational exposures. Classical early studies in the 1950s identified a higher risk among nickel refiners who had worked at the Clydach plant in South Wales before certain process changes occurred in the late 1920s. An early study also identified a high risk of ethmoid
A high risk for sinonasal cancer has also been identified among workers in the leather industry, workers exposed to formaldehyde, workers in nickel refining and those exposed to hexavalent chromium compounds and also studies in the textile industry. Besides these exposures, elevated risks for sinonasal cancer were found in case-control studies for a variety of other occupations.77 Most studies, however, lacked the power to demonstrate statistically significant associations of this rare disease with specific jobs. Few other risk factors have been identified for

sinus cancer in furniture makers in Buckinghamshire. This study led to a major epidemiological exercise involving data linkage in the Oxford region. A further cluster of mixed cell type, mixed-site sinus cancers emerged in the Northampton area, thus leading to the assertion that leather goods manufacture – in particular, boots and shoes – carried a risk of neoplasia of the sinuses and nasal cavity.

Since the 1960s, a large excess risk for sinonasal cancer, particularly adenocarcinomas, has been repeatedly documented among workers in wood-related occupations.8,75,76

BCC, basal-cell carcinoma; NMSC, non-melanocytic skin cancer; SCC, squamous cell carcinoma.
sinonasal cancer, apart from occupational exposures and smoking.

Studies that provided results by histology, mostly distinguishing squamous cell carcinoma and adenocarcinoma, indicate that some of the identified risk factors for sinonasal cancer are related to specific histological types. In a number of individual studies and in a pooled analysis of case–control studies, the higher risk for wood workers was specifically associated with sinonasal adenocarcinoma (Table 85.11). The increased risks for smoking have mostly been found for squamous cell carcinomas and, in some cases, with undifferentiated carcinomas. The findings of this study indicate that the two major risk factors for sinonasal cancer (SNC) are tobacco smoking causing about 20 per cent of all SNCs and occupation causing about 30 per cent. These results also indicate that in the case of SNC specific exposures can be linked to morphology. Wood dust and, to a lesser extent, leather dust and formaldehyde were predominantly associated with adenocarcinomas, a pattern which appears to be specific to this tumour.

NASOPHARYNGEAL CANCER

Cancer of the nasopharynx is a very rare neoplasm with an incidence of less than one per 100 000 in most populations, although it is more common in some geographical regions and ethnic groups in Southeast Asia. Formaldehyde has been shown to be associated with cancer of the nasal cavity in rodents. A large study in the United States among 25619 workers (865 708 person-years) employed in ten US formaldehyde-producing or -using facilities among workers exposed to formaldehyde with extensive quantitative exposure assessment has shown an increased risk of nasopharyngeal cancer. Although findings are not entirely consistent among studies, it is generally accepted that formaldehyde causes cancer and the IARC has evaluated formaldehyde as a human carcinogen on the basis of this evidence.

STOMACH CANCER

The main clinical epidemiological feature of stomach cancer is the falling incidence of the condition in developed countries, which has been linked to better nutrition. Helicobacter pylori infection has been identified as one of the main risks for gastric cancer. Nitrosamines, which are proven and potent animal carcinogens, have been linked to human exposure in that the secondary amines in fish and preserved meat and vegetables could be converted to nitrosamines by gastric hydrochloric acid. Most epidemiologic studies of stomach cancer have focused on diet and lifestyle factors. There are numerous studies which have identified increased risks in various occupations and industries, including quarymen and stone cutters, coal and metal miners, rubber workers, construction workers, chemical and petrochemical workers, workers exposed to dioxins and farmers. The specific exposures evaluated are asbestos, coal dust and nitrogen oxides, mineral and metal dusts, wood dusts, nitrosamines and others. However, the evidence is not convincing for any of these exposures.
HEPATOCELLULAR CARCINOMA

The most important causes of liver cancer are infections with hepatitis B and C viruses and exposure to aflatoxins that have been consistently shown to be risk factors for hepatocellular carcinoma. Recent evidence\(^8^3\) has also shown that exposure to vinyl chloride is associated with hepatocellular carcinoma. Among the occupational exposures that are suspected to cause hepatocellular carcinoma are polychlorinated biphenyls and trichloroethylene. The available evidence, however, does not allow firm conclusions.

ANGIOSARCOMA OF THE LIVER

Angiosarcoma of the liver is a tumour that is extremely rare in the general population, and that has been unequivocally associated with exposure to vinyl chloride monomer. A case report of three cases of angiosarcoma of the liver in men who had been employed in the manufacture of PVC resins provided the first evidence of an association between vinyl chloride and cancer in humans.\(^8^4\) The case report was particularly informative because of the rarity of the tumour. Epidemiological evidence for the carcinogenicity of vinyl chloride in humans derives principally from two large, multicentric cohort studies, one of which was carried out in the United States\(^8^5\) and the other in Europe.\(^8^3\) Both studies found a substantial increase in the relative risk for angiosarcoma of the liver, and the European study, which had carried out extensive quantitative exposure assessment, also showed a clear trend of higher risk with increasing cumulative exposure (Table 85.12).

CANCER OF THE PANCREAS

Occupational exposures associated with cancer of the pancreas include studies of chemists and also radiologists. In the latter case, the excess risk appears to be for those exposed before 1929. This cohort effect may thus be a legacy of earlier, less well-controlled workplace exposures, although the absence of such a finding from other large-scale studies of workers exposed to ionizing radiation weakens the assertion that this physical agent alone was the responsible carcinogen. Among the chemical agents suspected to cause pancreatic cancer are some chlorinated organic solvents and chlorinated pesticides, including DDT (dichlorodiphenyltrichloroethane). The most complete meta-analysis of occupational exposures to chlorinated hydrocarbon (CHC) solvents and pancreatic cancer\(^8^6\) included 24 studies and was based primarily on studies that addressed exposure directly. Suggestive weak excesses were found for trichloroethylene (meta-relative risk (MRR) = 1.24, 95 per cent CI, 0.79, 1.97), polychlorinated biphenyls (MRR = 1.37, 95 per cent CI, 0.56, 3.31), methylene chloride (MRR = 1.42, 95 per cent CI, 0.80, 2.53) and vinyl chloride (MRR = 1.17, 95 per cent CI, 0.71, 1.91), but not for carbon tetrachloride. Job title studies on metal degreasing and dry cleaning revealed significant MRRs (2.0 and 1.4, respectively).

COLORECTAL CANCERS

Occupational exposures have rarely been implicated in colorectal cancers. There has, however, been a recent flurry of interest in whether workers in the polypropylene production industry could be at increased risk. However, earlier cluster reports appear not to be confirmed on further review. Intriguingly, a recent report suggests a tentative association between colorectal cancer and the manufacture of the anti-knock agent, tetraethyl lead. One of the few established risk factors of colon cancer, however, is lack of physical activity: since occupation is one of the main determinants of physical exercise in adult populations, it can be indirectly implicated in the causation of this neoplasm.

BRAIN TUMOURS

Brain tumours show a bimodal frequency distribution with a small peak in childhood and a second, larger peak in the seventh decade. The majority of adult malignant tumours are astrocytoma or undifferentiated glioblastoma. Mortality rates are rising in industrialized countries, but this may be, at least in part, due to improved accuracy of certification. Occupational factors have been invoked in recent years and both professional and manual occupations had been reported to be at increased risk. These include laboratory workers, petrochemical plant workers and embalmers. Potential chemical exposures include certain organic solvents, as well as ionizing radiation. Recent additions to this list might include lead, but the greatest interest of late has centred on the possibility that electric fields or magnetic fields (or both) from residential or occupational exposure might be associated with an increased risk of brain tumours. Thorough reviews of residential exposure studies and meta-analysis of the brain cancer risks from occupational exposures have failed to resolve...
the issue. Ongoing large international studies with extensive exposure assessment will provide new information (see Chapter 55, Extremely low frequency electric and magnetic fields).

BREAST CANCER

Breast cancer risk has been reported in women employed in jobs that entail exposure to organic solvents. These include dry cleaners, hairdressers, aircraft maintenance, textiles, electronics manufacturing and others. In addition, animal experimentation has shown that organic solvents have been associated with mammary gland tumours in rodents. However, the overall evidence for an association between occupational exposure to organic solvents is weak.

Studies in recent years have identified that women engaged in shift work may have an increased risk of breast cancer. About 15–20 per cent of the working population in Europe and the United States is engaged in shift work that involves night work. Shift work is more prevalent in some occupations, such as the healthcare, industrial manufacturing, mining, transport, communication, leisure and hospitality sectors. Night work is disruptive for the circadian clock. There are several rodent models that have shown an association of tumour development with a disruption of the circadian system and with reduced nocturnal melatonin concentrations or removal of the pineal gland where melatonin is produced. Epidemiological studies on nurses engaged in shift work at night and of female flight attendants have shown a modest increased risk (Figure 85.7). Most of these studies suffer from potential uncontrolled confounding by reproductive factors and cosmic radiation. If these risks are proven, given the high prevalence of shift work and the high background incidence of breast cancer, night shift may prove to be among the most important occupation-related risk factors for cancer. Further research on potential modification of effect in relation to light intensity may help evaluate aetiology of the disease and also potential preventive measures.

Estimates of risk of cancer attributed to occupational exposures

There exist several estimates of the proportion of cancers that can be attributed to occupational exposures (Table 85.13). These include the estimates for the US population by Doll and Peto and by Harvard University, by Dreyer et al. for the Nordic countries, by Nurminen and Karjalainen for Finland, a recent estimation for the UK and also estimates by the WHO (WHO Comparative Risk Assessment). Attributable risk estimates have also been provided in specific countries/areas for selected cancers for the EU, the United States, and France among others.

Two approaches have mainly been followed to estimate the proportion of occupational cancers among all cancers. One is based on the estimation of attributable risk fractions for specific cancers (usually based on case–control studies) that are then applied directly to the number of deaths from cancer (see, for example Ref. 5). The second is based on an estimation of the number of workers exposed, an evaluation of the cancer risk associated with each exposure and a subsequent estimation of the number of cancer cases or deaths attributed to this exposure (e.g. Ref. 74).

The most well-known estimates are those by Doll and Peto for the population of the United States that concludes that 4 per cent of all cancers could be attributed to occupational exposures. This estimate is an average and may differ in subgroups of the population and for different types of cancer. Doll and Peto defined three categories of cancers: those definitely produced by occupational exposures with an attributable risk (AR) of more than 1 per cent, those possibly produced with an AR of 0.5–1 per cent and those not associated with occupational exposures. The first category included neoplasms of the mesentery and peritoneum, liver and intrahepatic bile ducts, larynx, lung, pleura, nasal sinuses and remaining respiratory, bone, skin other than melanoma, prostate, bladder and leukaemia. The attributable risks for each of these cancers are shown.

![Figure 85.7](image)

Figure 85.7 Meta-analysis of female night workers and breast cancer risk in 13 studies. Reprinted from European Journal of Cancer, 41, Megdal SP, Korenke CH, Laden F et al., Night work and breast cancer risk: A systematic review and meta-analysis, 2023–32, Copyright (2005), with permission from Elsevier.
in Table 85.14. According to the Doll and Peto estimates, the proportion of cancer attributed to work is higher for men than for women, and also higher for manual workers compared to non-manual. It has been pointed out that the 4 per cent estimated is much higher if this percentage is calculated for preventable cancers. The estimates of Doll and Peto were mainly based on studies evaluating exposure of the 1950s and 1960s and also reflected the knowledge on occupational carcinogens of that time. Since then, knowledge on occupational cancer has considerably expanded and has also included populations not previously studied, particularly women. This would tend to result in higher estimates of the attributable risk than those estimated by Doll and Peto. On the other hand, in industrialized countries exposure to ‘classical’ occupational carcinogens has been drastically reduced by controlling exposure in the work environment or by transporting dangerous occupations and industries to developing countries. This would tend to result in lower estimates of the attributable risk than those estimated by Doll and Peto.

Rushton et al. provided for the population of the United Kingdom among the most complete and recent estimates of the proportion of cancer attributed to occupational exposures (Table 85.15). Attributable fractions and numbers were estimated for mortality and incidence in 2004 for bladder, lung, non-melanoma skin, sinonasal cancers, leukaemia and mesothelioma. The agents and occupations selected were those classified by the IARC as group 1 and 2A carcinogens. In 2004, 7317 deaths (4.9 per cent of the total) were estimated to be attributable to work-related carcinogens for the six cancers assessed. Of those, 6259 were in men (8 per cent) and 1058 in women (1.5 per cent). The estimates for cancer incidence were 13 338 cases (4.0 per cent) of the total cancer registrations. Of those, 11 284 were in men (6.7 per cent) and 2054 in women (1.2 per cent). The attributable risk percentages by cancer site are shown in Table 85.15. Asbestos contributed to over half the occupational attributable deaths, followed by silica, diesel engine exhaust, radon, work as a painter, mineral oils in metal workers and in the printing industry, environmental tobacco smoke (in non-smokers), work as a welder and dioxins. Occupational exposure to solar radiation, mineral oils and coal tars/pitches contributed significantly to skin cancer incidence. Industries and occupations that contributed a large number of deaths and/or registrations include construction, metal working, personal and household services, mining (not metals), land transport and services allied to transport, roofing, road repair/construction, printing, farming, the Armed Forces, some other service industry sectors and manufacture of transport equipment, fabricated metal products, machinery, non-ferrous metals and metal products, and chemicals.

### Table 85.13 Number of deaths per year from all cancers, lung cancer and bladder cancer in Europe and North America in 2002, attributable to occupational exposure according to different estimates. Estimates for number of deaths in each region were retrieved from GLOBOCAN (www-dep.iarc.fr).

Occupational cancers

Kogevinas et al. conducted pooled analyses of epidemiological studies in EU countries for four cancers (lung, bladder, larynx, sinonasal) including more than 13,000 subjects. They found similar estimates as those proposed by Doll and Peto.

The number of cancer deaths (all cancers, lung cancer, bladder cancer) attributed to occupational exposures using the estimates by Doll and Peto, Nurminen and Karjalainen and by Rushton are shown in Table 85.13 for Europe and for North America. Estimates for number of deaths in each region were retrieved from GLOBOCAN (www-dep.iarc.fr/). Cancer deaths due to occupational exposures vary from around 68,000 to 1,480,000 for Europe and from around 25,000 to 52,000 for North America. The estimated numbers for lung cancer range from 44,000 to 82,000 for Europe and 19,000 to 34,000 for North America, and those for bladder cancer from 4,500 to 5,500 for Europe and 1,200 to 1,400 for North America.

Existing estimates indicate that most occupational cancers occur among men due to the historically higher prevalence of exposure to occupational carcinogens among men. In most countries, the largest number of cancers attributed to occupational exposures is due to cancers of the lung and bladder. Numerous agents are associated with these two cancers including fibres and dusts, metals, radiation, combustion products and aromatic amines. Other specific cancers that contribute to the total number of occupational cancers are mesothelioma attributed nearly entirely to exposure to asbestos, sinonasal cancer attributed to wood dust, metals and formaldehyde, leukaemia and lymphomas attributed to solvents, pesticides, radiation and others. Mesothelioma contributes a significant number of occupational cancers in those countries where asbestos fibres have been extensively used such as the United States and the United Kingdom. In the United States, 85 per cent of all mesotheliomas can be attributed to asbestos exposure mostly in the occupational environment.

According to Naud and Brugere, in European Union countries, the number of occupational cancers officially notified in 1999–2000 was far below the estimated numbers of occupational cancers, similar to the pattern observed for other occupational diseases (Table 85.16). In those countries with the most extensive systems of notification of occupational cancers, around 10 per cent of all cancers that could be attributed to occupational exposures are notified as such. In most countries, this percentage is far lower and the under-reporting of cancers is extreme in some countries, such as Spain, where fewer than ten cancer deaths per year are notified as being of occupational origin.

Although the estimates for occupational cancers vary considerably, all main estimates indicate that some tens of thousands of cancer deaths in Europe and in the United States can be attributed to exposures in the workplace. There are no valid estimates for developing or newly developed countries. It can be expected that the number of cancer cases due to occupational exposures in countries such as China,
India or Brazil, will significantly increase in the coming years. Only a minor fraction are recognized as of occupational origin. This under-reporting severely undermines any attempt to prevent further cases.

**Contribution of occupational cancers to social inequalities**

The occurrence of social class differences in cancer incidence and mortality is well documented. Wide differences by socioeconomic status are observed in industrialized countries for all cancers combined and for many specific cancers, such as the lung, stomach and others. Occupational exposures are responsible for about 5 percent of the total of human cancers in industrialized countries and these cancers are concentrated among manual workers and in the lower social classes. Occupational exposures are therefore one of the contributing factors for the occurrence of social class differentials in cancer. Direct evidence on the extent of the contribution of occupational exposure to carcinogens to social class differences is lacking. Boffetta et al. estimated the contribution of occupational exposures to the occurrence of social class differentials using 1971 cancer mortality data for England and Wales based on 25–64 years cumulative rates reported by Logan. Proportions of cancers attributable to occupation were derived from Doll and Peto, taking into account cancer sites that have been strongly related with occupational exposures. All occupational cancers were assumed to occur among manual workers. One-third of social class differences in all cancer mortality between non-manual social classes (categories I, II and III non-manual of the Registrar General’s classification) and manual social classes (categories III manual, IV and V) could be attributed to occupational exposures (Table 85.17). For lung and for bladder cancer, about one-half of the differences could be attributed to occupation.

**Table 85.16** Estimated number and officially recognized occupational cancers in different EU countries (data from Ref. 99, with data for Spain from Kogevinas et al.103).

*Rate ratio, after excluding cancers attributable to occupation.*

Proportions of cancers attributable to occupation were derived from Doll and Peto. England and Wales, 1971 (data from Boffetta et al.104).
It is the clinician of first or second referral who has to take this responsibility. In view of the limited number of trained occupational physicians, the doctor consulted by the worker is likely to be a family doctor or a hospital consultant who has had little or no training in occupational medicine.

In other chapters of this book, considerable attention is given to the clinical presentation and management of occupational diseases. Such an approach is unlikely to be as helpful in the identification of occupation-related cancers. As a general rule, cancers that are of occupational origin are not distinguishable from non-occupational cancers whether in clinical features, natural history, pathological findings or other special investigations. A patient with lung or bladder cancer due to occupational factors will be diagnosed in the same way and using the same procedures as one without occupational factors. Where distinguishing features are relevant, they will be cited in the text.

One feature which has been noted with a number of occupationally related tumours is the possibility that the occupational cancer may present earlier than the non-occupational varieties. Thus, a patient aged 45 years with bladder cancer or one in his 30s with lung cancer – particularly if there is no history of tobacco consumption – should heighten the suspicion of the clinician that this might be an occupationally related tumour. For rarer tumours, such as angiosarcoma of the liver, pleural or peritoneal mesothelioma and nasal sinus cancer, for example, the occupational causes may outweigh the chances of finding such a tumour from other causes – known or unknown. The clinician thus needs to be aware of these varieties and their close links with occupation.

Given that occupation accounts for all or part of the tumour process in 5 per cent of cancers, physicians should contemplate occupation as a possible aetiological factor each time they see a new case of cancer. The rarity of the tumour may be the intellectual stimulus needed to consider workplace causes. It was occupational physicians at an American tyre manufacturer who were alerted to the carcinogenic potential of vinyl chloride monomer because of four cases of the extremely rare angiosarcoma of the liver in their workforce. However, it was an ear, nose and throat surgeon who first realized that woodworking was the common factor in her small series of rare adenocarcinoma of the ethmoid sinus.

A patient with a common tumour, such as lung or urinary bladder cancer, presents greater diagnostic difficulty. Nevertheless, many urothelial surgeons are now aware that occupation should be investigated when dealing with bladder cancer, where occupational exposures currently cause around 10 per cent of all tumours in Western Europe and North America. Similarly, it is our experience that haematologists commonly consider occupation when reviewing the possible causes of adult leukaemia, particularly the myeloid varieties.

The identification of work-related medical problems depends most importantly on the occupational history. Physical examination and special investigations may lead to a suspicion of a workplace agent as the cause of the disease but, ultimately, it is essential to obtain a thorough occupational history. A sentence or two in the family and social section of the medical history is not good enough.

The standard texts in occupational medicine have sections on the information that needs to be elicited in a good occupational history. This book on occupational diseases is no exception (see Chapter 3, The occupational history). From the point of view of occupational cancer, it is essential that this enquiry of ‘work relatedness’ goes back far enough in the patient’s life to be sure of including relevant exposures. That means at least 20 years and sometimes as many as 40. Several databases and publications available on the internet may help in the identification of occupational causes of cancer. These include lists and frequency of occurrence of carcinogenic exposures by industry, such as CAREX, or lists of carcinogens by cancer site as identified by the IARC.

Figure 85.3 shows a spot map of cases of bladder cancer occurring in a tyre factory in England where the association with exposure to 2-naphthylamine was clearly shown. All cases of bladder cancer occurred in sectors of the plant where 2-naphthylamine had been used. A simple visual inspection gave strong clues for aetiology. In current times in industrialized countries, it is (fortunately) extremely rare to identify occupational causes of cancer in similar ways. First, exposures to carcinogens have diminished. Second, employment patterns have changed and it is less common to have the same job in the same department for decades. Work mobility together with changes in production practices seriously complicates the identification of carcinogens. In addition, both big and small industries tend to subcontract several jobs/tasks, such as cleaning or maintenance, that were previously done within the industry. This poses serious problems in the control of exposures and the identification of hazards since many of the subcontracted companies performing tasks such as cleaning do not tend to be stable and in addition may have a high turnover of personnel.

Three examples seen by us illustrate complications in the identification of occupational causes of cancer.

EXAMPLE 1. THE SUSPICION THAT OCCUPATION MIGHT BE OF AETIOLOGICAL RELEVANCE

A 70-year-old man was admitted to hospital for a cardiovascular assessment following symptoms likely to be due to coronary artery disease. At routine examination on the ward, the junior member of the medical team undertook the ‘standard’ clinical history and proceeded to the physical examination. She, quite properly, did not restrict the physical assessment to the cardiovascular system and, as a result, discovered an indolent ulcer on the patient’s scrotum. Further enquiry revealed that the patient’s family doctor had been treating this lesion with emollient creams for over two years, without success. The examining
physician, working in an area of the country where scrotal cancer was no rarity, then turned again to the occupational history. The question: ‘What is your job?’ received the answer: ‘I am retired’. She persisted (rightly) ‘Yes, but what did you do before you retired?’ The reply gave the answer: ‘I was a multip spindle lathe operator for 30 years.’ The patient’s mineral oil-induced scrotal cancer was excised the following day. Fortunately, in this case, the junior doctor was not put off by the ‘retired’ answer, and, equally fortunately, the patient had an uncomplicated work history which gave the occupational link straight away. Detailed questioning may be required, as the second case demonstrates.

EXAMPLE 2. THE NEED FOR A THOROUGH LIFETIME REVIEW OF OCCUPATIONAL HISTORY

A 65-year-old woman was admitted to hospital with breathlessness and chest pain. A pleural effusion was clinically detectable and a pleural tap revealed a blood-stained fluid which on microscopy was found to contain mesothelioma cells. In this case, the suspicion of an asbestos-related aetiology was readily apparent, but as a ‘housewife’ the exposure history appeared to be lacking. There began a painstaking review of the patient’s life experiences. Finally, a crucial fact emerged. For a brief period of her early married life she was employed outside the home. She had worked during the Second World War for a short time and, for six months of that time, had filled gas masks with a ‘blue fibrous material’ 40 years before the onset of her symptoms of pleural mesothelioma.

EXAMPLE 3. INSPECTION OF WORKPLACE PRACTICES MAY BE IMPORTANT: OTHERS MAY BE POTENTIALLY AT RISK IN THE WORKPLACE

A third case, again of scrotal cancer, highlights a further area for the clinician. While working as a part-time occupational physician for a small engineering company, one of us saw an employee for a routine post-sickness absence medical. At that consultation, the employee stated that he was well, but asked for the form from ‘the Social Security’ to be completed so that he ‘would get money’. The form – for Industrial Injuries Disability – stated that the man had undergone surgery for scrotal cancer. In this case, the diagnosis and treatment in the individual case was complete. What was now needed was a review of workplace practices for others at potential risk in the multip spindle lathe section of the factory. On inspection, conditions were not good: there was poor hygiene for both skin and lung exposure to oils and oil mist, no formal policy for personal protection and no health surveillance for skin pathology.

These cases illustrate the importance of three aspects of a good clinical history:

- the suspicion that occupation might be of aetiological relevance;
- the need for a thorough lifetime review of those occupations;
- the need for somebody to consider others potentially at risk in the workplace.

Recognition of the importance of the first two aspects may not solve the problem even if occupation is the cause of the cancer. Thist is because patients may not know the relevant chemical (or physical) agents to which they were exposed or they may know them only by trade names or even nicknames. Second, the job titles used by patients may shed no light on the exposure issues and, finally, even if the employing company was known, it is possible that it has ceased to trade by the time of the enquiry. Use of certain chemicals is a problem, but employment in the chemical manufacturing industry compounds these difficulties. While the final product may be known and the exposures well documented, the range and complexity of possible exposure to intermediates can be staggering and may defy analysis even by the company’s chemists. A fourth example might illustrate this point.

EXAMPLE 4. IDENTIFYING THE CAUSAL AGENT MAY BE COMPLEX: THERE MAY BE MORE THAN ONE EXPOSURE CAUSING THE SAME CANCER IN THE SAME WORKPLACE

A chemical company manufacturing a range of pesticides noted, in the course of its sophisticated and extensive health surveillance programme, that some workers had developed skin lesions reminiscent of solar keratoses. Cursory statistical analysis suggested that the risk for these workers of developing these premalignant skin lesions was in excess of what might be expected. A thorough review of the manufacturing process, the worker exposure profiles and the intermediates involved suggested that certain plant improvements would eliminate some suspect agents and greatly diminish worker exposure to others. Action was prompt and health surveillance stepped up. A decade later, further cases of keratosis were noted – some in plant operatives who had never worked with the old process. The disturbing message was that the previous plant review had either failed to reduce exposure to the putative carcinogen(s) or, more likely and more disturbing, those suspect agents were not the cause of the keratosis. The problem here is not ignorance nor incompetence, but the sheer complexity of the chemical process with hundreds of organic chemicals, alone or in combination, being potential sources of risk and exposure.

In such cases, the clinician has every reason to fail to find an aetiological agent, but, for every case like that, there are many more where a simple careful account of workplace experience can pay dividends.

Finally, two practical points about investigating a patient with suspected occupational cancer: (1) These investigations can be very time consuming. Not only is it necessary to obtain a detailed lifetime occupational history in order to clarify whether a workplace factor is responsible for the tumour – and, if so, which one(s) – but it is also necessary
to ask about workmates who may have a similar disease. In our experience, a patient with an occupational disease is rarely, if ever, an isolated finding. Few patients are uniquely exposed at work and thus a case of occupational cancer should be assessed to be, in effect, the index case of what might turn out, on further enquiry, to be a cluster of cases. However, given the relative rarity of cancer, most cases will be individual cases particularly in smaller enterprises. (2) The clinician should, if possible, acquire information about the worksite either directly from the occupational health service or, if this is not possible or not sanctioned by the patient, make enquiries from the employer about the job and about any other relevant workplace exposures which might cast some light on the suspected association with occupational exposure. While textbooks may help here, much useful assistance can be gained from talking to the local representatives of the national government agency responsible for health and safety at work. In the UK, this is the Employment Medical Advisory Service of the Health and Safety Executive. They might confirm the clinical suspicion or the enquiries may stimulate their investigations, locally and nationally, for further cases in similar workplaces. Where available, academic departments of occupational health serve a similar function and should be capable of providing the clinician with a second opinion on the case, as well as literature searches for published evidence of occupational risks for that cancer site, in addition to information on whether the suspect agent or process has been reported to be linked with tumours at that site.

In summary, the difficulties of identifying occupational factors in relation to cancer in the clinical setting are:

- ignorance of the risk by the worker – or management;
- failure of the clinician to consider an occupationally related aetiology – for that patient or for others at risk in the same workplace;
- diversity of chemical nomenclature;
- variable degrees of worker exposure to single or complex chemical mixtures;
- movement of workers between jobs, work areas or industries;
- failure to record previous occupations to the current (or last) one;
- long latency-induction times for cancer;
- job obsolescence;
- company closure;
- busy clinical workload.

Finally, it is important to note that for a clinician a new case might be yet another example of an occupational cancer already extensively reported in the specialist literature. It might, however, be the first case.

**Prevention of occupational cancer**

There are numerous examples of successful prevention of occupational cancer. Prevention may be primary or secondary. For primary prevention to be a practical proposition, it is necessary to know of the existence of proven aetiological agents and then to know that separation of humans from exposure to the agent is feasible. Primary prevention may also be efficient through the implementation of general measures for control of exposures as has happened in many industries in Europe and North America after the 1970s-1980s. Such measures were not necessarily focusing on one agent, but through improvements in work practices and changes in industrial processes may have resulted in efficient measures of primary prevention through a control of a wide range of occupational exposures. Secondary prevention usually means early detection of the disease process, and, most important, presumes that early detection will lead to an improved prognosis following treatment.

In this context, several regulatory actions exist both at the national and international level. The European Parliament regulates the protection of workers from the risks related to exposure to carcinogens or mutagens at work through Directive 2004/37/EC. The directive indicates that any activity likely to carry the risk of exposure to carcinogens or mutagens, the nature, degree and duration of workers’ exposure must be determined on a regular basis in order to assess any risk to workers' health or safety and decide the steps to be taken. All routes of exposure must be taken into account, including absorption into and/or through the skin. Particular attention must be paid to workers who are especially at risk. The directive lays down exposure limit values, as well as preventive measures. In addition to this more standard approach to the protection of workers and consumers, the European Union has implemented the REACH initiative. REACH is a new European Community Regulation on chemicals and their safe use (EC 1907/2006) that entered into force on June 1, 2007 and that deals with the registration, evaluation, authorization and restriction of chemical substances. REACH is based on the idea that industry itself is best placed to ensure that the chemicals it manufactures and puts on the market in the EU do not adversely affect human health or the environment. This requires that industry has certain knowledge of the properties of its substances. The benefits of the REACH system are not yet apparent and it is expected that they will come gradually, as more and more substances are phased into REACH. REACH also calls for the progressive substitution of the most dangerous chemicals when suitable alternatives have been identified.

In industrialized countries, there have been significant improvements in prevention and control of exposure to occupational carcinogens. Improvement of work conditions and control of occupational carcinogens in newly industrialized countries or in developing countries is a major challenge.

**PRIMARY PREVENTION**

In theory, all occupational cancers are preventable in that they result from workplace exposure. This is particularly so, since many occupational carcinogens have been...
successfully identified. All that is required to prevent the disease is elimination or drastic reduction in the level of exposure. Thus, the most efficient policy would be to ban the offending agent. In practice, this is less straightforward, for a number of reasons:

- The exposure may be defined only in terms of a very complex mixture, for example organic solvents or polycyclic aromatic hydrocarbons, or as a whole industrial process or even as a section of an industry or a large occupational category, for example painters. This may make it difficult to envisage, apart from general hygiene measurements (often effective in themselves), what more targeted control procedures one could adopt.
- The substance/process may be perceived to be of great societal importance. Benzene would be a good example here. It is the basic building block for so much of the aromatic organic chemical industry that its ‘exclusion’ from industry is difficult to conceive. It is also a natural ingredient of fossil fuels and thus would be difficult to eliminate even if the desire to do so were prevalent. In these situations, it is crucial to reduce the level of exposure to very low levels that are unlikely (with available knowledge) to cause disease.
- The substance has substitutes, but substitution is either expensive or the substitutes themselves are not without risk. Asbestos is undoubtedly a major cause of occupational cancer. Some of the more hazardous (amphibole) varieties have been largely excluded from commercial use, but it took a much longer period to exclude chrysotile asbestos from use. Chrysotile asbestos is believed to be less hazardous than other types of asbestos, at least in relation to mesothelioma, and has a combination of valuable properties not easily found in synthetic substitutes. Substitutes for chrysotile, such as man-made vitreous (mineral) fibres, may not be without risk, although it appears that this risk (if existent) is far lower than that of asbestos. All types of asbestos have been banned in many areas of the industrialized world.
- The agent itself is of limited economic importance, but its presence in an economically important industry is difficult to control. Radon exposure in metalliferous mining serves as an example here: effective control of radon exposure is extremely difficult, yet the need to mine for metals in these environments remains.

Nevertheless, the principle remains that reduction, substitution or, ideally, elimination of the known workplace carcinogens is of great public health importance. The lesson of vinyl chloride monomer shows that exposure to a vital chemical agent can be reduced sufficiently to eliminate a relevant tumour – even if one doubts in theory that a ‘threshold’ exposure exists. In other cases, such as 2-naphthylamine, purer ingredients or effective substitutes have been formed, thereby reducing workplace-related disease and death. However, even in the case of 2-naphthylamine and bladder cancer, analyses conducted many years after this ban identified an excess bladder risk in nearly all studies available (Figure 85.4). This could be due to a continuous increased risk among workers exposed in the past to 2-naphthylamine or probably to the presence of other carcinogenic substances in this industry. Where exposure, albeit at a reduced level, continues, every effort should be made to shorten the duration of exposure and to reduce exposure to very low levels. The earlier the action, the earlier the effect of reduction of exposure will be recorded.

SECONDARY PREVENTION

Primary prevention, although ideal, will never in the real world be the answer in every case. Therefore, secondary prevention in the form of early detection of human effect needs to be involved as well (not instead of). On the face of it, the earlier the neoplastic process is detected, the easier it should be to cure the patient. In practice, this is not so clear cut. This is not the place to discuss the general question of screening nor to describe in detail the attributes of a good screening test. For some cancer sites, screening is effective in leading to prevent cancer or to better cure/survival rates, as is the case of cervical cancer or breast cancer. However, there are no efficient secondary prevention strategies for occupational cancers, although there has been extensive research on the prevention of, for example, lung cancer and mesothelioma in asbestos-exposed workers through x-rays or cytological examination of sputum.

In summary, the whole purpose of detecting cancer is to cure or prevent other cases of cancer. Discovery of new workplace-related cancers by clinical acumen and the establishment of causative factors by epidemiological study provide the firm scientific basis for vigorous preventive action. Treating the cause of cancer has variable success. Eliminating a known cause ensures that, at least for the future, the need for treatment is obviated.

METHODOLOGICAL ISSUES IN EPIDEMIOLOGICAL RESEARCH ON OCCUPATIONAL CANCER

Epidemiological studies have significantly contributed to the recognition and control of occupational diseases and work exposure to carcinogens. In addition, studies on occupational cancer have been among the first to develop methods for the conduct of (historical) cohort studies applying the concept of person-years. A report on lung cancer and mortality in an arsenical powder-producing factory published at the British Journal of Industrial Medicine in 1948 by A Bradford Hill and E Lewis Fanning constitutes probably the first description of how to perform a historical cohort study. Note that the authors did not have the information to conduct such a study and instead performed a proportional mortality study. The first historical cohort study was published by Sir Richard Doll in 1952, evaluating the mortality among gas workers.
The main characteristics of studies on occupational cancer are similar to those in other areas of epidemiology. There exists similarity on the basic principles such as that of the study base (the population from which the study population originates) or the fact that incidence is the main measure for disease. In this part of the chapter, we discuss specific items related to the design and analysis of epidemiological studies on occupational cancer. We do not discuss designs that are rarely applied on studies on occupational cancer, such as cross-sectional studies (although many biomarker-based studies are essentially cross-sectional). We also discuss some aspects related to exposure assessment that have considerably developed in recent years.

Formally, case series should not be considered as epidemiological studies. Frequently, what is reported is an accumulation (cluster) of cases in an industry or job, mostly concerning rare diseases. The report of a series of cases of liver angiosarcoma among workers in the polymerization of vinyl chloride is a classical example. Case series can help identify new carcinogens as was the case for angiosarcoma of the liver and vinyl chloride monomer (VCM), benzene and leukaemia in shoe workers, or mesothelioma in asbestos-exposed workers, and may lead to a successful intervention. However, a case series can also represent an anecdotal occurrence and can be affected by reporting bias. Most of the time, case series do not refer to defined populations and frequently do not identify causal associations.

Types of study in occupational cancer

COHORT STUDIES

The cohort design is the one that has most frequently been applied in occupational cancer epidemiology. In these studies, populations of specific industrial sectors are examined or, occasionally, a sample of the general population is examined. Once a specific population has been identified, exposure information is collected and subjects are followed up to evaluate cancer incidence or mortality. In prospective cohort studies, information on exposure of each individual is selected and workers are followed in time. Retrospective cohort studies can only be conducted if complete registers of workers are available in an industry and also if mortality or cancer incidence data are available.

Identification of the cohort

The identification of the cohort is the first step in the design of the study. In most of the studies, the exposed group is usually identified through the payroll registry of the industry. Sometimes, labour union registries are also used. For example, in a study of wood workers in the United States, the exposed population was identified through its labour union (United Furniture Workers of America). Nevertheless, the usual lack of detailed and complete information about the occupational history of the workers in this type of registry makes it difficult to interpret the results. Finally, occupational disease registries have been used occasionally, for instance, when studying workers suffering silicosis or mercury poisoning in relation to the later occurrence of lung or other cancers.

The main concern in the design of an epidemiological study is the internal validity. For this reason, it might be necessary to apply restrictive criteria in the cohort identification. This will, in turn, depend on multiple factors, like the cost and the time of the feasibility of the study. For instance, sometimes it is not possible to identify and follow up the temporary or emigrant workers, mainly because the occupational registries for these groups of workers are neither complete nor precise. The restriction of a cohort to a subgroup of workers does not affect the validity of the study, but it implies an important loss of information. Once the inclusion criteria have been defined, each subject that fits in these criteria should be included in the study, and followed up until the end of the follow-up period. If the study population does not include all eligible subjects according to the criteria established initially, it is possible that individuals that were not identified have a difference with respect to the exposure characteristics and/or their vital status.

Determination of the vital status

In mortality studies, the research of the vital status (follow-up) is performed by matching the personal identifiers of the cohort members (name, date of birth, registry number, national identity number, social security number, tax number, etc.) with the national mortality registries. One of the main concerns in cohort studies is the identification of the vital status of most of the individuals participating in the study. Although no strict criteria have been established to define the acceptable losses to follow up, the validity of results should be treated with caution if the loss to follow up is more than 20 per cent. There are different options to deal with losses to follow up and its contribution to the study in persons-year: (1) Delete from the study all individuals that have been lost during follow up, although this results in an unnecessary loss of information. (2) Assume that all subjects lost to follow up will be free from the disease at the end of the study, contributing to the persons-year at that particular moment; this will result in an underestimation of the disease risk of the cohort. (3) Count only the persons-years of the subjects lost to follow up only to the date of the last contact. This third option is the most justifiable, since all known information (persons-year) is included in the analysis.

Cause of death is usually obtained from death certificates and, in many industrialized countries, this information is relatively accurate. Most retrospective cohort studies on occupational cancer have not validated cause of death using other information, such as clinical records. However, validity of cause of death information may depend on type of tumour examined. In a study of dioxins...
and cancer, an excess risk for soft-tissue sarcoma was observed, with a standardized mortality ratio (SMR) of 338, including four deaths identified through death certificates. The histological review of the tissue samples indicated that two of the four sarcomas were misclassified as such, and other sarcomas have not been diagnosed correctly. When comparing national mortality rates, the SMR should be calculated from the information in the death certificates registry, and not be based in a review of the cause of death by a group of experts. As a result, in the dioxins study, the risk of sarcoma was calculated correctly on the basis of the four deaths from sarcoma, but the validity of the results could have been questioned due to the large classification error.

Selection of a comparison group

In the occupational cohort studies, two comparison groups are used: (1) external comparison groups (usually country mortality rates) and (2) internal comparison groups, identified in the same cohort. Occasionally, both types of comparison groups might be used in the same study.

The use of an external comparison group has been extensive, particularly in the past in historical (retrospective) cohort studies on occupational cancer. The most common procedure is to choose the population of the country as a comparison group and then calculate the SMR. The indirect standardization (analysis of the SMR) is the technique most commonly used to adjust the rates in the occupational cohort studies. The SMR is the ratio of the total number of observed deaths to the number of expected deaths, provided that the study population has mortality rates similar to the comparison population group. There are some advantages to use the population of the country as a reference population. First, it is of interest to know how the cohort rates behave before the country rates. Second, the mortality rates per age group, sex and calendar year are usually available to both at national and international level (World Health Organization). Finally, the use of national mortality rates has the statistical advantage that they are stable, which is especially important when studying rare diseases. Nevertheless, the use of national mortality rates has some disadvantages. Where working populations are the object of study, the comparisons may be biased due to the healthy worker effect. Another disadvantage is the difficulty of controlling for potentially confounding factors that have not been measured, such as lifestyle-related factors in the study region. This problem can be partially solved when using other defined external populations as the reference population. In this case, comparisons can be made only with the working population rates, as in northern European countries, in regional or local populations, or with other external cohorts, for instance, other industrial populations. The use of regional rates is recommended when there is a prior knowledge that morbidity or mortality will vary considerably between different regions. The main advantage of using an external industrial cohort as a reference is the reduction in the bias due to the healthy worker effect, and that the two populations will probably be very similar in their lifestyle factors. In consequence, the importance of potentially confounding factors, such as tobacco, will probably be lessened. In summary, the selection of an external occupational cohort as a reference group has several advantages. However, the selection should be made carefully with the aim of making the two groups as comparable as possible in relation to factors such as age, gender, social class or average duration of the job, and that the reference group is not exposed to occupational risk factors related to the study disease. Moreover, unstable rates in the reference group (regional or local population, external industrial cohort) may limit the accuracy of the effect estimates, especially when examining rare diseases such as leukaemia or lymphoma.

Internal comparison group

When using an internal reference group, the comparisons are restricted to the experience of persons-time of the same cohort. In this situation, the reference category will be the disease rate associated with the persons-time of the non-exposed or low-exposed subjects. In this type of study, the quantity and quality of the data are similar in both comparison groups. Selection bias (including healthy worker effect) will also be similar between exposed and non-exposed individuals. However, unstable rates in the reference group might be a limiting factor in the accuracy of the risk estimates, specifically when rare diseases are under study. In addition, the variability of the exposure might be small in the same cohort, so it might not be possible to identify an internal reference group of non-exposed subjects. For instance, in an international cohort study of styrene workers, it was not possible to identify adequately an internal group of non-exposed workers. In this study, the comparisons were limited to exposed individuals classified into quintiles of the cumulative exposure, being the lowest quintile exposure group (less than 10 ppm-year) of the reference group.

CASE–CONTROL STUDIES

In case–control studies, exposures in the past of people with a disease (cases) are compared to those of subjects without the disease (controls). The main features of case–control studies on occupational cancer are similar to those of other risk factors. Two types of case–control studies on occupational cancer epidemiology can be distinguished: (1) community (population)-based studies and (2) nested case–control studies within an industrial cohort.

The only unique feature of community-based studies on occupational cancer is the measurement of occupational exposures. Questionnaires are the most frequently used methods to obtain information on occupational exposures, specifically information on occupation, industry, tasks at the job and dates of employment. While workers may fully recall the jobs they have performed, they may
not recall or know the specific substances to which they were exposed. Studies based on cancer registries or death certificate data, are primarily used to generate new hypotheses on exposure disease relationships or are used for surveillance purposes. These studies are based on existing records, such as mortality or cancer incidence records. The main advantage of these studies is their low cost and the availability of already collected data. The main problem is the lack of detailed exposure information on occupational exposures even in studies that may do extensive record linkage between different registers as has been frequently performed in Scandinavian countries.

Nested case–control studies within a cohort is a study design that has been frequently used in occupational cancer epidemiology. Many occupational cohorts collect only limited occupational and disease information and may not have more detailed information both on the exposures in the workplace or of other exposures, such as smoking, alcohol, etc. This information could be obtained for a small subsample of the occupational cohort within the context of a nested case–control study in which cases occurring in the cohort are compared with a set of controls (rather than with the total cohort). For example, a nested case–control study on non-Hodgkin lymphomas and soft-tissue sarcomas was conducted within an international study of 25,000 workers exposed to phenoxy herbicides, chlorophenols and dioxins. Thirty-two cases of lymphoma and 111 of sarcoma were matched to 158 and 55 controls, respectively.43 A panel of three industrial hygienists examined the detailed work records of these subjects regarding their exposure to 21 chemical agents. An increased risk both for lymphomas and sarcomas was found for exposure to the herbicides and to dioxins. This type of detailed evaluation would have been impossible if it were to be done among the 25,000 workers of the original cohort. In addition, an evaluation of the total cohort would have added very little in terms of statistical power.

The case–cohort design is another type of nested case–control study. The main feature of the case–cohort design is that the controls are selected randomly from the subjects present at baseline, i.e. when the cohort started. Case–cohort studies may include multiple cancers as their outcome, using the same set of controls. Among the advantages of case–cohort studies is that one control group can be used for many cancers making this design more efficient in terms of cost. Also, this design allows the calculation of absolute risks (in comparison to relative risks).

A case–cohort study on several cancers was conducted in Shanghai, nested within a cohort of 267,000 women employed at the Shanghai Textile Industry Bureau (STIB) and that had originally been enrolled in an intervention study on breast cancer screening.111 Complete occupational history was obtained for 102 incident cases of oesophageal cancer and 646 cases of stomach cancer, and for a reference group of 3188 women. A wide range of occupational exposures were evaluated by industrial hygienists and an increased risk of oesophageal cancer was associated with exposure to silica (HR = 15.8, 95 per cent CI, 3.5–70), while a protective effect was found for exposure to the endotoxins that are present in cotton dust.

### Issues in design and analysis

**HEALTHY WORKER EFFECT**

The healthy worker effect (HWE) refers to the lower mortality observed in many worker studies compared to that of the general population. The lower rates observed among workers is, in part, due to the fact that people with serious diseases or those who are disabled are excluded from the labour market. Therefore, a comparison of workers’ health with that of the general population may be inappropriate if this effect is not taken into account. This bias has been traditionally described as a selection bias, although it can also be described as a problem of confounding.108

The healthy worker effect can be determined by three components:

1. **Selection in employment.** The HWE occurs mainly due to the initial selection of healthy subjects in the labour force. Healthy individuals have more chance of searching to occur and for getting selected. In one of the first studies describing the HWE,112 the overall SMR for the workers in a vinyl chloride polymerization plant was 0.75 and the SMRs were low for most specific diseases.

2. **Selection out of employment.** This aspect of the HWE (also called the healthy worker survivor effect) may occur when prolonged exposures are examined. Workers with longer duration of employment may have lower disease rates than those with shorter employment periods. This happens because sick workers tend to abandon employment. An increased disease risk in the first years after leaving employment has been observed in several studies.

3. **Duration of follow up.** The HWE is stronger during the first period after employment and diminishes as employment becomes longer. In the study by Fox and Collier,112 mortality from all causes increased with duration of follow up: for 0–4 years the SMR was 0.37, for 5–9 it was 0.63, for 10–14 it was 0.75 and for more than 15, 0.94.

Different methods can be applied to control for the HWE. The most direct method is to take into account the initial employment status and compare the cancer risk of the study population with that of workers in other jobs/departments in the same or in another cohort. Given the inverse correlation of the HWE with length of follow up, this effect can be examined through stratification by follow-up time. When cancer mortality is examined, the HWE becomes very much attenuated after around 20 years of follow up.
Selection out of the labour force can be partially controlled by taking into account employment status. In the classical study by Fox and Collier, they examined mortality depending on whether workers continued working in the industry or not. Mortality among those who left the industry was about 50 per cent higher than that of workers continuing working. More recently, Steenland and Stagner examined the same problem by categorizing person-years into those active (years during employment) and those non-active (years after leaving employment) and found the same pattern as Fox and Collier only for ages before retirement.

CONFOUNDING IN OCCUPATIONAL CANCER STUDIES

In occupational cancer studies, general factors, such as tobacco smoking or obesity, can be considered as alternative explanations to increased cancer mortality in an occupational cohort. This is plausible since several lifestyle factors vary within a population by socioeconomic status. In many countries, tobacco smoking is more frequent, for example, in lower socioeconomic classes at least among males and those same classes have a higher prevalence of exposure to occupational carcinogens. It is noteworthy, however, that studies of occupation and lung cancer have found smoking to be a relatively infrequent confounder even though the association of the potential confounder with the general population. It is also necessary to know the prevalence of exposure to the potential confounder in the study population and also in the reference population, e.g. the general population. It is also necessary to know the strength of the association of the potential confounder with the disease, e.g. smoking and lung cancer. This information allows estimation of the amount of the increased risk among exposed workers that could be explained by the confounder.

Internal analyses within the cohort of workers among those exposed and those non-exposed to a specific agent, in part, overcome the problem of confounding since a relatively safe assumption can be that lifestyle does not vary systematically among manual workers employed in different departments of the same industry.

LATENCY ANALYSIS

A cancer due to an occupational exposure will occur on most occasions, many years after first exposure. Analysis of epidemiological data should take into account the latency period of the disease and should evaluate the time periods during which exposures could have caused the disease.

One of the methods used to evaluate latency is to perform a lagged analysis. In this approach, exposures occurring in periods that are not evaluated to be relevant for the occurrence of a cancer, are ignored, as for example exposures during the last period before diagnosis. It is assumed that the induction of the cancer had occurred at an earlier period and therefore any posterior exposure would be considered irrelevant. For example, in a worker exposed to asbestos fibres from 1960 to 1990 and diagnosed with lung cancer in the year 1990, a classical analysis would calculate his exposure to asbestos during the whole 30-year period. By contrast, a lagged analysis applying a five-year lag would assume that any disease occurring shortly after diagnosis (in this example five years) could not have been caused by the exposure. Therefore, the real period at risk would start at the fifth year of follow up, at which time the worker would be assigned his exposure of five years earlier.

The use of time-windows is an extension of the lagged analysis. This approach intends to identify the most relevant exposure period for the occurrence of disease. With the time-windows approach, exposure occurring at both early and late periods may be ignored. Identification of the most relevant time-window is made empirically by examining risk in consecutive windows. Table 85.18 shows an example of the application of this methodology in a study on asbestos exposure and lung cancer. The highest risk is observed in the time-window from 20 to 24 years before disease occurrence, particularly when risk estimates for different periods are mutually adjusted. This indicates that the increased risk of cancer in this study could be attributed to exposures occurring mainly before 20 years from diagnosis.

INTERACTION

Diseases are caused by more than one factor and the risk of acquiring a disease depends not only on the separate effects of each factor, but also on the way different factors

combine. How to define and measure the combined action of two or more factors has been long discussed in epidemiology and different terms have been used: interaction, effect modification, synergism (and antagonism), biological or statistical interaction. There is confusion in the use of the term ‘interaction’ mainly due to the different meaning of this term in statistical theory and in biology.

It serves no practical purpose to use the term ‘interaction’ in epidemiology without specifying what type of model (or scale) was used to evaluate the association of exposure and disease. The additive and the multiplicative models are those most used. There are arguments for using both models, although the multiplicative model has been used more frequently in aetiological cancer epidemiology both for empirical and theoretical reasons.

There are only a few examples of well-studied interactive effects in the causation of disease. In occupational cancer, epidemiological interaction has mostly been investigated between tobacco consumption and exposure to asbestos and to ionizing radiation. In recent years, the interaction between occupational exposures and genetic polymorphisms has also been examined.

Table 85.5 shows incidence rates for lung cancer among workers exposed to asbestos in relation to smoking. The pattern observed indicates a possible multiplicative pattern of interaction with asbestos-related risk being equally elevated among non-smokers and smokers, i.e. around five times. However, note that because smokers not exposed to asbestos (122.6/100 000) have a much higher risk than non-smokers unexposed to asbestos (11.3/100 000), the multiplication of this risk by approximately 5 due to asbestos exposure results, in absolute terms, to a very great increase in risk among exposed smokers. There are a few, although not well-proven, examples of interactions of occupational exposures and smoking, including arsenic and nickel and lung cancer.

**Evaluation of exposure in occupational cancer studies**

Methods to evaluate occupational exposures have been considerably improved in recent years and incorporate modelling techniques and the application of biomarkers. New approaches have also been applied in the construction of questionnaires and methods to evaluate them.

Strategies applied to evaluate occupational exposures depend on the study design applied, the population studied and the resources and prior information available. Exposure could be directly measured at the workplace in a prospective study, could be estimated using questionnaires in a case–control study or based on job records in a retrospective cohort study. Several techniques can be further applied to estimate past exposures, for example use expert opinions, job exposure matrices (JEM) or applying exposure models. Modern exposure assessment methods may evaluate pathways of exposure including, for example, sources of exposure, personal exposure estimates, use of protective equipment and also incorporate uncertainty in the measurements (Figure 85.8). Many occupational cancer studies have been retrospective cohorts that have based exposure estimates on existing job records and, occasionally, additional exposure information from the workplace. In cancer case–control studies, questionnaires have been the main source of information used, frequently in combination with expert opinions and JEMs.

**QUESTIONNAIRES**

Questionnaires have been extensively used in case–control studies irrespective of whether these are community based or nested within a cohort and usually request detailed information on jobs, tasks, industries worked, specific exposures, use of protective equipment, etc. It has generally
been observed that questions on specific chemical exposures have a low sensitivity, i.e. many exposed subjects do not report that they have been exposed. In nested case–control studies, exposure assessment is easier mainly because the number of jobs, tasks and exposures is more limited than those observed in a general population study.

Supplementary questionnaires have been used in several occupational cancer case–control studies to retrieve more detailed information for specific carcinogens, e.g. asbestos, or to a whole list of carcinogens. These supplementary questionnaires are used in subjects who report having worked in jobs or industries in which a specific carcinogenic exposure may occur. Specific questions relate to the materials used, tools, machinery, tasks performed, so as to evaluate with more certainty the probability and level of exposure. These detailed questionnaires are further analysed using a predetermined algorithm or through a case-by-case evaluation by experts.

For example, a study on occupational causes of bladder cancer in Spain120 used 63 supplementary questionnaires for specific occupations, e.g. welders and machinists, or for specific industries, e.g. the textile industry.121 These modules covered several exposures of interest, e.g. PAHs, diesel engine exhaust and solvents, that could occur in multiple workplaces. The use of such questionnaires, undoubtedly, provides important exposure information, but requires considerable expenditure in terms of time and money and also requires good knowledge of the workplace in order to prepare the questionnaires.

Industry questionnaires which collect information on industrial processes, exposures and accidents of specific industries have been used in studies on occupational cancer, for example the study in the pulp and paper industry of the IARC.122 In this IARC study, information was collected in industries worldwide which participated in the study of industrial processes, volumes of production of specific compounds, use of primary materials, circumstances of industrial accidents, use of protective equipment, etc. This information was later coupled with information from the workers in the cohort to develop exposure estimates.

**JOB EXPOSURE MATRICES**

Job exposure matrices have been extensively used in occupational cancer epidemiology. JEMs are simply a matrix (or table) showing which occupations are exposed to specific chemicals and this information is based on prior knowledge of exposures of specific occupations. This method allows a nearly automatic assignment of exposures in the matrix to the subjects of the study, provided a complete occupational history is available for each subject. There exist several general and specific JEMs, using different methodologies, designed to cover different objectives and exposure areas.123–127 Some have been constructed on the basis of expert opinion,123,124 while others are based mostly on measurements in the workplace.127 FINJEM, which was developed in Finland, is among the most widely used general JEMs (FINJEM)128 and has been applied in several other countries. Some JEMs have been constructed for specific industries or exposures, such as a JEM on electromagnetic fields in the occupational environment.

The main advantages of JEMs is the low cost of using them once they have been created and the high repeatability of the estimates, since for a specific job one would attribute the same specific exposure estimate. The main disadvantage of JEMs is the potentially important exposure misclassification even though, in principle, this should be non-differential. This is a result of the fact that the same exposure is attributed to workers of the same job, even though it is known that exposure may vary considerably between workers or between workplaces among those doing the exactly the same job. This type of misclassification tends to reduce the risk estimates of a study towards null (i.e. to no association).

**EVALUATION OF EXPOSURE BY EXPERTS**

Evaluation by experts is considered among the most valid approaches when examining occupational exposure assessment.129 In this approach, a group of experts (industrial hygienists, chemists) use their professional experience to evaluate if a worker has been exposed to a chemical or physical agent, on the basis of information they have on the occupational history of the worker and their own knowledge on exposures in the specific occupation/industry. The most quoted study was a multisite case–control study in Montreal which examined around 260 specific exposures.130 The occupational history of the subjects in the study was examined by a group of experts who attributed to each subject the probability and extent of exposure to each chemical. In most case–control studies applying such an approach, the number of chemicals evaluated is much smaller. Frequently, the evaluation by experts is used in combination with other methods. For example, a JEM can first be applied and then experts evaluate only those subjects classified by the JEM as potentially exposed. This approach considerably reduces the experts’ workload, which otherwise is one of the main disadvantages of this method. In addition, a problem of this method is potentially the lack of repeatability, particularly if the experts are not very experienced.

**EXPOSURE MODELS**

The most precise methods for evaluating occupational exposures are those using direct measurements in the workplace sometimes combined with the use of biomarkers. However, in most cases, this type of information is not available, or is available only for a subgroup of workers. In these cases, the use of exposure models can be considered to attribute exposure levels to the whole study population. Stochastic models are those that are based on existing measurements in a subgroup of workers that are then applied through regression or other modelling to the total
Biomarkers and mechanisms

Carcinogenesis is a multistep process driven by carcinogen-induced genetic and epigenetic damage in susceptible cells that gain a selective growth advantage and undergo clonal expansion as a result of proto-oncogenes or the inactivation of tumour suppressor genes. The first stage of carcinogenesis, tumour initiation, involves the exposure of normal cells to a chemical, physical or viral carcinogen that causes a genetic change or changes resulting in ‘initiated cells’ (Figure 85.10). The next step, tumour promotion, is related to the acquisition of increased survival or proliferation of the ‘initiated cells’ as compared to normal cells. This process enhances the probability of additional genetic damage in the expanding population of these cells and might move the initiated cell, to pre-neoplastic lesions, to a malignant tumour and finally a clinical cancer.

Biomarkers can play an important role in the identification of key events in this multistep carcinogenesis process. More specifically within occupational cancer, biomarkers can be used to enhance exposure assessment, identify key events along the pathway from exposure to disease, determine sources of genetic susceptibility, and categorize tumours into more homogenous entities at the molecular level. Furthermore, new discovery technologies, including whole genome analysis, mRNA expression arrays, proteomics and metabolomics/metabonomics (i.e. the study of cellular metabolites) now enable investigators to broadly explore biologic responses to exogenous exposures, to evaluate potential modification of those responses by variants in essentially the entire genome, and to define tumours at the chromosomal, DNA, mRNA and protein levels. It is beyond the scope of this chapter to describe all biomarkers related to specific cancers and occupational exposures. Instead, we will describe the different types of biomarker that have been applied within occupational cancer research and provide some examples.

Tumour biomarkers

Both genetic changes (e.g. mutations and cytogenetic abnormalities) and epigenetic changes (e.g. altered transcription
secondary to methylation and acetylation) in tumours that affect gene expression may provide important aetiologic clues. It has been postulated that certain chemical carcinogens can cause specific somatic mutations in oncogenes and tumour suppressor genes, leaving a DNA ‘fingerprint’ that can help identify tumours caused by this mechanism. Over the last decade, one of the most studied genes in epidemiology has been the TP53 tumour suppressor gene because of its multiple important roles in carcinogenicity, and the high frequency and broad spectrum of mutations observed in most types of cancer. A database of all somatic p53 mutations reported to date maintained at the IARC has been particularly useful for detecting relationships between particular types of cancer, mutations and exposures (www.iarc.fr/p53).146–148 Studies of TP53 mutations as DNA fingerprints of exposures in several tumour types support the rationale of inferring environmental exposures from tumour gene mutations.149 A well-established example is the G:C→T:A transversion mutation in codon 249 of TP53 in hepatocellular carcinomas, which has been attributed to dietary aflatoxin B1 exposure in high-risk populations.150 Another commonly cited example is the high frequency of G:C→T:A transversion mutations of TP53 found in lung tumours from smokers.147,151 Hepatic angiosarcomas in people with occupational exposure to vinyl chloride carry TP53 mutations almost exclusively at A:T base pairs,152 while skin cancers associated with exposure to sunlight have TP53 mutations at dipyrimidine sites that are usually G:C to A:T transitions. Comparing mutational spectra of a given tumour from a patient with a well-documented occupational exposure to the mutational spectra of the same genes from the same kind of tumours in patients with no history of occupational exposure could thus render some insight into the chemical carcinogens involved.

Endogenous or exogenous exposures might increase the risk of cancer by causing epigenetic changes, such as DNA hypermethylation of cytosine in CpG-rich promoter regions in tumour suppressor genes, leading to loss of function and tumorigenesis.153–155 Several environmental exposures have been associated with altered levels of gene methylation. In one study, decreased repeated-element methylation in gene LINE-1 was observed after exposure to traffic particles.156 Hypermethylation in p15 and hypomethylation in MAGE-1 were associated with increasing airborne benzene levels.157 In another study,158 inverse correlations were found between global methylation levels and persistent organic pollutant concentrations in the blood of Inuit populations.

Comparison of chromosomal alterations in tumour tissues from subjects with different exposures might provide insight into the molecular mechanisms by which exposures promote cancer. For instance, high levels of arsenic exposures have been found to be associated with an increased number of chromosomal gains and losses detected by comparative genomic hybridization (CGH) in bladder tumours.159 This could reflect that arsenic-related tumours are less genetically stable than tumours unrelated to arsenic exposure. Conventional cytogenetic techniques, such as fluorescent in situ hybridization (FISH), have enabled the detection of chromosomal sites that might contain critical genes in haematological malignancies and other types of cancer, such as specific translocation breakpoints and subtypes of leukaemia, and lymphoma.160 For instance, translocation t(14;18), the long-arm deletion of chromosome 6 [del(6q)], and trisomy 12 are frequently observed in lymphoma patients. Rearrangements of the MLL gene located on chromosome 11q23, such as t(4;11) and t(6;11), are common in therapy-related leukaemias resulting from treatment with topoisomerase II-inhibiting drugs. In addition, FISH virtual karyotyping with SNP arrays has become available recently facilitating high-throughput investigations of numerical alterations in specific chromosomal regions or whole chromosomes. These techniques can be applied in the future to investigate if there are chemically specific chromosomal alterations in tumours.

**Intermediate end points**

Intermediate biomarkers directly or indirectly represent events on the continuum between exposure and disease.132,138,161–163 One group of intermediate biomarkers, biomarkers of early biologic effect,132 generally measure
early biologic changes that reflect early, non-clonal and generally non-persistent effects. Examples of early biologic effect biomarkers include measures of cellular toxicity, chromosomal alterations, DNA, RNA and protein expression, and early non-neoplastic alterations in cell function (e.g. altered DNA repair, altered immune function). Generally, early biologic effect markers are measured in substances such as blood and blood components (red blood cells, white blood cells, DNA, RNA, plasma, sera, etc.) because they are easily accessible and because, in some instances, it is reasonable to assume that they can serve as surrogates for other organs. Early biological effect markers can also be measured in other accessible tissues such as skin, cervical and colon biopsies, epithelial cells from surface tissue scrapings or sputum samples, exfoliated urothelial cells in urine, colonic cells in faeces, and epithelial cells in breast nipple aspirates. Other early effect markers include measures of circulating biologically active compounds in plasma that may have epigenetic effects on cancer development (e.g. hormones, growth factors, cytokines).

Chromosomal aberrations in peripheral blood lymphocytes have been extensively used as the classic biomarker of early genotoxic effects in cross-sectional studies of populations exposed to occupational carcinogens. Several cohort studies have reported that the prevalence of chromosomal aberrations in peripheral lymphocytes can predict subsequent risk of cancer. The predictive performance of this biomarker was shown to be similar irrespective of whether the subjects had been smokers or occupationally exposed to carcinogenic agents. Similar observations have been made for micronuclei (MN) frequency in peripheral blood lymphocytes of disease-free individuals. In some studies, MN frequency was found to be predictive for future cancer death. In contrast, such associations were not observed for the sister chromatid exchange assay, another biomarker of genotoxicity also measured in peripheral lymphocytes. These results do suggest that the identification of chromosomal aberrations and/or micronuclei due to occupational exposures should be seen as an indication of a possible increased risk for the development of cancer. Besides these specific markers of chromosomal damage, other studies have focused on the occurrence of specific chromosomal aberrations due to occupational exposures. An example of this is a study on translocations t(14;18), t(4;11) and t(6;11), which are associated with lymphoma and therapy-related leukaemias, among benzene-exposed subjects. Interestingly, besides aneuploidy (both monosomy and trisomy) of all seven chromosomes studied (2, 4, 6, 11, 12, 14 and 18), benzene also induced translocations between chromosomes 14 and 18, t(14;18), known to be associated with follicular non-Hodgkin lymphoma among the highly exposed workers. Data obtained from this study add to the evidence that benzene might be related to the occurrence of lymphoma.

There are a wide range of other biological markers that have been applied as markers of possible carcinogenic mechanisms associated with occupational exposures. These include, among others, the measurements of DNA and protein adducts, oxidative stress markers, immunologic and hormonal factors. Although these studies can provide important mechanistic insights into possible disease mechanisms, they have not been formally validated as intermediate markers. As such, the interpretation of these studies has to be performed with some reservation as the exact relevance to cancer remains often unknown.

### Susceptibility markers

Traditionally, family history has been used in epidemiologic studies as a crude marker for inherited susceptibility to cancer; however, identification of specific susceptibility factors requires the use of biomarkers. Susceptibility biomarkers can be measured at the genotypic level (variations in DNA base sequences) or at the functional/phenotypic level (e.g. metabolic phenotypes, DNA repair capacity). While phenotypic measures are closer to the disease process and can integrate the influences of multiple genetic and post-transcriptional influences on protein expression and function, genotypic measures are considerably easier to study in epidemiological studies since they are stable over time and less prone to measurement error.

The most common types of genetic variation are single nucleotide polymorphisms (SNPs) and over a million already have been identified. Most published occupational epidemiological studies on possible interactions between occupational exposures and genetic polymorphisms on cancer risk have evaluated one or a few promising candidate genes mostly related to the metabolic pathway. These studies have rendered largely inconsistent findings mostly due to the limited size of these studies. One of the few positive examples is the possible interaction between NAT2 acetylation status and benzidine exposure on the risk of developing bladder cancer. In a pooled analysis of two studies on the possible interaction between NAT2 acetylation status and bladder cancer risk among benzidine-exposed workers, a lower risk for developing bladder cancer was found among subjects with a slow NAT2 genotype (OR = 0.3, 95 per cent, CI 0.1–1.0).

Currently, technological advances are enabling researchers to move beyond evaluating only a few genetic variants, to a more comprehensive evaluation of hundreds of variants in important aetiologic pathways (e.g. carcinogen activation and detoxification, DNA repair, inflammation, apoptosis), to the entire genome through genome-wide association studies (GWAS). An illustration of the progress of the use of genotyping methods in occupational research can be found in a study on haematological effects among a cohort of 250 workers exposed to benzene and 140 controls. Initial gene–environment analyses in this study were based on candidate gene approaches focusing on genes involved in the metabolism of benzene (four genes, four SNPs), DNA double-strand break repair (seven genes, 24 SNPs) and...
cytokine and cellular adhesion molecule pathways (20 genes, 40 SNPs). Nonetheless, the use of exposure markers in occupational epidemiology could potentially lead to more accurate and/or more biologically relevant exposure estimates than ‘classical’ methods. Examples of this are the studies on hepatocellular carcinoma (HCC) and aflatoxin exposures. In an early ecological study, mean aflatoxin B1 (AFB1), estimated through analysis of market samples of commonly eaten foods, showed an almost perfect linear relationship when plotted against mortality rates of liver cancer (Figure 85.11). However, when exposure was assessed on an individual basis via a structured questionnaire in a later study, no association was found between AFB1 exposure and HCC. This finding stood in sharp contrast to the very strong association between the presence of urinary aflatoxin biomarkers, especially aflatoxin-N7-guanine (AFB-N7-gua) and risk of HCC in the same population. These data highlighted that in this particular case the assessment of AFB1, a food contaminant, by questionnaire is inadequate and that the use of urinary markers improved the exposure classification of the study subjects.

It is certainly not a given that the use of biomarkers of exposure will lead to a better assessment of exposure. The successful application of exposure markers depends both on assay performance and on intrinsic properties of the marker itself (half-life, intra- and interindividual variation). It is beyond the scope of this chapter to discuss these points in detail and we refer to textbooks that discuss these issues in more detail. Before deciding to use a specific biological marker to assess exogenous exposures to investigate a specific hypothesis, there are a number of factors that should be assessed. One should verify that the marker is indeed detectable in human populations and that its kinetics are known. A repeated-measurements sampling strategy should be designed to be able to evaluate interindividual variation relative to intra-individual variation, and in addition duplicate samples should be included in the design to assess laboratory variation. Furthermore, the timing of sample collection in combination with the biological half-life of the biomarker should be optimized.

**Biomarkers markers**

Biomarkers of exposure generally aim at measuring the level of an external agent or its metabolites, in either the free state or bound to macromolecules. The range of biological samples that can be obtained and analysed includes blood, urine, exhaled breath, hair, nails, milk, faeces, sweat, saliva, semen and cerebrospinal fluid. The choice of biological sample depends on the substance of interest, its characteristics (e.g. solubility, metabolism, transformation and excretion), and how invasive the method to obtain it is. As such, several biomarkers can be available to represent the same exposure, including the parent compound itself, a metabolite, or a macromolecular DNA or protein adduct.

Whereas ‘classical’ methods of exposure assessment provide an estimate for exposure from one route of exposure only (e.g. inhalation through the respiratory system, ingestion through the gastrointestinal system, or absorption through the skin), biological monitoring has the theoretical advantage of integrating exposures from all exposure routes. In addition, it also covers unexpected or accidental exposures and reflects interindividual differences in uptake, metabolism, genetic susceptibility and excretion. However, some exposure biomarkers can also be formed endogenously and levels may then reflect both endogenous formation and exogenous exposures. Nonetheless, the use of exposure markers in occupational health research on metabolic genes. Studies on genome-wide interactions (GEWIS) are forthcoming. However, it is questionable if occupational studies will be amendable for these large-scale approaches given the inherent limited size of industry-based studies. Hospital- and population-based case-control studies might be more suitable given the much larger number of cases. However, the prevalence of specific occupational exposures are likely to be low in these studies resulting in low power to investigate gene–environment interactions. This could be solved by establishing large consortia of case-control studies; however, successful standardization of the exposure assessment across these studies will determine the eventual success of GEWIS in occupational research.
The effect of modifiers should be known and all major sources of variance should be quantified.

In summary increasing knowledge of the biological mechanisms involved in the development of occupational cancer, together with the technological advances in analytical platforms for genetic polymorphisms, gene transcripts, proteins and small molecular weight compounds, will allow a broad exploration of aetiologic factors in biologic samples from subjects in occupational studies. Clearly, the statistical analysis and interpretation of study findings and their effective and ethically appropriate translation to the individual and general population will be challenging. We are optimistic, however, that the application of biomarkers in occupational cancer research will lead to better identification of new risks, the identification of potential susceptible populations and might lead to the detection of cancer-exposure specific markers.

Key points

- Cancers of the lung, urinary bladder, mesothelioma, nasal cavity, liver (angiosarcoma), leukaemia and non-melanocytic skin are among those most consistently associated with occupational exposures.
- About 150 agents occurring in the workplace are considered as carcinogens.
- Around 5 per cent of all cancers are attributable to workplace exposures.
- Occupational cancers are preventable and this makes their identification even more necessary. However, the number of cancers notified as occupational is extremely small.
- In industrialized countries, the work environment is much more secure than it was in the past. An increasing number of workers in developing countries are exposed to occupational carcinogens.

ACKNOWLEDGEMENTS

Parts of this chapter have been adapted and updated from a book chapter entitled Application of biomarkers in cancer epidemiology, by Garcia-Closas et al. in Cancer epidemiology and prevention and from a book chapter entitled Urinary bladder cancer, by Kogevinas et al. in A textbook of cancer epidemiology, 2nd edn, edited by Adami et al.

INTRODUCTION

The worldwide acceptance rate for patients commencing renal replacement therapy (RRT) programmes is rising. This international increase is reflected in figures from the United Kingdom, but in some developed countries such as the United States, the acceptance rate has recently remained relatively stable.1

In the UK, the current overall annual acceptance rate of new patients starting renal replacement therapy (RRT) is approximately 113 per million.2 After commencing dialysis, one year’s dialysis treatment costs the National Health Service (NHS) between £20 000 and £25 000 per patient,3 with a greater personal cost to the patient and their family. RRT overall, takes up >2 per cent of the total NHS budget.4

In the United States, between the combined years of 2001 to 2005, the incidence of reported end-stage renal disease from glomerulonephritis, secondary glomerulonephritis vasculitis, interstitial nephritis, pyelonephritis, hypertension and malignant renal tumours, was approximately 41.1 per cent.5

While immunological and vasculopathic associations are recognized in the causation of chronic kidney disease, occupational factors may also be relevant. In this regard, the nephrotoxicity of heavy metals has been studied for a long time, and evidence also links occupational organic solvent exposure with various kidney diseases.

This chapter reviews the renal effects of such workplace exposures.

HEAVY METALS

Metals are probably the oldest toxic materials known to man. Lead usage may have begun more than 4000 years ago when supplies were obtained as byproducts of silver smelting. Indeed, Hippocrates in 370BC is credited with the first description of abdominal colic in a man who extracted metals. However, many of the metals of workplace concern today are only recently known to man. In 1817, cadmium was first recognized in ore containing zinc carbonate. Approximately 80 of the 105 elements in the periodic table are regarded as metals, 30 or so of which form compounds reported to produce toxicity in humans and of these only ten are known to be nephrotoxic. The renal toxicological profile of metals such as indium and tantalum, which are used increasingly in newer industries such as microelectronics, is unknown. With present day occupational and environmental standards, the acute and overt renal effects (such as acute renal failure) associated with exposures to lead and mercury are now uncommon. While there must be a full understanding of these well-recognized acute problems, conceptually what we now...
regard as the toxic effect of metals continues to broaden into the more subtle, chronic effects of long-term nephrotoxicity. In this respect, cause and effect may not always be obvious and allocating blame to particular agents can be difficult especially when there are small repeated exposures to one or more substances. Physicians interested in these nephrotoxic effects need to have an understanding of the metabolism of metals, including any renal cellular effects, and to recognize factors that might influence toxicity. Although treatment is clearly an important topic, prevention of toxicity through public health and worksite programmes, which include raising workers’ awareness and adherence to control measures is of equal or perhaps greater importance. Increasingly, emphasis should be focused on the detection of early and possibly reversible biochemical indicators of toxicity, such as renal tubular dysfunction in cadmium toxicity.

**LEAD AND RENAL DISEASE**

As an occupational and environmental toxin, lead is one of the most widely studied. Its use and indeed suggestions of lead poisoning in lead workers and the general population, date back to ancient times. In the UK, effective control of working with lead goes back many years with the introduction of the Lead Regulations.

Much of lead in the United Kingdom, comes from recycled scrap. Its uses in manufacturing have included electric batteries (27 per cent), electric cables (17 per cent), sheet, pipe, tubes (16 per cent), anti-knock in petrol (11 per cent), solder and alloys (9 per cent), pottery, plastic, glass, paint (4 per cent) and miscellaneous (15 per cent).

Clinical lead poisoning still occurs in some industries (see Table 86.1) as demonstrated in scaffolders involved in the renovation of previous lead painted structures with high levels of exposure. Other occupations at risk include workers in small/mobile workplaces where lead exposure may not be as obvious. Organic lead poisoning is still occasionally reported in tank cleaners who clean petrol storage tanks that have contained leaded petrol.

In addition, children may be exposed to sources such as lead paint and jewellery.

For over a century, an association between lead poisoning and renal disease has been recognized.

The kidney is the first target organ of heavy metal toxicity and the extent of this renal damage depends on the nature, dose, route and duration of exposure.

Four clinical manifestations of lead nephropathy are described: (1) acute lead nephropathy, (2) chronic progressive renal failure, (3) hypertension and (4) the presence of early markers of disturbed tubular function.

### Acute lead poisoning

Acute lead poisoning results from short-term, but massive lead absorption and is associated with abdominal colic, encephalopathy, peripheral neuropathy and anaemia. The major renal effect is disruption of the proximal tubular architecture and function, resulting in aminoaciduria, phosphaturia and glycosuria, collectively known as the Fanconi syndrome.

Histological changes include eosinophilic intranuclear inclusions in the proximal tubular cells, consisting of lead–protein complexes and mitochondrial swelling.

This condition may result in children from repeated ingestion of inappropriate materials, such as lead paint chips. The blood lead level at which this tubular disorder develops is usually in excess of 150 μg/100 mL and has been induced experimentally in animals fed dietary lead.

As with other forms of Fanconi syndrome, vitamin D-resistant rickets may develop and appears to be rapidly reversed following chelation therapy, which reverses both the tubular reabsorption defect and removes the inclusion bodies.

### Chronic, slowly progressive renal failure

This condition results from accumulating lead absorption, often from a recognized occupational source, although non-occupational causes have been identified, such as in childhood lead poisoning resulting from licking off the sweet-tasting lead paint, from the painted wooden verandas in Queensland.

In adults, chronic lead nephropathy may present as chronic tubular interstitial nephritis and may develop several decades after the exposure.

When lead is absorbed excessively, it is deposited mainly in the skeleton, from which it is slowly released once exposure ceases. This gradual release of lead over many years, may contribute to this delayed nephrotoxicity.

Chronic exposure to high levels of lead results in irreversible changes in the kidney, including progressive renal interstitial fibrosis, dilatation of the tubules and tubular atrophy (Figure 86.1). These changes are accompanied by a reduction in glomerular filtration and azotaemia, but are non-specific and common to many other types of renal injury. Typically, renal failure is evident only after many years of excessive lead absorption and can then be associated with hypertension and gout. Symptoms are subtle and patients often remain asymptomatic until significant reduction in renal function has occurred.

As discussed by Ekong et al., a blood lead level persistently above 70–80 μg/dL, is a recognized risk factor for chronic kidney disease. However, concern remains as to whether lower levels of occupational exposure may also contribute to nephrotoxicity in view of the ongoing endogenous exposure from bone and environmental exposure, the burden of which increases with age. Those individuals with hypertension, diabetes, existing chronic kidney disease and those of low socioeconomic status appeared more susceptible, probably due to a higher lead exposure.

As further illustrated by Ekong et al., research relating to the renal outcomes from occupational lead exposure has provided inconsistent results despite a large body of literature being available. This may be due to the smaller sample sizes and because the studies were often cross sections of currently employed workers, who were healthier than the general population. Few studies also included former workers. Furthermore, if renal function declined, workers who were followed in medical surveillance programmes were often removed from the source of the exposure. In other studies where exclusion criteria had been applied, the numbers excluded were not identified. Blood lead level rather than the cumulative measure has also been used and limitations existed due to the co-exposure with environmental cadmium.

Weaver et al. reported an initial period of hyperfiltration following exposure, resulting in an inverse pattern of lead dose with serum creatinine before renal function declined in a group of young South Korean lead workers, but not in the older workers. Khalil-Manesh et al. have previously demonstrated hyperfiltration in animal models with low and high lead exposure. The more highly exposed animals went on to develop tubulointerstitial fibrosis with less severe renal damage observed in the lower exposed animals.

**Hypertension**

Hypertension is a significant risk factor for cardiovascular and cerebrovascular mortality.

Navas-Acien et al. reviewed observational studies concerning lead exposure and cardiovascular end points using database searches and citations. They concluded that there was sufficient evidence to infer a causal relationship between lead exposure and hypertension.

Epidemiological studies in general population cohorts by Harlan, Nash et al., Pocock et al., and Schwartz suggested lead may elevate blood pressure in adults, at blood lead concentrations of <20 μg/dL, while studies utilizing measurements of lead in bone, such as those undertaken by Hu et al. and Korrick et al. found bone lead concentration to be a significant predictor of hypertension.

A pressor effect of lead at low dose has also been supported in animal investigations.

Meta-analyses, however, including those of Nawrot et al. and Staessen et al. have only found a weak association between blood pressure and blood lead levels, while Schwartz found inconsistent effects of blood lead levels on blood pressure. A review of the National Health and Nutrition Examination Survey III dataset also failed to
show any consistent relationship between blood pressure and blood lead levels.

Two recent occupational studies have been described and were in favour of an association between lead and hypertension. Telisman et al.54 followed 100 lead workers and 51 reference subjects. Variables including blood lead, delta-aminolevulinic acid dehydratase (ALAD) activity, blood cadmium, erythrocyte protoporphyrin (EP), body mass index (BMI) and blood pressure were measured. ALAD and EP were used as an indicator of biologically active or chelatable lead.

Elevated levels of zinc protoporphyrin (ZPP) and decreased levels of ALAD represent markers of haem synthesis inhibition and have been shown to reflect biologically active lead by Fenga et al.55 ZPP level in the blood is dependable on bone marrow lead during the preceding four months (red blood cell lifespan) and is unaffected by recent increases in the blood lead level. ALAD remains active in peripheral blood, thereby reflecting both current and long-term cumulative lead exposure.56

The ALAD gene codes for the ALAD enzyme. This requires eight zinc ions as cofactors for activation and catalyses the second step of haem synthesis, by the addition of two molecules of aminolevulinic acid, to form porphobilinogen, the precursor of haem. Lead is thought to inhibit haem synthesis partly by inhibiting ALAD, via the displacement of a zinc ion. Consequently there are increased levels of aminolevulinic acid in the plasma and urine.57

ALAD level activity is reduced in lead poisoning. This degree of ALAD inhibition may be used to indicate the degree of lead poisoning. ALAD remains active in peripheral blood and therefore reflects both current and cumulative lead exposure. It has been suggested that genetic polymorphism, such as those of ALAD and the vitamin D receptor genes, may modify led toxicokinetics and influence toxic risk to the kidney.58–61

In Telisman’s study,54 there was no significant difference in blood pressure between the two groups, which was thought to be due to the reference subjects having relatively high blood lead levels and body mass indices, but in the same subjects, a reduction in ALAD was significantly associated with increasing systolic blood pressure. Similarly, an increase in EP was associated with both an increase in systolic and diastolic blood pressures, after adjustment for confounding variables. This discrepancy was thought to be due to the fact that ALAD and EP better reflected biologically active or chelatable lead, rather than blood lead levels. The authors, therefore, concluded that long-term cumulative lead exposure could significantly increase blood pressure in moderately exposed male workers.

Fenga et al.55 followed a group of 27 workers (mean length of employment 2.97 years), in a lead battery storage plant and measured a number of variables, including blood lead concentration, Zn-protoporphyrin (ZPP), BMI, ALAD activity and blood pressure. Although the numbers were small, the results showed that long-term occupational exposure was related to a slight increase in the systolic and diastolic blood pressure, in workers with a higher (>15 μg/dL), but not with a lower blood lead.

The risk of lead-associated hypertension may be significantly reduced by preventative measures that lower chronic workplace lead exposure.

Early markers of disturbed renal function

Tubular dysfunction may be detected by the measurement of the excretion of tubular enzymes and microproteins which in turn can be used as early biomarkers of renal tubular dysfunction. Urinary N-acetyl-beta-D-glucosaminidase (NAG) for example, has been used as a marker of renal tubular dysfunction induced by lead in several studies,62,63 including in work performed on rats.64 Like beta-2 microglobulin (B2M), however, some studies have shown no effect on levels in the urine of lead workers, while other studies have found a rise.65,66 Suggestions have also been made that urinary NAG is less useful following chronic lead exposure, due to age-related changes which occur at later stages.67,68

Diagnosis of lead nephropathy

Ingestion and inhalation are the principal routes of lead exposure and lead absorption.69 Once absorbed, lead enters the bloodstream and is predominantly bound to erythrocyte proteins.70–74 The average clearance half-life after a short-term limited exposure is 35 days.73 As discussed by Hu et al.,75 clearance is via soft tissue and bone distribution, in addition to primarily, renal excretion. Faeces, sweat, hair and nails also excrete a small amount. Blood lead levels measured in whole-blood specimens may be used as an indicator of circulating lead level. The level varies according to external lead exposure and lead mobilization from tissue stores and, therefore, is better suited to assessing acute lead exposure. On the other hand, lead tibia and patella levels provide an indication of the cumulative dose over decades and include the largest pool that is available for mobilization into the blood.

Non-invasive, in vivo x-ray fluorescence (XRF) instruments have been used to measure the bone lead levels, utilizing emitting x-rays at the bone (Figure 86.2). This, in turn, activates electrons in different electron shells and the lead atoms respond by fluorescing. The more the fluorescence, the more the photons that are counted and the greater the lead exposure. Two types of x-ray fluorescence exist. L-line stimulates electrons in the L electron shell, but measures lead in the subperiosteal bone only. K-line x-ray fluorescence stimulates electrons in the K shell and detects lead in the full thickness of the bone, hence is better for lead measurement. Validation of this procedure has been demonstrated. KXRF used for the in vivo measurement of lead in bone, allows estimation of retained cumulative
lead dose in humans. It is safe, non-invasive and has been used for more than three decades, both for research and, in certain circumstances, the practice of occupational and environmental medicine.

The bulk of lead in bone is within compartments of cortical (more reliable and with a longer half-life) and trabecular bone, with only smaller amounts in bone tissue compartments which exchange rapidly with extracellular fluid and plasma. It has been suggested that in individuals with a peak lead exposure of many decades previously, tibia lead contributes little to the current blood lead levels due to its poor bioavailability. During physiological states, such as in pregnancy, post-menopausal osteoporosis and hyperthyroidism, greater circulating lead may derive from bone.

Blood and bone lead levels provide the best measures for estimating recent and cumulative lead, respectively. As an alternative to using KXRF, repeated and/or estimated measurements of blood lead over time may be used to calculate a cumulative blood lead index (CBLI). This equates approximately to multiplying the average blood lead level by the number of years of exposure (as μg × years/dL), also called the IBL index. Several studies have supported correlation between CBLI and tibia lead.

Finally, chelatable lead burden may be measured as lead excreted in the urine, collected over 4–24 hours, after the administration of intravenous ethylene diamine tetra-acetic acid (EDTA) (Figure 86.3) or oral meso-2,3-dimercaptosuccinic acid (DMSA). This measurement has been used in epidemiological studies, but there is debate whether this contributes further to studies that were measuring blood and bone lead.

Current guidelines and recommendations

The measurement of whole blood lead level remains the standard method of monitoring lead-exposed workers at present. In the United Kingdom, the Control of Lead at Work Regulations from 2000, has lowered the blood lead level for inorganic lead workers to 60 μg/100 mL, the threshold thought to cause proximal tubular injury.

Results from studies, however, do vary concerning the blood lead level above which renal dysfunction occurs. Some show linear correlations between serum creatinine and blood lead level above 40 μg/100 mL, while others show no effect at levels less than 60 μg/100 mL.

Germany has set a blood lead suspension limit of 40 μg/100 mL. In the United States, lead industries have
introduced a voluntary programme to reduce blood lead levels to below 40 µg/100 mL. American legislation, however, suggests removing a worker if the level exceeds 60 µg/100 mL or if three levels taken over a six-month period exceed 50 µg/100 mL, until the level falls below 40 µg/100 mL.

Management

The management of lead nephropathy may be divided into primary and secondary prevention.

Primary prevention may be achieved by the following actions:

- by identifying susceptible groups, such as those individuals with pre-existing renal impairment, diabetes mellitus or with genetic predisposition and monitoring them more closely;
- by minimizing environmental exposure in general so that background lead levels other than industrial exposure are kept low;
- by minimizing industrial exposure and ensuring adequate monitoring at regular intervals (usually determined by baseline blood lead level and changes in exposure);
- by providing appropriate protective equipment;
- by ensuring appropriate personal hygiene.

Secondary prevention involves removing the exposed worker from the lead source and the use of chelation therapy.

Chelation therapy is used to reduce the blood lead level by increasing urinary lead excretion. These agents are organic compounds which link together metal ions and thereby enable their elimination from the body. The ideal chelating agents are water soluble and able to penetrate the cell membrane, having little effect on other metals.

Agents used include 2,3-dimercaprol (BAL) and its analogues meso-2,3-dimercaptosuccinic acid (DMSA) and sodium 2,3-dimercaptopropane (DMPS). D-penicillamine (DPA) and chelators belonging to the polyaminocarboxylic groups, such as derivatives of ethylene diamine tetra-acetic acid (EDTA) and diethylene triamine pentacetic acid (DTPA), are also used.

Lin-Tan et al.\textsuperscript{95} reported an improvement in renal function and a slowing in the progression of renal insufficiency with EDTA chelation in patients with chronic renal insufficiency secondary to environmental lead exposure.

In animals, DMSA chelation has also been shown to improve renal function, and to treat nephropathy\textsuperscript{94} and hypertension,\textsuperscript{95} associated with long-term exposure to low levels of lead. Foglieni et al.\textsuperscript{96} have suggested in rat models that improvement in renal function may be the result of nitric oxide stimulation and a reduction in reactive oxygen species levels.

Previous animal studies suggested DMSA was not capable of chelating lead from the bones, but only from soft tissue.\textsuperscript{97} Cory-Slechta et al.\textsuperscript{98} however, showed that lead could be mobilized from bone and kidney and redistributed initially to the brain and liver in rats. Levels in both brain and liver declined subsequently with calcium disodium EDTA injections, but no net loss from either tissue occurred over the five-day treatment period, despite a decline in blood lead levels.

The use of chelators may be associated with a number of side effects. For example, Kiran et al.\textsuperscript{99} described how some of the EDTA derivatives could cause hypocalcaemia and renal side effects, such as tubular cell necrosis, haematuria, proteinuria (thought reversible once treatment had ceased). Powell et al.\textsuperscript{100} has also described how chelation of endogenous essential metals could potentially occur.

DMPS and DMSA are considerably less toxic compared to older agents such as BAL, but newer agents including the monoisoamyl DMSA (MiADMSA), an ester of DMSA, have been developed further to optimize the effects.

Chelation therapy should be tailored to each individual patient, especially as controlled clinical trials have not been able to confirm consistent symptom improvement or a reduction in mortality in patients with lead encephalopathy.\textsuperscript{101} In general, chelation therapy is used as the mainstay of treatment for acute lead nephropathy.

The use of combination chelating agents has been suggested. In addition to combining therapy with some naturally occurring antioxidants (vitamins), Swaran et al.\textsuperscript{102} found co-administrating vitamin E during chelation with DMSA or MiADMSA in rats, had a beneficial role in reducing body lead burden. They also suggested that vitamin C therapy during chelation might reduce oxidative stress, but human studies on vitamin C and lead absorption have shown mixed results.

Kalia et al.\textsuperscript{103} reinforced the potential importance of micronutrients, such as calcium, iron, zinc, selenium and copper, in reducing toxic metal absorption and as an adjunct in chelation therapy, to maintain essential metal status, but the excess and prolonged use of zinc might inadvertently cause the chelator to bind to the zinc instead.

Mortality

Several mortality studies (Table 86.2) have indicated an excess of death due to renal disease among cohorts of workers exposed to lead, but methodological problems related to the numbers of cases observed and the selection of controls or census data from the general population, may have limited their value.

Cardiovascular disease risk

Some mortality studies have suggested hypertensive cardiovascular disease\textsuperscript{112} and cerebrovascular disease\textsuperscript{111} are
more frequent causes of death among lead workers in comparison with the general population.

The National Health and Nutrition Examination Survey (NHANES) provides an observational database and a snapshot of the health and nutritional status of the United States population, through physical examinations, clinical and laboratory tests and interviews. As part of the NHANES III study by Schober et al.,113 mortality analysis was performed on 9757 general public participants above and including 40 years of age, who had had a blood lead level estimated. Blood lead levels as low as 5–9 μg/100 mL were associated with an increased risk of death from all causes, cardiovascular disease and cancer, but the significance of these findings was not clear.

Renal cell cancer

Conflicting results have been reported in the past concerning lead exposure and renal cancer risk. Some studies have suggested an increased risk,33,114–116 while others have shown either a weak association or no association at all.117–121 There were, however, limitations in some of these studies concerning numbers, follow-up time and lack of information regarding potential cofounders.

Conclusions

Lead is known to cause a range of renal diseases in exposed subjects. Excess lead is deposited mainly in the skeleton and can be released over a number of years following exposure cessation, resulting in delayed nephrotoxicity.

Cohort studies on lead-related renal outcomes have provided inconsistent results partly due to the small sample size, mixed exposure and the lack of a definitive early marker(s) of renal damage in lead exposure. An association with hypertension and increased mortality has also been suggested.

The diagnosis of lead toxicity is based on whole blood lead monitoring, as other measures are not widely available. Management should focus on identification of those individuals at increased risk of exposure and primary prevention. Newer forms of chelating agents and combination therapies have been used, but should be individually tailored to minimize side effects.

In Europe and the United States, the provision of lead-exposed workers with better protection, regular monitoring and personal hygiene provision, have all played a part in reducing lead absorption and clinical poisoning. Industries have also been moving away from lead-based materials. However, stringent monitoring and adherence to appropriate lead levels must be maintained for safety. There have been suggestions that the current blood lead guidelines, including in the United Kingdom, need to be revised to a lower recommended level. The European Scientific Committee on occupational exposure limits, for example, has suggested a reduction to 30 μg/100 mL.

Although such measures are being discussed in developed countries, in the developing world with the expansion of industry and the development of obesity and diabetes, we may see an increase in chronic lead nephropathy in the future.

### CADMIUM

The use of cadmium in industry grew steadily after its discovery in 1817 by Strohmeyer. The first three cases of acute poisoning by cadmium were reported in 1858 by the Belgian physician, Sovet, in workers using silverware polishes containing cadmium carbonate. Following reports of Stephens in 1930 and Hardy and Skinner in 1947, Friberg described the clinical syndrome of cadmium nephrotoxicity with renal impairment and proteinuria in 1948. Further studies in Italy, Japan, Sweden and the UK confirmed these observations and defined the proteinuria as tubular in origin.122,123

NEM, no excess mortality; EM, excess mortality.
Even though cadmium usage is much less than before, it is still used in the electroplating of other metals such as steel, iron, copper and as an alloy. In addition, it is being used in the printing and aircraft industry, pigments, dyes and in the electrodes of nickel/cadmium batteries. Some individuals may become acutely overexposed to this metal in the industry, but there is also evidence that continued low-grade cadmium exposure may result in progressive renal failure. Accordingly, efforts have been made to reduce its usage.

Metabolism and toxicity

The acute absorption of cadmium as dust or fume may induce a severe gastrointestinal disturbance or pulmonary oedema; chronic low-dose exposure may lead to a proximal renal tubular reabsorptive defect.

It has been suggested by Barbier et al.\textsuperscript{124} that cadmium induces tubular toxicity, after accumulating in the renal cortex. The resulting renal effects have been supported by a large number of studies that demonstrated a variety of urinary abnormalities, including the increased excretion of proteins, enzymes, amino acids and calcium.\textsuperscript{125,126}

Glomerular dysfunction has also been demonstrated in workers with heavy exposure to cadmium.\textsuperscript{127–129} Animal experiments have suggested that cadmium may enhance the glomerular filtration of proteins, through a depletion of the glomerular polyanion involving sialic acid and its charge.\textsuperscript{130–132} It has been suggested that subtle changes in glomerular permeability may occur, as manifested by the increased urinary excretion of transferrin and albumin and may precede the onset of proximal tubular impairment.\textsuperscript{126} Roels \textit{et al.}\textsuperscript{129} suggested that glomerular impairment may occur as a result of the development of a degree of interstitial nephritis secondary to the tubular toxicity. Others have postulated that cadmium may be directly toxic to the glomerulus.\textsuperscript{133,134}

Epidemiological studies of cadmium workers have revealed an increased risk of kidney stones in those with a high cadmium level.\textsuperscript{135,136} Furthermore, there was a dose–response relationship between cumulative cadmium exposure and kidney stones.\textsuperscript{135} One case report described a cadmium worker who went on to develop nephrolithiasis ten years after being exposed to cadmium fumes.\textsuperscript{136} The authors concluded that in susceptible individuals, even minimal tubular lesions may predispose to stone formation. In male rats injected with cadmium, an increased incidence of stone formation was observed in the kidneys and bladder of these animals.\textsuperscript{137}

The accumulation of cadmium in the liver induces the synthesis of a low molecular weight binding protein called \textquoteleft{metallothionein}.\textsuperscript{138} In the kidney, cadmium is mostly bound to this protein. Cadmium toxicity is thought to be due to unbound cadmium ions. These free cadmium ions may have differing effects on the cells. Some of the mechanisms that have been postulated, include the blocking of the calcium transport in the cell,\textsuperscript{139} lipid peroxidation of membranes\textsuperscript{140,141} and depletion of metal cofactors for the metalloenzymes, caused by the displacement of essential metals from metallothionein.\textsuperscript{142}

In rats, chronic cadmium exposure has been shown to cause metabolic acidosis, possibly due to an inhibition of renal bicarbonate reabsorption.\textsuperscript{143} The same researcher went on to show how cadmium intoxication may impair the Na\textsuperscript{+}/H\textsuperscript{+} exchange activity of the proximal tubular brush–border membrane and a reduction in Na\textsuperscript{+}/H\textsuperscript{+} exchange-3 expression in the membrane, which facilitates the reabsorption of filtered bicarbonate.\textsuperscript{144}

Diagnosis of renal dysfunction

MARKERS OF RENAL TUBULAR DYSFUNCTION

Tubular dysfunction is a salient feature of cadmium nephrotoxicity and tubular proteinuria is being used as a surrogate marker of cadmium nephrotoxicity.

Tubular proteinuria develops as a result of reduced tubular reabsorption of low molecular weight (LMW) proteins, which are usually taken up preferentially by the proximal renal tubules. In early tubular dysfunction, the urinary excretion of these LMW proteins is disproportionately increased compared with high molecular weight proteins and may be used as markers of early tubular dysfunction.

Even a slight reduction in tubular reabsorption, may result in a large increase in the urinary excretion of microproteins,\textsuperscript{145,146} including urinary beta-2-microglobulin (B2M) and retinol binding protein (RBP). Urinary B2M, however, is unstable in acidic urine (pH <5.6), whereas urinary RBP is much more stable.

The normal level of urinary B2M/RBP is regarded as <300 \mu g/g creatinine. A B2M or RBP level of 300–1000 \mu g/g creatinine has been correlated with the development of incipient cadmium tubulopathy and a level of 1000–10 000 \mu g/g creatinine, with irreversible tubular proteinuria. Finally, a level of >10 000 \mu g/g creatinine, has been correlated with overt cadmium nephropathy, usually associated with a reduced glomerular filtration rate (GFR).\textsuperscript{145}

Alpha-1-microglobulin is another LMW protein, but is considered a less sensitive marker of tubular dysfunction, due to its greater molecular weight.\textsuperscript{146} However, some studies have suggested its use as a screening marker for environmental cadmium exposure.\textsuperscript{147,148} Other tubular markers that have also been suggested include the urinary human Clara cell protein-CC16 or protein 1 in women.\textsuperscript{149} The same protein is secreted by the prostate, reducing its sensitivity and specificity in men.

CADMIUM MEASUREMENT

Blood cadmium concentration falls rapidly after acute exposure and is, therefore, seldom used as the sole marker
of acute toxicity. However, in subjects with a past history of high chronic exposure, blood cadmium level may increasingly reflect body burden rather than current exposure.  

In newly exposed workers, the concentration of cadmium in blood increases linearly to reach a plateau at about four months.  

In workers currently exposed to cadmium, blood cadmium levels reflect mainly the uptake of the metal over the preceding few months. After an individual is removed from the exposure, the respective contributions of current exposure and body burden are progressively reversed. In cases of former cadmium workers with high levels of cadmium in tissues, the influence of the body burden becomes more prominent.  

In excessive acute exposure, urinary cadmium levels may be high, but in general, urinary cadmium is an indicator of cumulative body burden. As the renal cortical levels exceed 100–300 μg Cd/g of renal cortex, the urine cadmium level increases, either as a result of renal losses or failure to reabsorb filtered LMW cadmium complexes, because of the renal tubular dysfunction. The non-invasive technique of in vivo neutron activation analysis, enables more diagnostic precision without the need for biopsy analysis of cadmium.  

In workers moderately exposed to cadmium and in the general population, the urinary excretion of cadmium (expressed in terms of creatinine or as 24-hour urine output), is a reliable indicator of the body burden of cadmium. Indeed, the level of urinary cadmium correlates better with the duration of exposure compared to blood cadmium. It was interesting that the urinary excretion of cadmium was found by a Belgian group to increase progressively with age, in parallel with the body burden, until the age of 50–60 years. The measurement of metallothionein in the urine of cadmium workers may be used to provide information similar to urinary cadmium.  

In 1993, Roels et al. recommended the use of different thresholds of cadmium urine concentration, to correlate with renal abnormalities. In their classifications, a urine cadmium concentration of 2 μg/g creatinine was associated with biochemical alterations. A urine cadmium concentration of 4 μg/g creatinine was linked to high molecular weight proteinurias and tubule antigen disturbance. Finally, at 10 μg/g creatinine of urine cadmium concentration, LMW proteinurias were observed. The latter was thought to be the threshold for developing microproteinuria, the critical effect predictive of a decline in renal function.  

In the past, there has been much debate as to whether cadmium-induced renal function was reversible. More recently, several clinical studies have supported the reversibility of tubular dysfunction. In one observational study of 32 male workers, the evolution of cadmium-induced renal tubular dysfunction was observed. The results indicated that reversible tubular dysfunction occurred in those with urinary B2M levels between 300 and 1500 μg/g creatinine and those with urinary cadmium levels of less than or equal to 20 μg/g creatinine. In individuals with levels above these values, the cadmium-induced tubular dysfunction progressed, despite a reduction or cessation of the cadmium exposure. Similar reversibility of tubular dysfunction was observed in a cadmium factory where workers had been followed prospectively for four years. During this time, the urinary tubular protein markers, blood and urinary cadmium levels were monitored and showed a reduction in the urinary LMW protein level as the exposure conditions improved.  

Trzcinka-Ochocka et al. similarly followed a group of 58 workers working in a nickel cadmium factory and after they had been removed from the cadmium exposure there was a general reduction in the tubular protein levels and urinary RBP. There was even some suggestion of reversibility in the rate of glomerular filtration rate decline, even in cases of relatively high past exposure.  

**Treatment**  

Once early renal tubular dysfunction is evident, the most important aspect in the management of cadmium tubular toxicity is the removal of the subject from further exposure.  

As cadmium is tightly bound to metallothionein in the kidney and liver, finding an effective chelating agent is challenging. Nephrotoxicity can be produced by chelating agents that remove cadmium from the liver and then excreting it via the kidneys. The chelation and elimination through bile, is used in practice to remove cadmium from the liver. Sodium N-(4-methoxybenzyl)-D-glucamine dithiocarbamate, is one of the most effective chelating agents for removing cadmium from the liver and kidneys. Even though the new chelating agents are more effective and less nephrotoxic, their use is mainly in acute rather than chronic cadmium exposure.  

**Current recommendation in the workplace**  

The Control of Substances Hazardous to Health Regulations (COSHH) requires employers: (1) to assess risk and to implement precautions to prevent or adequately control or reduce exposure to airborne cadmium below the workplace exposure limits (WEL) for long-term exposures equivalent to an eight-hour time-weighted average (TWA) reference period (0.03 mg/m 3 for cadmium sulphide and cadmium sulphide pigments and 0.025 mg/m 3 for the remaining cadmium compounds); (2) to maintain all fume and dust controls in appropriate working order; (3) to ensure the presence of a monitoring programme; and (4) to arrange any health surveillance as appropriate.  

In the United States, the Occupational Safety and Health Administration (OSHA) division of the Department of Labor, has recommended an action level for workplace exposure to cadmium of 2.5 μg/m 3 of air, calculated as an
eight-hour TWA exposure. During any eight-hour working shift of a 40-hour working week, the permissible exposure limit is equivalent to a TWA concentration that must not exceed 5 μg/m^3 of air for all cadmium compounds. In addition, other trigger levels for medical surveillance have been identified. A urinary cadmium level at or below 3 μg/g creatinine, a beta-2-microglobulin level at or below 300 μg/g creatinine and a blood cadmium level at or below 5 μg/L of whole blood, require only the minimum level of periodic medical surveillance. However, if these levels are exceeded, the employer is required to reassess the employee’s occupational exposure to cadmium within two weeks and to correct any deficiencies within 30 days. The finding of a urinary cadmium over 7 μg/g creatinine, or a whole blood cadmium over 10 μg/L, or a B2M level over 750 μg/g creatinine plus a urine cadmium over 3 μg/g creatinine, or a whole blood cadmium over 5 μg/L during either an initial or follow-up medical examination requires removing the employee from further cadmium exposure.165

PREVENTION

This mainly involves minimizing exposure through various strategies to reduce exposure to fume and dust and by providing adequate personal protective equipment, where appropriate, and maintaining a high standard of occupational hygiene measures.

PROGNOSIS

Although several studies have suggested the reversibility of cadmium-induced tubular dysfunction, the development of end-stage renal disease has been reported in a few heavily exposed cadmium workers.166,167 A study168 which included both cadmium-battery production workers and individuals residing in cadmium-polluted areas, also concluded that cadmium exposure contributed to the development of end-stage renal disease even at lower levels of exposure.

There was suggestive evidence of an increased risk of nephritis and nephropathy after high cadmium exposure,169 but no statistical significance was reached in this or in the other studies regarding renal deaths.170,171

MERCURY

Most of the occupational health problems caused by mercury arise through its use in its elemental form. The high vapour pressure of elemental mercury results in potential exposure whenever the metal is used or handled. Although the skin is not a barrier to mercury, absorption occurs mainly via inhalation. Mercury readily crosses biological membranes and is rapidly oxidized to divalent mercury in the blood and within cells.

Mercury is mined in Russia, China and Almaden in Spain. Large-scale use of elemental mercury occurs in the chloralkali industry, although this is decreasing as newer technology takes over and provides other means for producing chlorine and sodium hydroxide. Elemental mercury is still used in temperature- and pressure-measuring equipment and in the manufacture of fluorescent and discharge lamps, as well as amalgams used in dentistry. Occupational exposure to elemental mercury is more widespread than exposure to mercury compounds. In the western hemisphere, there has been a general reduction in the use of mercury over two decades, especially in the chloralkali processes, where its use is expected to cease by 2010.172

Although mercury salts are widely used as toxins in animal experimental models of acute renal failure, mercury-related toxicity in humans is largely due to industrial or accidental exposure. The biotransformation to the organic salts, such as methyl, ethyl and phenoxymethyl mercury, may occur in industrial and agricultural processes.173 These organomercurials can accumulate in proximal renal tubular cells where toxicity is determined by the intracellular interactions between the sulphhydryl groups, lysosomes and phospholipid membranes.173 The tubular toxicity has been associated with an increased leakage of tubular antigens and enzymuria174 and biochemical alterations including a reduction of excretion of some eicosanoids and glycosaminoglycans at a low urinary pH.

Mercurochlor chloride (Hg2Cl2, calomel) is relatively non-toxic. It was widely used as a medicine until the twentieth century. In contrast, mercuric chloride (HgCl2, corrosive sublimate) has a relatively high vapour pressure and water solubility, is highly nephrotoxic and is used to produce acute renal tubular necrosis in animal experiments. Similar toxicity is produced by both the phenyl and methoxymethyl mercuric salts.175 The biological half-life of inorganic mercury that is retained within the kidney is approximately two months.176

Reversible proteinuria has been a recognized feature in workers with mercury exposure greater than 50 μg/m^3. Many workers exposed to mercury have enhanced urinary mercury excretion without adverse renal effects.177 The diagnosis of mercury-induced renal disease is currently based on a known exposure plus renal dysfunction.

An increased prevalence of proteinuria has been found in cross-sectional studies among exposed workers.174,178,179 The same authors have reported increased urinary enzymuria indicative of an effect on the renal tubules,174,180–182 These reported effects have generally been small and may be reversible with cessation of exposure,183 but the long-term clinical significance of these findings is as yet unclear.

Urinary mercury and whole blood mercury levels have been used to assess the biological occupational exposure to mercury.184,185 As detailed by Gompertz in 1982,186 urinary mercury reflects the average exposure over the preceding two to four months, but this level can fluctuate in the day with a diurnal variation. Blood mercury tends to reflect exposure and uptake over the past few days. Unexposed subjects normally have a level of less than 5 μg/L or 5 μg/g creatinine, but the unexposed reference
range is dependable on the dietary intake of mercury especially from fish. In the case of Sweden, such normal blood mercury values have been reported to be as high as 13 μg/L (65 nmol/L).  

**Current recommendation in the workplace**

In the United Kingdom, the biological values for inorganic mercury is limited to a urinary mercury level of 20 μmol/mol creatinine in the urine or 35 μg/g creatinine. The long-term exposure limit of 0.025 mg/m³ eight-hour TWA has been set for mercury and its inorganic divalent compounds. A lower long-term exposure limit of 0.01 mg/m³ eight-hour TWA has been set for alkaline mercury which is thought to be more toxic. In the United States, it has been suggested that the biological exposure index (BEI) for total inorganic mercury in the blood should be 15 μg/L.

**Clinical studies**

Autopsy studies have shown that mercury from dental amalgam may result in increased amounts of mercury in the renal cortex to almost nine times the normal range and up to 433 ng/Hg/g of renal cortex, but no adverse effects have been identified from this source of exposure. Accidental or suicidal ingestion of as little as 0.5 g of mercuric chloride can lead to typical oliguric acute renal failure with proximal tubular necrosis (Figure 86.4). The clinical picture in the first few days is dominated by gastrointestinal haemorrhage due to erosive gastritis. The prognosis for renal recovery is good with dialysis and supportive therapy. The administration of intravenous DMPS (dimercapo-1-propane sulphonate) in the first 24–48 hours and before the development of oliguria may limit the extent of the renal failure.  

Nephrotic syndrome (proteinuria >3.5 g/day) has been reported sporadically following exposure to both elemental and organic mercury. In children, the use of mercury ointment or powder has been associated with the development of acrodynia or pink disease, but mercury exposure and the development of nephrotic syndrome has been rarely described in the occupational setting. In some individuals, mercury may be a triggering agent for immune reactions leading to proteinuria. In cases where renal diseases occur, membranous nephropathy is most commonly observed, although minimal change nephropathy and anti-glomerular basement membrane (GBM) antibody-mediated disease have also been described. An increased prevalence of circulating anti-GBM antibody of the antilaminin variety has been reported in male workers exposed to mercury vapour. More recent studies have suggested that anti-double strand nuclear antibody (DNA) and total IgE may also play a role as their circulating concentrations have been shown to positively associate with the concentration of mercury in both urine and blood.

It has been shown in both human and experimental animals that the proteinuria associated with low or moderate exposure to mercury at work usually resolves following withdrawal from exposure. The immunopathological mechanism of the renal response in humans is not clear. The renal lesion in rats involves immune complex deposition, anti-GBM antibody deposition, complement and polyclonal B cell activation. The lack of a dose–response curve in the development of renal disease in both humans and animals would indicate that this is an idiosyncratic response.

In an outbreak of chronic methyl mercury poisoning in 1956, several hundred adults ingested contaminated fish from the Minamata Bay in Japan and went on to develop ‘Minamata disease’ which was predominantly a neurological disorder, with only minor renal involvement and low molecular weight proteinuria without albuminuria or renal failure.

![Figure 86.4](image-url)
Treatment of mercury toxicity

In managing acute, inorganic mercury poisoning treatment with chelators should be initiated after cessation of exposure. Thiol-based chelating agents, such as dimercaprol, DMSA and dimercaptosuccinic acid (DMSA), are used. DMSA may be administered at a dose of 10 mg/kg orally, eight hourly for five days.

In cases of chronic poisoning, patient removal from the exposure source is the most important step taken to reduce or reverse proteinuria. The use of chelators may be considered in cases where there has been a high degree of exposure, but no other specific treatment is recommended.

URANIUM

Uranium is a naturally occurring heavy metal, used by the military and in the nuclear industry. Depleted uranium is a byproduct of uranium enrichment and enters the body through wounds, ingestion and inhalation. Toxicity occurs either through its chemical properties or its radioactivity.

The uranyl ion circulates bound to transferrin and is freely filtered at the glomerulus as the bicarbonate complex. This complex breaks down to UO which then binds to proteins and phospholipids in the proximal renal tubule, where it has a half-life of approximately one week.

Various animal experiments have been undertaken regarding uranium toxicity on the kidney. Banday et al. recently demonstrated the specific alterations in the activities of metabolic and membrane enzymes and antioxidant defences following acute exposure in rats who were given a single nephrotoxic dose of uranyl nitrate, while Thiebault et al. focused on cell death caused by uranium and suggested that DNA damage was reversible at low concentration (200–400 μmol/L), but became irreversible leading to cell death, at higher uranium concentrations.

Effects on the kidney from chronic uranium exposure are not as well established. Zhu et al. however, used animal experiments to demonstrate the renal effects of chronic exposure. They implanted depleted uranium (DU) fragments of three doses into rats and compared them with controls, which were implanted with biologically inert materials. Tissue samples were obtained at days 1 and 7 and months 3, 6 and 12. It was found that DU concentrations in the kidney peaked at 90 days post-implantation and although they then began to decrease slowly, remained at a relatively high level even at 360 days post-implantation. Changes in the basement membrane and proximal tubule were seen on electron microscopy and it was concluded that DU could accumulate in the kidneys for a long period, causing kidney injury.

Hodgson et al. in a Health Protection Agency document, reviewed the scientific literature and suggested uranium concentrations at which kidney injury could occur. They concluded that acute exposures which led to concentrations of about 1 μg uranium per gram of kidney, has been associated with minor kidney dysfunction, while chronic levels which led to similar kidney dysfunction are less well established, probably below 0.3 μg uranium per gram of kidney.

Clinical nephrotoxicity has largely been confined to subjects employed in developing the atomic bomb (the Manhattan project) during the Second World War. The acute tubular necrosis produced in animal models is thought to be similar in aetiology to that seen in these workers.

A worksite hazard study of renal toxicity in uranium mill workers demonstrated significantly increased urinary excretions of B2M, catalase and alkaline phosphatase, compared with non-exposed controls even though the abnormalities remained within the accepted normal range. The clinical significance of these findings remained unclear, however, as many workers had urine uranium levels in excess of the acceptable limit of 30 μg/L (126 nmol/L).

Recently, Vacquier et al. reported on a cohort of 5086 uranium miners employed for at least one year between 1946 and 1990. The mean duration of follow up was just above 30 years. Cause of death was ascertained, radon exposure reconstructed for each year and exposure–risk relationships estimated. They observed a significant excess of kidney cancer deaths (standardized mortality ratio 2, 95 per cent confidence interval, 1.22–3.09). This was not associated with cumulative radon exposure.

CHROMIUM

Like many other heavy metals, chromium is selectively taken up by the proximal renal tubule, and acute tubular necrosis following massive absorption has been described. Although chronic renal failure due to long-term exposure to chromium has not been described, LMW proteinuria with increased urinary excretions of B2M and RBP have been reported in chromium workers. A urine chromium of 10 μg/g creatinine (32 μmol/mol creatinine) has been suggested as a threshold for nephrotoxicity after the finding of proximal tubular enzymuria in workers exposed to ferrochromium. Others have not found any abnormalities in the urinary excretion of transferrin, albumin or RBP in platers exposed to hexavalent chromium and in whom urine chromium levels were less than 19 μg/g creatinine (61 μmol/mol creatinine).

BERYLLIUM

A syndrome similar to sarcoidosis may be induced by the long-term exposure to beryllium. The common features include pulmonary fibrosis, hypercalcaemia and hypercalciuria. The cause of the hypercalcaemia is likely to be the same as in sarcoidosis and other granulomatous disease and is thought to be due to excessive extrarenal production of 1,25-dihydroxy vitamin D, although this is unproven.
Renal complications, such as interstitial nephritis, may rarely develop.

**ARSENIC**

Acute renal tubular necrosis may develop after exposure to arsine gas. Arsine is a powerful haemolytic agent. Within a few hours of inhalation, acute circulatory collapse and haemolysis accompanied by haemoglobinuria, jaundice and abdominal pain may occur. Acute renal tubular necrosis sets in after a few days. Haemodialysis is required for renal support and removal of the arsenic haemoglobin complex by exchange transfusion may be life saving. Chronic renal failure may persist if the patient survives the acute illness. Similarly, persistent renal disease has been described following ingestion of illicitly distilled spirits (moonshine) contaminated with arsenic.

**BISMUTH, COPPER AND GADOLINIUM**

Acute tubular necrosis has been described after the use of bismuth therapeutically and after self-poisoning with copper sulphate. However, neither metal has been observed to be nephrotoxic in the occupational environment. An unusual syndrome of nephrogenic systemic fibrosis has been observed in renal failure patients rarely after investigations by magnetic resonance imaging when a gadolinium-based agent has been included as contrast material.

**CRYSTALLINE SILICA**

Exposure to crystalline silica is mainly through inhalation of dust containing quartz in mines, quarries and other sites (Figure 86.5).

In addition to silicosis, several studies have suggested an association between silica exposure and the development of renal disease. Some of the mechanisms that have been suggested include direct toxicity of the silica particles in the kidney, or indirectly through an autoimmune mechanism.

In a cohort of 2820 male ceramic workers in Lazio who entered a health surveillance programme between 1974 and 1987, a retrospective assessment of the effect of cumulative exposure to silica on end-stage renal disease was undertaken. Six of the workers appeared in the kidney registry, giving rise to a relative risk of 1.87. The cumulative exposure was 0.2–3.8 mg/m³ per year. Three of these six workers developed kidney failure as a result of glomerulonephritis. Two workers also suffered from silicosis, one of whom had a necrotizing glomerulonephritis and positive perinuclear antineutrophil cytoplasmic antibodies (p-ANCA). The researchers concluded that exposure to silica was associated with an increased risk of end-stage renal disease after a short or medium latency period, but...
this study was only able to detect those workers requiring dialysis. The long-term renal disease incidence was not studied.

An increase in end-stage renal disease cases was observed in a further cohort study of 4626 silica-exposed workers in the industrial sand industry in the United States. However, the same researchers were unable to confirm a similar finding in 1328 workers with definite silicosis. A combination of selection bias and the smaller number of cases in the second study, were possible limiting factors.

Several case–control and cohort studies have demonstrated an increase in ANCA-positive cases in those exposed to silica, but a definite association between silica exposure and ANCA-associated vasculitis has remained unproven. A recent population-based, case–control study carried out by Hogan et al. attempted to evaluate the association of life-time silica exposure with the development of ANCA-small vessel vasculitis (SVV). A total of 129 case patients were enrolled. Their occupations were assessed and a silica exposure score was formulated before the groups were subdivided into none, low/medium or high life-time exposure. An increased risk for disease was found in those cases with high exposure, compared to those with no exposure. The authors concluded that a high life-time silica exposure was associated with ANCA-SVV. The same researchers carried out a further case controlled study in 2001 with results showing that 46 per cent of patients with ANCA-SVV had silica dust exposure, compared to 20 per cent of the controls. In a more recent study of 86 males exposed to silica dust in Bohemia, there were no cases of ANCA-associated vasculitis, although there was an increase in ANCA positivity. It has been suggested that this increase in ANCA may have occurred as a result of endothelial damage caused by the generation of oxygen free radicals from phagocytes and an increased interleukin-12 production. However, it is likely that other factors are required to induce systemic vasculitis.

An excess mortality from chronic non-malignant renal disease has been reported, but not confirmed in a more recent cohort of 2670 sand workers.

ORGANIC SOLVENTS AND RENAL DISEASE

Although the nitro-, amino- or chloro-derivatives of benzene have a known association with uroepithelial tumours, there is now a considerable body of evidence suggesting a role for organic solvent exposure in the development of non-neoplastic renal diseases. The term organic 'solvent' refers to hydrocarbons, such as aliphatic, alicyclic, aromatic, halogenated hydrocarbons (carbon tetrachloride, trichloroethylene) and the commonly abused solvents toluene and xylene. Hydrocarbons are often used as solvents in industrial manufacturing practices because of their lipid solubility (Figure 86.6). Solvents are absorbed through the lungs, skin and gastrointestinal tract and are metabolized usually by cytochrome P450-dependent enzymes present in the liver, kidneys, lungs and other tissues. Solvents are known to be neurotoxins, affecting both the peripheral and central nervous systems. However, occupational exposure to hydrocarbons with resulting nephrotoxicity is less well understood and in this section we review the evidence.

CASE REPORTS AND EXPERIMENTAL STUDIES

Case reports describe an association between organic solvent exposure and the development of acute tubular necrosis, chronic tubulo-interstitial damage and different types of glomerulonephritis and Goodpasture’s syndrome. In parallel with these clinical observations, experimental studies in animals have identified organic solvent exposure as a factor in the development of both tubular and glomerular lesions. Thus, glomerular lesions similar to those found in Goodpasture’s disease have been induced in rats exposed to petroleum vapours and the nephrotic syndrome with severe glomerulonephritis and renal impairment, which is not dependent on either deposition of fibrin or coagulative mechanisms, has been induced in rats fed N,N1 diacetylbenzidine (N,N1-DAB). Similarly, mesangial proliferative glomerulonephritis and tubulo-interstitial disease, which again did not appear to be mediated by glomerular deposits of antigen–antibody complexes, has been described in rats after the administration of carbon tetrachloride.

Long-term exposure to organic solvents is associated with proximal tubule cell apoptosis, a potential mechanism of progressive renal fibrosis and renal failure.
CASE–CONTROL STUDIES AND PROGRESSIVE RENAL FAILURE

The majority of early case–control studies from different research groups reported a significantly greater exposure to organic solvents in patients with glomerulonephritis compared with control groups, and demonstrated evidence in favour of a possible role for chronic solvent exposure in the development of various types of glomerulonephritis, such as proliferative glomerulonephritis, membranous glomerulonephritis, post-streptococcal glomerulonephritis or rapidly progressive glomerulonephritis.

However, the evidence presented in some of the older studies may be criticized on one of the following grounds: (1) the unsatisfactory nature of the control group, (2) the possible bias of the unblinded interviewers, (3) the failure to consider recall bias, (4) failure to define a credible measure of solvent exposure, (5) the diversity of glomerular disease pattern and (6) the stage of disease studied.249 More carefully performed studies had addressed these criticisms and generally now suggest that hydrocarbon exposure is more probably associated with progression of the disease and worsening renal function.249–254

A histopathological type of glomerulonephritis may be important in this association with clearly characterized risks of progression of renal failure associated with solvent exposure particularly among patients with membranous glomerulonephritis and IgA nephropathy,255 and possibly in patients with focal segmental glomerulosclerosis.252

A negative study failing to support this relation has been published,256 but index patients within this study were not well characterized in terms of the histopathological diagnosis of glomerulonephritis. The most recent carefully controlled and characterized prospective case-controlled ‘cohort’ study of patients with glomerulonephritis further supported this association and noted that the risk incurred by organic solvent exposure and progressive renal failure was mediated only partly by baseline proteinuria.255 This lends further credence to the concept that this progressive renal damage is mediated through concomitant tubular rather than glomerular injury.251

Nonetheless, it would be inappropriate to discount a carefully designed earlier study,257 where solvent exposure was significantly greater in patients with incipient (microalbuminuria) and overt (macroalbuminuria) diabetic nephropathy than those with no clinical evidence of nephropathy.257 The suggestion of this study was that solvent exposure may also possibly play a role in the progression of diabetic nephropathy in patients with type I diabetes mellitus.

Histological evidence of tubulointerstitial damage in primary glomerular disorders would appear to correlate with severity of renal impairment and can predict the future outcome of renal disease.258 This relationship between solvent exposure and morphological parameters of tubulointerstitial damage was carefully examined in 59 patients with biopsy-proven primary glomerulonephritis.251 Solvent exposure correlated significantly with both relative interstitial volume, an index of tubulointerstitial damage, and serum creatinine, a marker of kidney function. Furthermore, solvent exposure was greater in patients with progressive renal failure compared with those with stable or improving renal function, suggesting a close and possibly causal relationship between occupational organic solvent exposure, concomitant tubular damage and progressive renal failure in patients with glomerulonephritis.

CROSS-SECTIONAL STUDIES

The rarity of glomerulonephritis in the general population makes a prospective cohort-analytic study of solvents in exposed populations logistically impossible.259 Cross-sectional studies comparing parameters of renal dysfunction in solvent-exposed and matched non-exposed workers is feasible and the few such studies performed generally suggest an association between certain solvent exposures and renal damage.260–267 Thus, in one study,260 workers exposed to moderate amounts of styrene, toluene and a mixture of mainly aromatic compounds were found to have slight but significantly increased urinary excretions of erythrocytes, white/tubular epithelial cells and albumin compared with a non-exposed group. Likewise, workers mainly exposed to aliphatic and acyclic hydrocarbons were shown to have increased proteinuria and tubular enzymuria (lysozyme and β-glucuronidase) in the absence of albuminuria, findings which were indicative of tubular rather than glomerular dysfunction.261 In a study of 20 000 workers, the prevalence of proteinuria was found to be higher in those exposed to hydrocarbons than in those who were not.262 A significant shift of the cumulative frequency distribution of the urinary albumin concentration towards higher values has also been shown in workers exposed to styrene.263

Two other studies have used more sensitive markers of kidney damage. In one,264 male oil refinery workers with exposures to hydrocarbons below the current US threshold limit values, were found to have significantly higher urinary excretions of albumin and (brush border) renal tubular antigen and a higher prevalence of circulating anti-laminin antibodies than a non-exposed group. In the other, the study population was classified into heavy, moderate and low hydrocarbon exposure groups (based on retrospective life-long hydrocarbon exposure scores using a method similar to that used in a recent study268) and the findings were compared with those of a control group.265 The control group was unsatisfactory because 50 per cent of the controls had a past history of heavy metal exposure. Despite introducing this bias, the workers exposed to hydrocarbons were found to have an increase in the urinary excretion of glycosaminoglycans (a marker of glomerular basement membrane damage) and fractional albumin clearance.265 The latter effect may have been secondary to an interaction between hypertension and hydrocarbon exposure.

Further studies have suggested that this interaction was significantly associated with abnormal proteinuria, an
increased serum laminin concentration, albumin excretion rate and NAG activity. Furthermore, exposure to hydrocarbons seemed to accelerate the age-dependent decline in kidney function. This contrasts with earlier studies from the same group suggesting that long-term moderate exposure to solvents did not entail a significant nephrotoxic risk.

Similarly, two studies yielded contrasting conclusions about renal function in subjects occupationally exposed to perchloroethylene. In one, no association could be found between exposure and renal outcome in workers exposed to perchloroethylene in dry cleaning shops. In the other, the findings were consistent with both glomerular and tubular dysfunction in workers exposed to low levels of perchloroethylene in dry cleaning (Figure 86.7) and indicated that solvent-exposed workers, especially dry cleaners, may need to be monitored for the possible development of chronic renal disease.

In view of the ongoing controversy in this area of nephrology, we undertook one further such cross-sectional study in a car manufacturing plant with workers exposed to various solvents at their worksite. The paint sprayers exposed to paint-based solvents had a significantly higher prevalence of renal impairment than the other groups (Figure 86.8) and a higher prevalence of abnormal total proteinuria and enzymuria than controls. Workers exposed to petroleum-based paints had a significantly higher prevalence of abnormal proteinuria, transferrinuria, tubular proteinuria and enzymuria, but albuminuria was similar in all groups. These results suggested that chronic solvent exposure may be associated with both clinical and subclinical renal dysfunction.

We have found evidence of endothelial activation and early basement-membrane disturbance resulting in autoantibody production as suggested by depressed serum laminin (marker of basement-membrane turnover) and elevated autoantibodies to laminin and Goodpasture’s antigen (markers of anti-GBM antibody-mediated disease) in individuals occupationally exposed to paint and petroleum-based solvents (Figure 86.9). Unfortunately, there are no follow-up data on the renal outcome of these subjects. However, a recent study of a matched cohort of paint sprayers from a different car plant suggested that the proximal tubule damage mentioned above may be reduced by improved respiratory and skin protection at the worksite.

![Figure 86.7](image1)

**Figure 86.7** Distribution of workers exposed to perchloroethylene (PCE) and matched controls classified on the basis of 13 selected early markers of renal damage. According to discriminate function 87 per cent of subjects were correctly classified ($\chi^2 = 69.9, 13$ df, $p < 0.001$). Reproduced from Ref. 270 with permission.

![Figure 86.8](image2)

**Figure 86.8** Dottogram of serum creatinine levels in three groups of workers in a car plant. Group 1 (paint sprayers) had a significantly different distribution from group 2 (transmission shop workers) and group 3 (body shop workers). Evidence of renal impairment was present in 11 per cent of group 1. The dotted line represents the upper reference limit derived from external controls. Reproduced from Ref. 250 with permission from Oxford University Press.

![Figure 86.9](image3)

**Figure 86.9** Distribution of levels of serum anti-laminin antibodies in three groups of workers in a car plant (group 1 paint sprayers, group 2 transmission shop workers, group 3 body shop workers and group 4 normal external controls). In group 1, there was approximately a six-fold increase in the proportion of subjects with anti-laminin antibody results compared with controls. Reproduced from Ref. 272 with permission from Oxford University Press.
COHORT STUDIES

A cohort study involves a sample of a population exposed to solvents who are compared with an age- and sex-matched cohort of unexposed individuals who are then followed for an outcome assessment, such as mortality due to renal failure (see Chapter 6). Such studies may offer valuable information in the investigation of the association between solvent exposure and glomerulonephritis. However, the diagnostic categories of ‘nephritis and nephrosis’ or ‘genitourinary diseases’ are likely to be invalid representations of renal mortality. Thus, in four large cohort studies of solvent-exposed workers, the risk of death (standardized mortality ratios) from renal causes was lower than otherwise expected in occupationally exposed cohorts. The basic assumption for mortality studies is that the toxic effects are lethal. Such studies cast little light upon possible slight-to-moderate effects of exposure. Furthermore, the outcomes of ‘register studies’ are always difficult to interpret: diagnostic criteria may vary between and even within studies and the exposures are often vaguely or too generally defined. This may partly be explained by the influence of the well-documented healthy worker effect on non-cancer mortality frequently observed in occupational cohorts. Moreover, mortality studies do not take into consideration those workers who take early retirement on health grounds (e.g. patients with end-stage renal failure requiring dialysis treatment), although the medical condition may eventually account for the individual’s death.

MECHANISMS OF SOLVENT-INDUCED NEPHROTOXICITY

The mechanism underlying solvent-induced nephropathy remains speculative despite solvents being well-recognized tubulotoxins in both clinical and experimental settings. Glomerulonephritis appears to be mainly an immune-mediated disease and there is experimental and clinical evidence of an immunosuppressive potential of various solvents. Experimentally, solvent exposures have induced glomerular lesions in the presence of concomitant tubulointerstitial injury. It is, therefore, possible to speculate that in susceptible individuals, low-grade tubular damage from chronic exposure to solvents may provoke local autoimmunity by releasing either sequestered or altered tubular and basement-membrane antigens (antibodies to proximal tubular antigens, laminin, Goodpasture’s antigens) with activation or damage of the overlying endothelium, which results in the development of glomerulonephritis. Autoimmunity may be favoured by the immunosuppressive effects of solvent exposure. Furthermore, carbon tetrachloride nephrotoxicity can be inhibited by whole body irradiation exposed at each injection, favouring the role of primary tubular damage and local autoimmunity in the possible pathogenesis of solvent-induced glomerulopathy.

An alternative hypothesis is that potentially glomerulotoxic immune factors arise independently of solvent exposure and that solvents merely facilitate the deposition of these mediators of immune damage in renal tissue. However, occupational exposure to solvents is widespread and glomerulonephritis and tubular interstitial disease are infrequently seen, which could suggest the operation of as yet undefined possible genetic or idiosyncratic factors in this association.

Whatever the mechanism of solvent nephropathy, the observations serve to remind us that an occupational and recreational history should be obtained from patients with progressive renal failure and that they should receive counselling regarding relevant exposures. With improved means of reducing exposure to solvents in occupational settings (Figure 86.10), these risks should gradually reduce.

Figure 86.10  Boat paint sprayers with protective equipment and using air-fed masks.
Key points

- End-stage kidney failure is a personal and financial disaster for affected patients and an increasingly large cost burden for world healthcare programmes.
- While immunological and vasculopathic associations are recognized in the causation of chronic kidney disease, occupational factors may be relevant and should be considered in all patients.
- The nephrotoxicity of heavy metals has been studied for many years. Evidence also links occupational organic solvent exposure and progressive kidney failure.
- Prevention of kidney toxicity from these agents through public health and work site programmes involving increasing awareness of risk and adherence to control measures provides more health benefit than limited treatment options.
- Increasingly, emphasis should be focused on the detection and early and possibility reversible biochemical indicators of toxicity, such as renal tubular dysfunction in cadmium toxicity.

ACKNOWLEDGEMENTS

This chapter is updated from Hunter’s Diseases of Occupations, 9th edn, Chapter 90, Nephrotoxic effects of workplace exposures by Gordon M Bell and Howard J Mason.

Neurotoxic effects of workplace exposures

MICHAEL J AMINOFF AND MARCELLO LOTTI

INTRODUCTION

Increasing numbers of chemical agents are being introduced into the occupational environment, and many of these agents are liable to produce neurotoxic effects manifested either as neurobehavioural changes or neurological deficits affecting cognition, motor control, sensation or autonomic function. Either the central or the peripheral nervous system, or both, may be damaged. This chapter will consider the main agents that have been implicated in the setting of workplace exposure. These may affect workers involved in the manufacture of potentially neurotoxic substances and those subject to industrial, agricultural, horticultural or military exposure.

A clinical or subclinical disturbance of function should be considered to have a neurotoxic basis only if certain basic criteria are satisfied. First, a temporal association should exist between toxin exposure and any clinical or other manifestations of neurological dysfunction. The tempo of the clinical disorder should be consistent with the biological effects and mechanisms of action of the presumed toxin. The course of the disorder should be arrested (sometimes after an interval during which mild progression occurs, the so-called ‘coasting’ phenomenon) when exposure to the putative toxin is discontinued. In some instances, it is possible to show that rechallenge (i.e. re-exposure to the likely toxin) leads to reappearance or exacerbation of the neurological disorder. Second, there should be no alternative explanation for the neurological dysfunction. Third, the manifestations of the presumed neurotoxic disorder should be similar to those in other cases of exposure to the same neurotoxin. Fourth, the presumed neurotoxic disorder should be biologically plausible, based on the known toxicity or effects of the toxin on biological systems. It may be possible to demonstrate a dose–response relationship in which the exposure dose is related to the development of the disorder or its severity. Fifth, it is sometimes possible to reproduce the presumed neurotoxic disorder experimentally under similar conditions of exposure in animals, thereby providing support for its aetiology, although a failure to reproduce it does not exclude the possibility of a neurotoxic disorder.

The assessment of neurotoxic effects poses a variety of problems, particularly with regard to the detection of mild or subclinical neurobehavioural disturbances related to chronic low-dose exposure or following a single episode of acute toxicity. Structured psychometric tests for investigating possible cognitive impairment are sensitive to focal disturbances in individual cortical regions. Potential confounding factors during testing, such as fatigue or exposure to alcohol and psychotropic drugs, have to be considered.
This also applies to the use of the electroencephalogram (EEG) and event-related evoked potential studies. For disturbances of motor function, quantitative tests of muscle strength and of coordination, body sway and balance are sometimes useful. Quantitative sensory testing may be helpful; a variety of modalities can be examined, including vibration and discriminative tactile sensibility, cold and warm thermal thresholds, and heat pain thresholds. Quantitative evaluation of autonomic (mainly cardiovascular) function is now a well-established procedure. Many of these tests are laborious and time-consuming, but less elaborate tests suitable for use in the field have been devised for some assessments.

Peripheral nerve function can be analysed using nerve conduction tests which assess function both in motor and sensory fibres. The sensitivity of measurements of motor and sensory nerve conduction velocity, in particular the former, is substantially greater than that for evoked muscle action potential and sensory nerve action potential amplitude. Strict temperature control during testing is vital. For the comparison of exposed workers with control subjects, the selection of appropriate control subjects is important. The use of sedentary office workers as controls for manual workers, for example, has led to erroneous conclusions, as manual workers frequently accumulate abnormalities of nerve conduction during their occupation as a consequence of repeated minor trauma or the development of subclinical entrapment neuropathies. Neuromuscular transmission and muscle function can be assessed by quantitative electromyography (EMG), but such testing is technically demanding.

Epidemiological studies involving case–control observations again demand scrupulous care in the selection of appropriate control subjects. For neurobehavioural observations, careful matching for age, sex, ethnic group and educational background is necessary. With these multiple problems in establishing a causal relationship between exposure to a particular neurotoxic agent and the occurrence of symptoms in a workforce, it is understandable that conflicting reports may arise, particularly as individual variations in susceptibility may complicate the issue. Animal experiments are not always informative because of interspecies differences, but may be crucial in clarifying the mechanism of action of toxic substances.

**ACRYLAMIDE**

Acrylamide polymers are used to separate solids from aqueous solutions in certain industries, and are constituents of adhesives and certain products, such as cardboard and moulded parts (see Chapter 42, Organic chemicals). The monomer, but not the polymer, is neurotoxic. Exposure typically occurs by inhalation or cutaneous absorption during the manufacture of the monomer or in the polymerization process. Acrylamide is also used for grouting in mines and tunnels; for this purpose, liquid monomer is pumped into the soil, where polymerization occurs after the addition of various catalysts, rendering the soil waterproof. Intoxication has occurred occasionally in workers involved in such grouting operations. It is also used, for example, in manhole sealing operations. Typically, the powdered grout is mixed with water to produce an aqueous grout solution containing 10 per cent solids, to which an activator is added. A second solution is prepared consisting of an initiator or catalyst, such as ammonium persulphate. The solutions are mixed and injected where required; the acrylamide polymerizes and the cross-linking agent binds the polymer chain together, converting the mixture into a gel. During the liquid and gel phases of the grout operations, the grout is hazardous to workers because of the risk of dermal contact and absorption.

Occupational exposure may result in an encephalopathy, with confusion, hallucinations, poor concentration, drowsiness, and other changes, depending on the duration and severity of exposure. A length-dependent sensorimotor neuropathy also occurs and is typically associated with hyperhidrosis and redness and exfoliation of the skin and occasionally with urinary retention. Cerebellar disturbances may be conjoined. Numbness of the feet is usually the earliest symptom. The tendon reflexes are lost at an early stage.

The neuropathy is arrested and may slowly reverse after discontinuation of exposure, but residual deficits — including sensory ataxia — are common. Histopathological studies show a distally predominant accumulation of neurofilaments in axons, and distal axonal degeneration in both the peripheral and central nervous systems. There is little secondary demyelination. On electrophysiological examination, maximal motor conduction velocity is normal or only slightly reduced, but compound muscle action potentials may be small and dispersed, with a prolongation in the distal motor latency. These changes have been attributed to degeneration and subsequent regeneration of the distal parts of the motor axons. In keeping with an axonopathy, sensory nerve action potentials are reduced or absent and this is the preferred electrophysiological means of monitoring workers who are at risk of developing the disorder.

More sophisticated electrophysiological studies have revealed that sensory fibres are more vulnerable than motor fibres, and large fibres more vulnerable than small ones. Function is disturbed especially in the short, intramuscular segment of the large-diameter stretch receptor afferent axons from gastrocnemius. Experimental studies have also indicated that sudomotor dysfunction occurs later than motor involvement and reflects damage to postganglionic sympathetic efferent nerve fibres.

The pathogenesis of acrylamide neuropathy is unclear. Both fast and slow axonal transport systems are affected in acrylamide neuropathy. Impairment of fast axonal transport is probably responsible for the accumulation of tubulovesicular structures and of slow transport probably underlies the formation of neurofilamentous axonal
swellings. The ability of the fast anterograde motor protein, kinesin, to interact with microtubules is affected; dynein–microtubule interactions (involved in retrograde transport) may similarly be impaired. There is also evidence of decreased synaptosomal neurotransmitter release, perhaps related to impaired neurotransmitter uptake into synaptic vesicles.

The effects on the nervous system are cumulative, and exposure must therefore be limited. Protective clothing (for example, gloves, head covering, face shield, goggles and overalls) limits dermal contact and a mask can be utilized to limit inhalation exposure. Bags of the monomer should carry warning labels about the means and hazards of exposure. Permissible airborne exposure limits of factory workers should be no more than 0.3 mg/m³ time-weighted average (TWA) according to recommendations of the Occupational Safety and Health Administration (OSHA) of the United States Department of Labor (American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV): 0.03 mg/m³ TWA and the National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL) 0.03 mg/m³ TWA). Myers and Macun described the occurrence of acrylamide neuropathy in workers in a small factory in South Africa who were exposed to varying levels of acrylamide while manufacturing polyacrylamide flocculants. Logistic regression showed dose–response relationships of exposure with symptoms, abnormal sensation, weakness, gait disturbances and cutaneous abnormalities. Acrylamide-related abnormalities occurred in 67 per cent of those with exposure exceeding the recommended exposure level of NIOSH, compared with lesser exposure.

The encephalopathy and mild peripheral neuropathy resolve following cessation of exposure to acrylamide, but recovery is incomplete in patients with severe neuropathies. There is no specific treatment to hasten recovery.

**ALLYL CHLORIDE**

Allyl chloride, a chlorinated hydrocarbon, is a colourless, yellow or purple liquid with an unpleasant odour. It is used in the manufacture of epichlorohydrin which is employed for the manufacture of epoxy resins. It is also used in the production of glycerine insecticides and in the synthesis of polyacrylonitrile. Precise information concerning risk of neurotoxicity in workers exposed to specific concentrations of allyl chloride is limited, but TLV is 1 ppm (3 mg/m³ TWA) in many developed countries including the United States. Toxicity to the liver and kidney generally overshadows any neurotoxicity, but outbreaks of polyneuropathy have occurred in two factories in China in the absence of liver and kidney dysfunction. Subjects in one factory were exposed to allyl chloride at levels of 2.6–6650 mg/m³ for between 2.5 months and six years and most had a mixed sensorimotor polyneuropathy; electrophysiological studies showed neurogenic abnormalities in ten of the 19 subjects examined, so that the prevalence of neuropathy was 52.6 per cent. At the other factory, exposures were at 0.2–25.13 mg/m³ for 1–4.5 years; symptoms of workers were clinically milder and few abnormal neurological signs were present, but electrophysiological abnormalities of mild neuropathy were found in almost 50 per cent of subjects. A central-peripheral distal axonopathy has been reproduced experimentally in mice. A multifocal intra-axonal accumulation of neurofilaments preceded axonal degeneration.

The diagnosis is based on the occurrence of symptoms, signs and electrodiagnostic abnormalities indicative of neuropathy in subjects with known exposure to allyl chloride and no other identifiable cause of neuropathy. Management involves the discontinuation of exposure and supportive measures. Improvement may occur, but may be delayed for months. There is no specific treatment.

### 1-BROMOPROPANE

1-Bromopropane has replaced ozone-depleting solvents for degreasing and cleaning metal and optical instruments and as a glue solvent. Central and peripheral neurological disorders have recently been associated with occupational exposures to it for months or years, but the clinical picture is not consistent. Features common to all reports include weakness of lower-extremity muscle groups, numbness, dysphagia and urinary difficulties. Diarrhoea is often present. Patients are unable to stand and some present with signs of a spastic paraparesis. Stretch reflexes may be normal, brisk or decreased, whereas vibration sense is always reduced. No involvement of cranial nerves has been described. Nerve conduction velocity and EMG studies are either normal or reveal a demyelinating or axonal neuropathy. Brain and spinal cord magnetic resonance imaging (MRI) may be normal or show increased T2 signal in the periventricular white matter and at lumbar levels. Laboratory tests, including cerebrospinal fluid (CSF), are normal except for pseudo-hyperchloraemia. Since most autoanalysers react with all halide anions, hyperchloraemia in these patients masks high levels of blood bromide, reported as high as 12.5 mEq/L. Functional recovery is slow and poor.

No severe neurological symptoms have been observed in workers exposed to less than 170 ppm 1-bromopropane and having urinary 1-bromopropane levels lower than 120 ng/L, but in another study mild signs of neurotoxicity were detected at environmental levels lower than 50 ppm. The proposed limit of exposure in the United States is less than 10–25 ppm.

Conflicting results have also been reported in rats after inhalation of 1-bromopropane at similar dose levels and length of exposure. No neuropathological changes were found in one study, whereas in another, ovoid debris of myelin was detected in tibial nerves together with swellings of preterminal axons in the nucleus gracilis.
CARBON DISULPHIDE

Carbon disulphide has been used as a soil fumigant, in the manufacture of viscose rayon and cellophane films, in the cold vulcanization of rubber, in perfume production, and as a component in certain varnishes and insecticides (see Chapter 39, Gases). It has also been used as a solvent for rubber, wax resins, various oils and certain other chemicals. Toxicity may result from inhalation, ingestion and possibly skin contact, and is not confined to the nervous system. Heavy exposure may occur during the production of viscose rayon when spinning machines are opened, and while cutting and drying.

In the United States, the OSHA-enforceable standard (permissible exposure limit or PEL) for carbon disulphide in workplace air is 20 parts per million (ppm) averaged over eight hours of exposure, and NIOSH recommends that workroom air levels of carbon disulphide not exceed 1 ppm for a ten-hour work day, 40-hour work week. The ACGIH has assigned TLV of 10 ppm as a TWA for a normal eight-hour work day and a 40-hour work week. The findings of a recent study, however, suggested that the current TLV is insufficient to protect against the neurological effects of carbon disulphide and led to the recommendation that it be lowered.21

Inhalation exposure to concentrations above 400 ppm leads to narcosis. An encephalopathy may result from acute high exposure, with headache, irritability, uncontrollable anger, disrupted sleep, memory disturbances, mood swings, mania, depression, suicidal tendencies, confusion and other psychiatric manifestations.22 Such symptoms may follow subacute exposure to levels in the order of 300 ppm, but are common also when workers are exposed chronically to concentrations averaging between 40 and 50 ppm; they are not to be expected at concentrations below 20 ppm.23 Minor intellectual, affective or motor changes may only be revealed by neuropsychological testing.

Long-term exposure to carbon disulphide may lead to a variety of behavioural or psychiatric disturbances,23 to extrapyramidal findings such as cogwheel rigidity, bradykinesia or dyskinesia, and to pyramidal deficits, such as a pseudobulbar palsy. A cerebellar syndrome may also occur, sometimes as a delayed manifestation of carbon disulphide exposure, perhaps as a consequence of concomitant age-related neuronal loss.24 The pupillary and corneal reflexes may be lost, a retrolubular optic neuropathy sometimes develops, and funduscopic examination may reveal a characteristic retinopathy with microaneurysms and punctate haemorrhages. In addition, there may be clinical or subclinical evidence of polynuropathy.25-27 Magnetic resonance imaging of the brain shows high signal intensities in the basal ganglia and subcortical white matter, suggesting small-vessel disease.28 The neuropathy develops after exposure to levels of 100–150 ppm for several months or to lower levels for several years. It is histologically similar to the neuropathy produced by n-hexane, with focal axonal swellings and accumulations of neurofilaments.

There is no specific treatment for the neurological complications of carbon disulphide intoxication, but further exposure must be prevented and general symptomatic measures may be helpful. The peripheral neuropathy may persist at least for some years after cessation of exposure, showing evidence of central involvement.28

CARBON MONOXIDE

Carbon monoxide (CO) is an odourless, colourless gas derived from the incomplete combustion of carbon-containing materials (see Chapter 39, Gases). The noxious effects are the result of hypoxia. It binds tenaciously to haemoglobin to form carboxyhaemoglobin (COHb) and also impairs the dissociation of oxyhaemoglobin so that tissue hypoxia is greater than for a comparable degree of anaemia. It also binds to myoglobin, cytochrome oxidase, cytochrome P450, catalases and peroxidases. Elimination of carbon monoxide is increased by breathing pure oxygen or, more rapidly, by hyperbaric oxygen. Some is eliminated by conversion to carbon dioxide (CO2).

Carbon monoxide poisoning may occur as a result of occupational exposure. The exhaust gases of internal combustion petrol engines contain carbon monoxide and may lead to occupational exposure in the workplace. Cases may certainly relate to industrial exposure, mainly in miners, garage employees and gas workers. The widespread misuse of equipment may lead to the appearance of outbreaks of carbon monoxide poisoning, as has occurred, for example, among Iowa farmers from the indoor use of pressure washers29 or from the indoor burning of charcoal briquets.30 A series of carbon monoxide (CO) poisonings has been reported in association with the industrial use of liquefied petroleum gas-powered forklifts in inadequately ventilated warehouse and production facilities (in a plastic manufacturing plant, warehouse and embroidery company). Employees at these facilities developed symptoms of carbon monoxide poisoning, and in some the correct diagnosis was initially not made because of the non-specific nature of their symptoms, so that they were sent home untreated from the hospital.31 Well-recognized industrial sources include catalytic cracking units in petroleum refineries and sintering of blast furnace feed in sintering plants. Carbon monoxide intoxication is also a major hazard for firefighters.

The current OSHA permissible exposure limit is 50 ppm (55 mg/m3) as an eight-hour TWA concentration; NIOSH has established a recommended exposure limit of 35 ppm (40 mg/m3) as an eight-hour TWA and 200 ppm (229 mg/m3) as a ceiling; and the ACGIH has assigned a TLV of 25 ppm (29 mg/m3) as a TWA for a normal eight-hour work day and 40-hour work week. The NIOSH limit
Monoxide exposure are questionable. Stewart concluded work environment. are available to monitor carbon monoxide levels in the monoxide emissions assessed regularly. Various devices spaces, adequate ventilation must be assured and carbon corrected. If motor vehicles are to be operated in confined of exposure and likely hazardous features should be tant: the workplace should be screened for possible sources treatment of the metabolic acidosis. Prevention is impor-
oxygen if available, and supportive measures including administration of oxygen, with hyperbaric atmosphere, the administration of oxygen, with hyperbaric oxygen if available, and supportive measures including treatment of the metabolic acidosis. Prevention is important: the workplace should be screened for possible sources of exposure and likely hazardous features should be corrected. If motor vehicles are to be operated in confined spaces, adequate ventilation must be assured and carbon monoxide emissions assessed regularly. Various devices are available to monitor carbon monoxide levels in the work environment.

Adverse neurological effects of chronic low level carbon monoxide exposure are questionable. Stewart concluded that visual perception was possibly marginally impaired at carboxyhaemoglobin levels of 5 per cent, but that cognitive function and the performance of complex motor tasks were not altered unless concentrations exceeded 10 per cent.

**DIMETHYLAMINOPROPIONITRILE**

Dimethylaminopropionitrile (DMAPN) has been used, along with acrylamide, in a grouting mixture. This combination is known to have caused peripheral neuropathy. It was then incorporated as a catalyst in the production of polyurethane foams. After its introduction in 1976–77, an unusual neuropathic syndrome developed in exposed workers, characterized primarily by autonomic involvement. This began with difficulty with micturition and was followed by erectile dysfunction and sensory symptoms in the feet and hands. These symptoms were accompanied by insomnia and fatigueability. Examination showed distal sensory loss in the limbs and also in sacral dermatomes, slight distal weakness and depressed ankle jerks. Gradual recovery ensued, but urinary and sexual dysfunction sometimes persisted. Exposure had probably occurred by inhalation, but it may also have occurred through the skin. Nerve biopsy showed loss of both myelinated and unmyelinated axons. Nerve conduction studies showed minor abnormalities in some patients, which normalized several months after exposure had ceased. There are incomplete data concerning exposure levels during industrial use and the relation of exposure to safety.

**ETHYLENE OXIDE**

Ethylene oxide (EtO) is used mainly as a chemical intermediate in the manufacture of textiles, detergents, polyurethane foam, antifreeze, solvents and various other products, and as a fumigant and to sterilize heat-sensitive products, such as operating gowns used by hospital personnel and patients (see Chapter 39, Gases). Its byproduct, ethylene chlorohydrin (EtC), is considered to be highly toxic, but the mechanism of toxicity is unclear. The principal hazards are carcinogenicity and mutagenesis, rather than neurological. Chronic exposure (inhalation or transdermal) to ethylene oxide and ethylene chlorohydrin, however, has been reported to lead to peripheral neuropathy and mild cognitive impairment in operating department nurses and technicians, although disposable operating gowns and drapes are now widely used. It has also been suggested that residual ethylene chlorohydrin in dialysis tubing after sterilization could contribute to the polyneuropathy encountered in patients receiving chronic haemodialysis. It is known that neuropathy can be produced by exposure of rats to ethylene oxide. This is a central-peripheral distal axonopathy that is diagnosed in humans on the basis of a history of exposure to a concentration deemed toxic, with improvement occurring on cessation of exposure. No specific treatment exists. The NIOSH REL is <0.1 ppm (<0.18 mg/m³) TWA; 5 ppm (9 mg/m³) ceiling, 10 min/day. The ACGIH TLV is 1 ppm (2 mg/m³). Ethylene oxide is considered to be a human occupational carcinogen and workers should be exposed to levels that are as low as reasonably practicable.
HEXACARBON SOLVENTS

For a fuller discussion of hexacarbon solvents, see Chapter 42, Organic chemicals.

Methyl \(n\)-butyl ketone and \(n\)-hexane

Methyl \(n\)-butyl ketone is a solvent that has been used in the manufacture of vinyl and acrylic coatings and adhesives, and in the printing industry. In 1975, Allen et al. reported an outbreak of polyneuropathy among workers in a plant producing plastic-coated and colour-printed fabrics. The temporal onset and cause of the outbreak correlated with exposure to methyl \(n\)-butyl ketone, which had recently replaced methyl isobutyl ketone, and new cases failed to appear after its elimination from the workplace. It has since become apparent that exposure via inhalation or skin contact to only small traces (a few ppm) of methyl \(n\)-butyl ketone is sufficient to lead to a neuropathy in exposed workers.

\(n\)-Hexane is a solvent used in various paints, lacquers and printing inks. It is also used in the rubber industry and in glues, and exposure may occur in workers involved in manufacturing shoes or sandals, laminating processes and cabinet finishing. Exposure in the range of 500–2500 ppm leads to an insidiously progressive, distal, sensorimotor polyneuropathy, sometimes accompanied by visual impairment (due to optic neuropathy or maculopathy) or facial numbness. \(n\)-Hexane has also been associated with the triggering of Leber hereditary optic neuropathy. Tendon reflexes may show only mild changes. There is marked slowing of nerve conduction velocity and terminal motor latency, in addition to signs of denervation in affected muscles and small or absent sensory nerve action potentials. The neuropathy results from a disturbance of axonal transport, and is associated with giant, multifocal axonal swelling with accumulation of axonal neurofilaments, and with distal degeneration in both peripheral and central axons accompanied by secondary demyelination. Differential diagnosis may be difficult unless there is evidence of \(n\)-hexane exposure in an occupational setting. \(n\)-Hexane and methyl \(n\)-butyl ketone are metabolized to 2,5-hexanedione, the agent predominantly responsible for their neurotoxic effects. This \(\gamma\)-diketone structure reacts with lysine \(\varepsilon\)-amines to form pyrrole adducts to axonal neurofilaments and secondary cross-linking derivatives, hampering axonal transport.

Acute exposure by inhalation to these hexacarbon solvents produces a pleasurable sense of euphoria, together with headache, unsteadiness, hallucinations and mild narcosis. The inhalation for recreational purposes of certain glues has been associated with the development of the same sensorimotor polyneuropathy described above.

The neurological deficit progresses for some months after occupational or recreational exposure is discontinued, and examination may show evidence of minor pyramidal dysfunction in addition to the neuropathy. Multimodality evoked potential studies have provided confirmatory evidence of central involvement at different levels of the nervous system (cord, brainstem and cerebral hemispheres) in workers exposed to \(n\)-hexane.

Current ACGIH TLVs for \(n\)-hexane and methyl \(n\)-butyl ketone for occupational exposures are 50 and 5 ppm, respectively.

Methyl ethyl ketone

Methyl ethyl ketone is a solvent used in paints and lacquers, printer’s ink and certain glues. Occupational exposure to methyl ethyl ketone has been monitored by measuring its concentration in the air of the working environment and also by determination of urinary levels at the end of a work shift. It was present with methyl \(n\)-butyl ketone in the mixture of chemicals that led to the outbreak of neuropathy referred to earlier. It has also been present with \(n\)-hexane in a number of compounds that have been inhaled for recreational purposes, with resulting development of a neuropathy. It is generally believed that methyl ethyl ketone does not itself cause a peripheral neuropathy, but that it may facilitate its development when exposure occurs to other hexacarbon solvents.

Chronic occupational exposure to methyl ethyl ketone through both skin contact and inhalation has been associated in a single graphics worker with the development of multifocal myoclonus, ataxia and a postural tremor that resolved over one month after exposure to the work environment was discontinued. Other similarly exposed workers were not affected, suggesting that individual susceptibility was an important factor. Ataxia and tremor, together with dysarthria, cognitive changes, headaches and respiratory difficulties, have also been reported in a labourer after acute exposure to a mixture of methyl ethyl ketone and toluene while spray-painting equipment in an enclosed, unventilated garage.

METALS

Metals are covered in more detail in Chapters 12–38.

Aluminium

Aluminium causes both an acute fatal encephalopathy and a chronic progressive encephalopathy in subjects with chronic renal dysfunction. Brain pathology is different from that in patients with Alzheimer’s disease and is mainly non-specific. Several epidemiological studies suggest, unconvincingly, associations between various environmental exposures to aluminium and sporadic Alzheimer’s disease, amyotrophic lateral sclerosis and Parkinson’s disease.
Epidemiological studies in workers exposed in an aluminium production foundry, during smelting and welding, showed no excess risk of neurological diseases. Overt manifestations of typical aluminium encephalopathy, such as seizures, myoclonus and speech disorders have not been reported in aluminium workers. However, several studies of occupational exposures reported small neurobehavioural changes in workers, although the results are controversial.\(^{53-55}\) Whereas plasma aluminium levels below 10 mg/L are considered safe in dialysis patients, neurobehavioural performance was assessed in workers with average aluminium blood levels between 1 \(\mu\)g/L and 14 mg/L. However, the strongest positive correlations between impaired neuropsychological performance and aluminium blood levels were found at the lowest and highest levels; intermediate ones were not correlated.

### Arsenic

Arsenic is a metalloid widely distributed in nature;\(^{56}\) contaminated waters in certain areas of Southeast Asia currently cause most cases of arsenic poisoning in the world.\(^{57}\) Exploiting the pro-apoptotic characteristics of arsenic, arsenic trioxide is used to induce remission in patients with acute promyelocytic leukaemia.\(^{58}\) Occupational exposures may occur in the manufacture of paints, fungicides, wood preservatives and semiconductors; in gold mining, copper or lead smelting; and in pesticide spraying.

Acute arsenic poisoning after massive ingestion may cause haemorrhagic encephalopathy and the lethal dose is estimated to be around 100 mg.\(^{59}\) The predominant neurological complication is peripheral neuropathy, which may rarely occur after repeated exposures. Neuropathy is inevitably accompanied by other manifestations of arsenic toxicity, including gastrointestinal illness, skin discoloration and anaemia, and begins with distal sensory symptoms, often painful, in the lower limbs and then in the hands; distal weakness follows. Following cessation of exposure, a prolonged gradual recovery may occur, but is usually incomplete. Electrophysiological features suggest a distal sensorimotor axonopathy,\(^{60}\) but proximal demyelination may be conspicuous at an early stage.\(^{61}\) However, pathological examination confirms axonal loss.\(^{62}\) Urinary arsenic excretion exceeding 25 \(\mu\)g over 24 hours might indicate poisoning if the laboratory can distinguish toxic inorganic from non-toxic organic arsenic originating from seafood.\(^{63}\) Levels between 0.1 and 0.5 mg/kg on a hair sample may also indicate chronic poisoning.

Arsenic causes oxidative stress and interferes with the function of numerous enzymes and of transduction cascades involving a variety of transcription factors.\(^{64}\) Despite numerous suggestions that include the use of dimercaptosuccinic acid (DMSA), there is no strong evidence to recommend specific chelating regimens for the treatment of chronic arsenic poisoning.\(^{65}\)

### Lead

Poisoning with lead is primarily related to inorganic lead compounds. Lead is widely employed industrially, and excessive exposure may therefore occur in a broad range of occupations. These include smelting, metal foundry work, battery manufacture and repair, demolition and ship-breaking, paint pigments and polyvinyl chloride manufacture, storage tank construction and repair, high technology industries, pottery production and railroad equipment repair, among many others. Nowadays, exposures are usually well controlled in major industries, but there are still industries in many less developed countries where clinical lead poisoning can occur. In occupational exposures, the current recommended permissible exposure limit to lead corresponds to 50 \(\mu\)g/m\(^3\) in most countries, whereas blood lead limits may vary between 30 and 70 \(\mu\)g/dL. The clinical manifestations differ between children and adults and this discussion is confined to the latter.

Very few cases of lead encephalopathy, if any, have occurred in North America and Western Europe in recent years as a consequence of prolonged and extremely high exposures. Early features are mental confusion and reduced alertness, possibly progressing to coma and seizures if exposure continues. Pathological findings are non-specific.\(^{66}\) Other signs of chronic lead poisoning associated with encephalopathy include neuropathy, autonomic dysfunction, microcytic hypochromic anaemia, nephropathy and hypertension.

Clinical lead neuropathy has also become a rarity. Lead neuropathy is predominantly motor in type, manifested by bilateral finger and wrist drop and bilateral foot drop. Distal sensory loss may also occur, but is less prominent. The tendon reflexes are depressed or lost. Other signs of chronic lead intoxication are always present, including anaemia and disturbances of haem metabolism, such as elevated erythrocyte protoporphyrins and urinary excretion of \(\delta\)-aminolevulinic acid and coproporphyrins. Differential diagnosis includes porphyria, but blood lead levels higher than 90–100 \(\mu\)g/dL and a 24-hour urinary excretion of lead higher than 2 mg after a single intravenous dose of the chelator ethylenediamine tetra-acetic acid (EDTA) are discriminatory. Prognosis depends on the severity of weakness, but is usually good after removal from exposure.

Electrophysiological studies reflect axonal injury with compound muscle action potentials of reduced amplitude, normal or slightly slowed motor conduction velocities, and mildly prolonged distal latencies. Fibrillation potentials, polyphasic motor unit potentials and other signs of denervation are also characteristic of lead neuropathy. Pathological findings are poorly characterized. Whereas segmental demyelination is observed in animals,\(^{67}\) nerve biopsy in human indicates an axonopathy\(^{68}\) in accordance with the electrophysiological changes. The mechanism of lead neurotoxicity is unknown.
Treatment is aimed at reducing the body burden of lead, but it is unclear whether chelation affords any benefit to patients with neuropathy. In cases with blood lead levels higher than 70–90 µg/dL, EDTA chelation is indicated with different time-schedules, depending on the amount of metal that can be successfully mobilized. Other chelators may also be used including meso-2,3-dimercaptosuccinic acid and penicillamine. However, caution should be exercised during chelation, because mobilization of lead from bone could possibly worsen toxicity.

Nerve conduction abnormalities are often reported in exposed workers with blood lead levels corresponding to 30–50 µg/dL, as well as an atypical purely sensory neuropathy in workers with blood levels above 40 µg/dL. These abnormalities of nerve conduction are of unclear significance and do not predict the occurrence of clinical neuropathy.

There is increasing concern that cognitive function may be affected in workers with low exposures to lead, but study results are controversial. Meta-analyses of studies correlating blood lead levels and various neurobehavioural tests in exposed workers have reached opposite conclusions. Whereas blood lead levels reflect recent exposure, other studies show correlations between cognitive impairment and cumulative lead exposure, as measured in various ways including assessments of lead in bone. Patella and tibia bone lead concentrations were also associated with glial effects on the hippocampus when assessed by proton magnetic resonance spectroscopy.

Suggestion have been made linking lead exposure to neurodegenerative disorders such as Parkinson’s disease, amyotrophic lateral sclerosis and Alzheimer’s disease, and to brain tumours, but there is insufficient evidence to support these associations.

Manganese

Manganese is a heavy metal essential to a variety of physiological functions, but it is also a neurotoxicant. Possible sources of manganese intoxication are occupational exposures of miners, smelters, welders, manganese alloy producers, cell-battery factory workers, and farmers using manganese-containing fungicides. An organic manganese compound is used to increase octane in fuel, raising concern about the health effects of airborne manganese. Patients with liver failure may also suffer from manganese poisoning, since approximately 80 per cent of dietary manganese intake is cleared by biliary excretion. Asymptomatic hepatitis infections may precipitate manganese neurotoxicity in exposed workers.

The clinical picture of manganese-induced parkinsonism is well characterized. The initial signs of neurotoxicity are usual behavioural and cognitive changes, including compulsive behaviour, accompanied by headache. Subsequently, a neurological syndrome resembling Parkinson’s disease develops after long-term exposures above 27 mg/m³. Manganese is characterized by symmetric extrapyramidal abnormalities, including gait dysfunction, postural instability, bradykinesia, rigidity, masked facies, rest and intention tremor, micrographia and speech disturbances. Dystonic manifestations frequently occur, such as facial grimacing and plantar flexion of the foot (‘cock-walk’).

Magnetic resonance imaging (MRI), positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are useful diagnostic tools for manganese-induced parkinsonism. Because of the paramagnetic quality of manganese, a bilateral symmetrical increased signal intensity on T1-weighted MRI is observed in the globus pallidus and midbrain in both manganese-intoxicated and asymptomatic manganese-exposed workers. As increased T1-weighted signals disappear following withdrawal of exposure, they reflect manganese exposure and not necessarily manganese. [18F]-dopa PET in manganese-intoxicated individuals is normal, suggesting that the nigrostriatal pathway is preserved. Similarly normal is the density of dopamine transporters, used as SPECT ligands, confirming the integrity of presynaptic nerve terminal of the nigrostriatal dopaminergic system.

Levodopa is generally unhelpful in the treatment of these patients. This lack of effect, coupled with negative findings in PET/SPECT studies, suggests that the damage in manganese intoxication is primarily of pathways postsynaptic to the nigrostriatal system. There are some indications from the Chinese literature of effective long-term treatment of manganese with p-aminosalicylic acid, although the mechanism is unknown. Upon removal from exposure, early neurobehavioural changes may be reversible, whereas manganese-induced parkinsonism often shows further progressive deterioration over five to ten years, until a plateau is reached.

Pathological studies show neuronal loss and gliosis primarily affecting the globus pallidus, the substantia nigra pars reticularis, and to a lesser extent the striatum. Lewy bodies are not present and the substantia nigra pars compacta and other regions are usually intact. Animal studies confirm the characteristics of manganese-induced parkinsonism.

Distinction from Parkinson’s disease is based upon medical history, clinical features, neuroimaging, sensitivity to levodopa and neuropathology. The lack of a history of manganese exposure, an asymmetrical impairment, typical rest tremors, normal T1-weighted MRI, decreased striatal uptake on PET/SPECT and, in particular, a good response to levodopa are indicative of Parkinson’s disease. Concurrent alterations of MRI and PET/SPECT may indicate Parkinson’s disease with incidental manganese exposure. The pathology of Parkinson’s disease is characterized by degeneration of dopaminergic neurons in the substantia nigra pars compacta, intracytoplasmic Lewy bodies and a reduction in striatal dopamine. Degeneration also occurs in other regions, such as the locus ceruleus, Meynert nucleus and dorsal motor nucleus of the vagus. These pathological changes are absent in manganese-induced parkinsonism.
Mercury

Occupational exposures to mercury vapour (Hg\(\text{vap}\)) may occur in chloralkali plants, mines, smelting, manufacturing of medical appliances and dental offices. Exposures to other forms of mercury, either inorganic or organic, may represent an environmental risk, but no longer an occupational one.

The main entry route of mercury is by inhalation, and since the brain is not protected from mercury vapour by the blood–brain barrier, deposition depends on the amount of unoxidized mercury that reaches the brain. Clinical manifestations of chronic mercury intoxication depend on the length and degree of exposure and are associated with air concentrations of mercury higher than 500 \(\mu\text{g/m}^3\) and urinary mercury levels higher than 300 \(\mu\text{g/L}\). Neurotoxicity will be common in the workplace at exposure levels to mercury vapour exceeding 50 \(\mu\text{g Hg/m}^3\).\(^{104,105}\) Signs of chronic intoxication are erethism, tremor and stomatitis. Whereas the latter may also depend on oral hygiene, neurological signs are thought to be due to oxidation of Hg\(^0\) to Hg\(^2\), which binds to thiol groups of proteins in the nervous system. The neurasthenic syndrome is characterized by non-specific symptoms and signs, such as insomnia, weakness, irritability, anxiety, loss of confidence and social withdrawal. Fine tremor initially involves the hands and originates centrally. Traditional clinical qualitative methods, as well as quantitative methods, have been used to assess tremor in either intoxicated or exposed workers.\(^{106}\) In milder cases, erethism and tremor regress slowly over a period of years following removal from exposure. Peripheral axonal sensorimotor polyneuropathy may also occur at levels of exposure similar to those causing neurasthenia and tremor, as evidenced clinically and electrophysiologically. Depending on severity and cumulative exposure to mercury, neuropathy may still be detected 20–35 years after the end of exposure.\(^{107}\)

Although many studies have been conducted on low-level mercury exposure in workers, a specific no-observed-adverse-effect level has not been derived. A WHO panel suggested the following broad guidelines.\(^{108}\) At exposures above 80 \(\mu\text{g} \text{ mercury per m}^3\), corresponding to a urine mercury level of 100 \(\mu\text{g/g} \text{ creatinine}, there is high probability of developing classic neurological signs. Exposures in the range of 25 to 80 \(\mu\text{g} \text{ mercury per m}^3\), corresponding to a urine mercury level of 30–100 \(\mu\text{g/g} \text{ creatinine}, increase the incidence in susceptible individuals of less severe neurotoxic effects, such as impaired psychomotor performance and tremor. The occurrence of non-specific subjective symptoms is also increased. At lower levels of exposure, there is no strong evidence of neurological effects.

Meso-2,3-dimercaptosuccinic acid is indicated in the treatment of mercury intoxication to remove the metal, but is unlikely to improve clinical signs.\(^{109}\)

Methyl bromide

Methyl bromide has been used as a fumigant, fire extinguisher, refrigerant and insecticide (see Chapter 39, Gases). Because of its high volatility, dangerous concentrations may accumulate in work areas and inhalation then leads to neurotoxicity. Clinical manifestations depend on dose and duration of exposure. Acute poisoning produces convulsions, pulmonary oedema, hyperpyrexia, coma and death. Other neurological manifestations of acute toxicity include psychosis, affective changes, ataxia, tremor and myoclonus.\(^{110,111}\) Seizures may also occur following exposure to low concentrations, as may headache, nausea, dysarthria, confusion, hyperreflexia and visual abnormalities.\(^{112}\)

Long-term exposure has been associated with a polyneuropathy\(^{112,113}\) that may occur in the absence of systemic symptoms.\(^{114}\) Paraesthesiae in the feet are followed by symmetric, distal sensory and motor deficits and areflexia. Gait ataxia may be conspicuous. Recovery to a variable extent occurs over the three to nine months following withdrawal from exposure. Visual disturbances and optic atrophy have also been reported.\(^{115}\)

Cavanagh\(^{111}\) related methyl bromide intoxication to altered glycolysis and pyruvate oxidation. The peripheral manifestations have been attributed to a distal axonopathy that reflects the altered metabolism of the neuronal perikaryon or an alteration of axonal transport.

A latent period of several hours or even one or two days may occur after exposure before the onset of symptoms, and victims may die without awareness that exposure to the odourless, colourless gas has even occurred. Chloropicrin is a common additive that leads to conjunctival and mucosal irritation, thereby warning of inhalation exposure to methyl bromide. Symptoms of toxicity may occur at a bromide level in the order of 3 mg/mL. With levels over 5 mg/dL, mental changes may lead to careless handling of the chemical by fumigators, and thus to even greater exposure.\(^{116}\)

In the past, chelating agents, haemoperfusion and N-acetylcysteine\(^{110}\) have been advocated for therapy, but their efficacy is uncertain. Otherwise, treatment is symptomatic and supportive. Clinical recovery may occur over a period of months. The OSHA PEL is 20 ppm (80 mg/m\(^3\)).
ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES

A large number of organophosphate (OP) and carbamate compounds are used as insecticides (see Chapter 43, Pesticides and other agrochemicals). Certain OPs have also been used as terrorism and chemical warfare agents. The use of OPs as drugs has been discontinued, but some carbamates, such as physostigmine, are still indicated in certain clinical contexts. Occupational exposures during spraying mainly occur through the skin, particularly in agricultural workers and in areas where insecticides are used to control vector-borne diseases.

These chemicals are inhibitors of acetylcholinesterase (AChE), causing an excess of acetylcholine at nerve endings. The degree and duration of AChE inhibition largely depend on the chemistry of the involved chemicals, which dictates rates of affinity, spontaneous reactivation and ageing of phosphorylated or carbamylated AChE.109

The clinical picture of acute OP and carbamate poisoning is characterized by cholinergic overstimulation throughout the body. Initial symptoms include anorexia, nausea and vomiting, abdominal pain and diarrhoea, hypersalivation, hyperlacrimation and excessive sweating, headache, dizziness and blurred vision. In most cases, these symptoms are associated with miosis, which may be the only sign in mild poisoning. More severe clinical signs include bronchoconstriction, muscle fasciculations, convulsions and coma. Death may occur because of respiratory failure or cardiac arrhythmias. Whereas the inhibition of AChE by carbamates is reversible, symptoms and signs of carbamate poisoning are less severe and of shorter duration.

Diagnosis is exclusively clinical. However, in severely ill patients with cardiorespiratory failure, an exposure to OPs may not initially be suspected and, conversely, patients with known exposure to OPs may present with unrelated illness. In such cases, signs of cholinergic overstimulation must be actively sought. There is usually a good correlation between the severity of signs and symptoms and the degree of AChE inhibition in red blood cells. However, this test has limited value in an emergency because severe OP poisoning requires prompt treatment and is inevitably associated with high AChE inhibition. Serial measurements of red blood cell AChE have no value in monitoring the clinical course of poisoning. Relatively lower levels of AChE inhibition in red blood cells, as well as the inhibition of plasma cholinesterase, may be difficult to interpret.117

Prompt treatment of poisoning by AChE inhibitors is not only life-saving, but will prevent a variety of neurological consequences due to prolonged hypoxia and seizures. Atropine is the cornerstone of treatment of OP and carbamate poisoning because it prevents the effects of acetylcholine by blocking its binding to muscarinic cholinergic receptors. Initial treatment of mild poisoning starts with 1-mg atropine intravenously and should be repeated every 10–20 minutes until clinical evidence of atropinization is achieved, and then maintained for 24–48 hours. If atropinization occurs rapidly, severe poisoning is unlikely. In severe cases, continuous intravenous atropine infusion may be required at a rate of 20 mg/hour. Atropine overdosage is unlikely and rarely serious.

Specific reactivators of phosphorylated AChE, such as oximes, are also indicated in OP poisoning, although their benefits have been questioned. However, data on the inefficacy of oximes are not convincing,118 and this potentially life-saving therapy cannot be dismissed.119,120 Therefore, treatment should be started with 1-g pralidoxime intravenously; if no improvement occurs, a second dose is given after 30 minutes or continuous infusion is commenced at the rate of 0.5 g/hour. Other oximes have different dosing regimens. Treatment with oxime is not recommended in carbamate and in moderate dimethoxy-OP poisonings, because rates of spontaneous reactivation of AChE are fast. Diazepam and supportive therapy are important.

Prognosis depends on the severity of poisoning and appropriateness of care. Pathology is non-specific unless severe hypoxia or convulsions occur. Although a variety of neurobehavioural changes have been reported several months after recovery from acute poisoning,121–123 the significance of these effects is unclear. Contradictory results have been reported in studies of possible neurobehavioural effects of long-term low-level exposures to anticholinesterase agents.124–125

In 20–50 per cent of cases of severe OP poisoning, weakness of respiratory, neck and proximal limb muscles develops (the so-called ‘intermediate syndrome’).126,127 The syndrome develops several hours after severe cholinergic overstimulation and is not a direct effect of AChE inhibition. Its pathogenesis is unknown, but the syndrome seems related to post-synaptic effects. Treatment is supportive and recovery time in surviving patients lasts up to 30–40 days.

Organophosphate-induced delayed polyneuropathy (OPIDP) is a rare toxic effect of certain OPs that, in the case of OP insecticides currently in use, occurs only after a severe episode of cholinergic toxicity.128,129 Whether neuropathy may also follow a severe intoxication by carbamates is unsettled.130 The usual initial complaint is of cramping muscle pain in the legs, followed by distal numbness and paraesthesias, beginning two to three weeks after acute poisoning. Progressive leg weakness then occurs, together with depression of the tendon reflexes. The arms and forearms may also be affected after severe exposures. This symmetrical, predominantly motor, neuropathy displays electrophysiological and histopathological features consistent with peripheral distal axonopathy. In time, there is complete functional recovery if spinal cord axons have been spared. Otherwise, irreversible pyramidal signs of central nervous system (CNS) involvement may become evident, particularly with severe exposures. There is no specific treatment for the disorder.

The mechanism of initiation of OPIDP is unknown, although the target has been identified. Neuropathy relates to inhibition of neuropathy target esterase (NTE) followed by ageing of the phosphoryl–NTE complex. Although these molecular changes occur within hours of exposure,
little is known about subsequent events that lead to
development of OPIDP.131

There is no evidence that long-term low-level exposures
to OP insecticides causes OPIDP or any other type of
neuropathy.124

**ORGANOCHLORINE PESTICIDES**

The chlorinated hydrocarbons constitute a wide range of
chemicals132 and include the organochlorine insecticide
dichlorodiphenyltrichloroethane (DDT) and others, such as
aldrin, dieldrin and lindane. They are only slowly degraded
and persist for long periods in animals and in the environ-
ment. Decline in neurobehavioural functioning and increase
of neuropsychological and psychiatric symptoms
have been reported in retired DDT workers.133 However, the
significance of these findings is unclear because the interval
since exposure was unknown. In fact, DDT neurotoxicity
depends on its temporary action on voltage-dependent
sodium channels. One member of this group, chlordecone
(Kepone) was responsible for a major episode of industrial
exposure in 1975 at a manufacturing plant in Hopewell,
Virginia, and also environmental contamination through
the James River which feeds into Chesapeake Bay.134
Workers developed a neurological illness characterized by
‘nervousness’, opsoclonus, tremor, clumsiness for manual
activities and mild gait ataxia.135 Slight memory impairment
was noticed. Slow but sometimes incomplete recovery
occurred. Benign intracranial hypertension was observed in
a small proportion of cases. Absorption was by inhalation of
dust. The mechanism of neural damage was not established
(see Chapter 43, Pesticides and other agrochemicals).

**PYRETHROIDS**

Synthetic pyrethroids are widely used insecticides.
Occupational exposures may occur in professional sprayers,
particularly in an agricultural setting and in tropical coun-
tries where these chemicals are used to control vector-
borne diseases. Pyrethroids are safe insecticides because of
their high selectivity for insects. Consequently, reports of
poisoning are relatively few.136 In mild cases of poisoning,
symptoms may be non-specific and include dizziness,
headache, anorexia, paraesthesias and fatigue; in more
severe cases, muscle fasciculation, convulsions and coma
occur. These effects may be caused by all pyrethroids.137 A
slowly progressive motor neuron disease indistinguishable
from amyotrophic lateral sclerosis138 has been reported
after heavy and prolonged exposure to various pyrethroids.
Partial improvement may occur a few weeks after cessation
of exposure. However, the occurrence of weakness and the
known mechanism of pyrethroid toxicity cast doubts on
the aetiology of this disease.

The most common effect of pyrethroids is paraesthesias,
in particular in the face and hands.139 This is considered a
local effect due to hyperexcitation of cutaneous sensory
fibres, because there is no correlation between the occur-
rence of paraesthesias and urinary excretion of pyrethroids
or their metabolites. Paraesthesias disappear within 24
hours and there is no specific treatment. Toxicity is purely
functional and depends on pyrethroid action on voltage-
dependent sodium channels, resulting in prolonged
inward sodium currents that lead to repetitive firing and
subsequently to membrane depolarization.140

**PESTICIDES AND PARKINSONISM**

Parkinson’s disease (idiopathic parkinsonism) is one of the
most common of the neurodegenerative diseases and
becomes increasingly common with advancing age. Its
pathogenesis is obscure, but both genetic and environmen-
tal factors have been implicated. Among environmental
factors, pesticide exposure has been recognized for some
time as an adverse risk factor for development of the
disease, but it is difficult to establish this with certainty.
Relevant environmental exposures may occur years before
the development of clinical features of parkinsonism, and
exposure to multiple potential toxins may lead to synergis-
tic or additive effects.141 Furthermore, the impact of any
environmental factors may be genetically determined.
Thus, persons exposed to pesticides or with polymorphisms
in the cytochrome P-450 2D6 (CYP2D6) gene have only
a slightly increased risk, whereas those with both have a
greatly increased risk of parkinsonism.142 Any toxin-med-
ated effect may remain subclinical until normal age-related
cell loss reaches a certain critical level. Finally, the lack of
precision in the available data, especially with regard to level
of exposure, compounds the difficulties in interpreting
studies. Most studies have examined exposure to any pesti-
cide or to broad groups, such as insecticides or herbicides,
and little information is available for specific agents or
factors affecting exposure, such as protective clothing.143

Parkinsonism has developed in humans who took
methyl phenyl pyridinium (MPTP) for recreational pur-
poses. MPTP is a protoxin and is converted in the body
to methylphenyl pyridinium (MPP), a toxin that causes
selective degeneration of the dopaminergic nigrostriatal
system, the cell population that degenerates in naturally
occurring Parkinson’s disease. MPP is structurally similar
to paraquat, a herbicide. MPP inhibits mitochondrial com-
plex I, as does rotenone, another pesticide. Various epi-
demiological studies have found a high risk of Parkinson’s
disease in relation to pesticide exposure, with odds ratios
in the order of 2 to 7 depending on the study.144–148 The
risk relates to duration of pesticide exposure.146–148 Thus,
Petrovitch et al.146 in a prospective cohort study with
30-year follow up of Hawaiian plantation workers, found a
relative risk for Parkinson’s disease of 1.0, 1.7 and 1.9 for
those who had worked on the plantation for 1–10, 11–20
and more than 20 years, respectively, compared to those
who had never done plantation work. Kamel et al.143 found
that the incidence of Parkinson’s disease was associated with cumulative days of pesticide use at enrolment, with personally applying pesticide more than half the time, and with certain pesticides.

Specific pesticides that have been incriminated include paraquat, organochlorine and carbamate derivatives. In Taiwan, where paraquat is widely used, the risk of developing Parkinson’s disease was increased more than six times in those exposed for more than 20 years. \(^\text{146}\) Animal studies support the belief that pesticides may be important in the aetiology of parkinsonism. Both rotenone and paraquat, for example, are toxic to nigrostriatal dopaminergic neurons. Case–control studies in humans have also related parkinsonism to farming, rural living and well-water consumption. \(^\text{149}\)

At the present time, it is fair to conclude that pesticide exposure increases the risk of developing Parkinson’s disease, but the mechanisms involved and risks with specific pesticides are not known and probably vary depending on genetic and other factors.

**STYRENE**

Styrene is used in the manufacture of reinforced plastic and certain resins (see Chapter 42, Organic chemicals). It is used especially in the construction of fibreglass-reinforced plastic boats and other articles, and significant occupational exposure may occur by contact and by inhalation. Exposure is often estimated using biological indices that are not specific for styrene, such as urinary mandelic acid or phenylglyoxylic acid concentration. Environmental measures of styrene may not reflect biological levels because there is considerable variation in styrene uptake and metabolism, depending on personal activities. Thus, both environmental and biological measures are required when exposure to styrene is being considered. Occupational exposure is typically not restricted to styrene, but also involves exposure to cleansing solvents and other chemicals, thereby complicating the interpretation of any disturbances that may arise in the workplace.

Concerns about the neurotoxicity of styrene have been underscored by its high lipid solubility. Acute changes in cognition, behaviour or level of consciousness occur at certain concentrations, but concerns regarding its safety in an industrial setting relate primarily to chronic, low-level exposure. A number of studies have been held to suggest that abnormalities in reaction time and psychomotor performance are induced by styrene at levels approaching current exposure standards, which range between 20 and 50 ppm in many countries. Following a critical analysis of this literature, Rebert and Hall\(^\text{150}\) found that this contention was unjustified, relating to misinterpretation of the data or to type I statistical errors, or that confounding factors had invalidated the various studies. Indeed, no compelling evidence could be found by these authors of persisting neurological sequelae to long-term, low-level styrene exposure.

The inadequacies of these various studies merit emphasis. Rebert and Hall\(^\text{150}\) noted that in many the documentation of exposure was poor and that the number of subjects studied was often very low when subgroups were considered, as when stratifying by level of exposure. Confounding factors were often problematic, demographic data and job characterization were usually incomplete, no attempt was made to validate self-reports of drug and alcohol use, and details of medication use were sparse. The potential effects of exposure to other chemicals were often neglected or minimized. Rarely was mention made of blinded procedures. A variety of statistical shortcomings was also conspicuous, including probable violation of certain statistical assumptions. The incidence of statistical significance was often overestimated because it was based on comparisons of non-independent measures and on multiple comparisons. In addition to these concerns, there was no general consistency in the literature and no clear indication of causal factors or biological mechanisms that might account for any real effects of styrene.

Several studies on occupational exposures have also suggested a relationship between inhaled styrene vapour and hearing loss. Evidence in rats indicates that styrene is harmful to the cochlea by causing hair cell degeneration. \(^\text{151}\) Lawton et al.\(^\text{152}\) reviewed the pertinent literature and concluded that the results are equivocal. In particular, investigations claiming styrene-induced hearing loss in exposed workers were affected by substantial shortcomings of experimental design and data analysis.

**TOLUENE**

Toluene is a solvent in paints and glues. It is also used to synthesize benzene, benzoic acid, nitrotoluene and other compounds. Exposure may occur in workers involved in laying linoleum or spraying paint, and in the printing industry (see Chapter 42, Organic chemicals).

The effects of exposure are primarily neurobehavioural. Chronic, high exposure may lead to cognitive changes, pyramidal tract findings, cerebellar ataxia, brainstem or cranial nerve disturbances, and tremor. \(^\text{153}\) Bilateral visual loss from optic neuropathy has been described, \(^\text{154}\) as also has ocular flutter or dysmetria and opsinclonus. \(^\text{155}\) Cognitive abnormalities are characterized by disturbances of attention, memory and visuospatial function. Apathy and a flat affect are common. Cerebral magnetic resonance imaging may show diffuse abnormalities of the cerebral white matter, the degree of which correlates with neuropsychological impairment. \(^\text{156}\) Diffuse cerebral atrophy and symmetric lesions in the basal ganglia and cingulate gyri have also been reported. \(^\text{157}\)

The level and duration of exposure necessary to produce clinical evidence of neurotoxicity is uncertain, and it is not clear what neurobehavioural effects are produced by long-term, low-level exposure. Exposure to toluene at a level of 125 ppm may produce no neurological symptoms, \(^\text{158,159}\) although minor abnormalities may be present...
on neurobehavioural studies. At levels of 250 ppm, there may be insomnia, nervousness and intermittent stupor. A peripheral neuropathy does not occur with toluene.

Toluene may induce auditory damage in animals, but evidence in humans of toluene ototoxicity and of synergism with noise is less convincing. Conflicting results evidence in humans of toluene ototoxicity and of synergistic effects observed below 20 ppm toluene, that is, the current ACGIH TLV.

**TRICHLOROETHYLENE**

Trichloroethylene was once used as an anaesthetic agent (see Chapter 42, Organic chemicals) and found widespread use as a dewaxing, degreasing and dry-cleaning agent. The solvent was present in paint removers and glues, but concerns over its toxicity have led to it being gradually replaced by safer solvents. Inhalation exposure to levels in the order of 50–200 ppm have led to changes in reaction time and performance on psychological tests in some but not other studies. At levels of exposure below 40 ppm, there is no convincing evidence of significant or long-term disturbances of cognitive function. The current permissible exposure limit (OSHA) is 100 ppm. With increasing exposure in an occupational setting, complaints of headache, fatigue, irritability, nausea and dizziness are common. Facial hyperaesthesia and masticatory weakness may result from dysfunction of the trigeminal nerve; other cranial nerves, such as the facial, optic and oculomotor, may also be affected. An autopsy study has shown fibre degeneration in the trigeminal nerve. The reason for the susceptibility of the cranial nerves is unknown. A case–control study and a mortality study found weak associations between trichloroethylene exposures and risk of brain cancer. However, other studies did not show an increase of brain cancer incidence and mortality.

**SOLVENT MIXTURES**

Prolonged, low-level, occupational exposure to mixtures of organic solvents occurs commonly, for example in house painters. Such exposure is reported to cause an encephalopathy or ‘organic brain syndrome’ characterized primarily by disturbances of memory, concentration and attention, and by changes in personality. However, the studies that form the basis of such claims generally fail to stand up to rigorous scientific scrutiny. These studies, which have originated mainly from Scandinavia, are primarily epidemiological in nature. Objections to them include concerns that other factors, such as alcohol or drug/medication use or the lingering effect of acute exposure to solvents, may have been responsible for the encephalopathic features that were described. In addition, precise details concerning work conditions and extent of probable exposure to solvents were often not obtained or provided, or there was an over-reliance on subjective recall in determining the severity and duration of exposure. Moreover, factors known to influence the neuropsychological tests used to document the presence of an encephalopathy, such as educational background, age, stress and cultural factors, were not taken fully into account in certain uncontrolled studies. The use of controls from other workplace settings may have led to bias when comparisons were made. This is especially important when test and control populations differ in educational or other factors that may have been responsible for their original choice of occupation or if one group is prone to certain occupationally related non-toxic disorders, such as anxiety syndromes.

This is well exemplified by the study of Gade et al. in which 20 solvent-exposed workers, mostly painters, were re-examined two years after they had originally been diagnosed with a chronic toxic encephalopathy. Their performance on neuropsychological testing was unchanged, but the previous impression of significant cognitive decline could not be substantiated when comparison was now made to a non-exposed control group and allowance was made for the influence of age, educational background and level of intelligence.

The existence of a chronic encephalopathy characterized solely by cognitive, affective and personality changes in those exposed for long periods to low levels of organic solvents remains uncertain. No definite causal relationship has been established and the underlying mechanism for such an association is elusive.

It has been suggested that loss of colour vision may be part of the effects related to chronic exposure to organic solvents. Although a recent review identified 13 studies investigating colour discrimination in workers and other subjects exposed to mixtures of solvents, no conclusions can be drawn due to design limitations and methodological irregularities.

**WARTIME EXPOSURE**

**Agent Orange and the Vietnam War**

Over a ten-year period during the war in Vietnam, American forces sprayed millions of gallons of herbicides to strip vegetation that might conceal or provide sustenance for opposition forces. The preparation known as Agent Orange was used most commonly; more than 11 million gallons of Agent Orange were used before spraying was discontinued in 1971 because of concerns about long-term safety. Over the years since then, public concern has increased about the potential health hazards of exposure to Agent Orange. In addition to numerous scientific studies, various governmental reports have been published that bear on the issue.

Agent Orange contained 2,4,5-trichlorophenoxyacetic acid, and one of its contaminants was 2,3,7,8-tetrachlorodibenzo-p-dioxin (or TCDD) (see Chapter 42, Organic chemicals). Concerns have been raised that the
exposure to the major TCDD-contaminated herbicides used in Vietnam was associated with the development of Hodgkin’s or non-Hodgkin’s lymphoma, soft-tissue sarcoma, chloracne and porphyria cutanea tarda and perhaps also of certain other neoplastic disorders.178 Attention here is confined to the potential neurotoxicity of these agents.

The literature is voluminous, but much of it is methodologically flawed. Careful analysis of it has revealed no compelling evidence of an association between Agent Orange exposure and the development of cognitive or neuropsychological disorders or of chronic peripheral neuropathy,178,179 Anecdotal reports suggest that peripheral neuropathy may develop acutely or subacutely following occupational exposure to herbicides,180–182 although the possibility cannot be excluded that the neuropathy in these cases related not to the exposure but to other factors, such as development of the Guillain–Barré syndrome. There are no data on the development of an acute neuropathy following Agent Orange exposure in Vietnam.

Exposure of the local population to dioxin followed the chemical explosion that occurred in an industrial plant at Seveso in Italy, but there did not appear to be an increased risk of acute neuropathy183 and the prevalence of peripheral neuropathy several years after the accident was not increased among those with heavy exposure to dioxin.184,185

In a recent report,186 15 workers who had been poisoned by 2,3,7,8 TCDD 35 years earlier were found to have changes in various combinations in their visual evoked potentials, EEG, colour vision, nerve conduction, SPECT and neurobehavioural responses. Interpretation of this report is hampered, however, by the limited number of subjects, lack of information on neurological status at the time of poisoning, lack of a control group and paucity of details concerning the examined parameters.

There is suggestive evidence that exposure to Agent Orange is associated with an increased risk of developing Parkinson’s disease.

**Gulf War syndrome**

Soon after their return home, military personnel who took part in the Gulf War in 1990–91 reported higher rates of an array of symptoms and a decreased perception of well-being. However, despite numerous investigations, there is insufficient evidence to define a single neurological disease entity. An early cross-sectional epidemiological study on US veterans deployed in Iraq ranked neurological signs and symptoms in three different categories: impaired cognition, confusion–ataxia and ‘arthroneuromyopathy’, suggesting a spectrum of neurological injuries involving the central, peripheral and autonomic nervous systems.187,188

In another small group of UK veterans, abnormalities of nerve conduction and cold thermal sensory threshold were reported.189 However, a subsequent large study using quantitative sensory and autonomic function studies did not detect differences between UK veterans and controls.190 Similar results were found in another controlled study, where no higher prevalence of polyneuropathy was found in US veterans deployed in the Gulf War when compared with non-deployed veterans.191 The results of autonomic function studies are also controversial. In one study on male veterans affected by Gulf War illness, heart rate variability was significantly lower than controls,192 whereas in another similar study this was not found.193 However, in the latter study, heart-rate variability was reduced compared with controls both at night and during the day in female patients affected by Gulf War illness or with fibromyalgia.

Epidemiological studies on Gulf War veterans have revealed an increased incidence of amyotrophic lateral sclerosis,194 particularly in young people diagnosed before the age of 45 years.195 However, these reports have been criticized on methodological grounds, such as the small numbers of cases and the choice of reference statistics. It should be concluded that service in the Gulf War remains an uncertain trigger for amyotrophic lateral sclerosis.196

Although a high incidence of post-traumatic stress disorders is expected as a result of war-time events, contradictory results have been found in specific studies of Gulf War veterans, as well as in studies on the incidence of common mental disorders.197–199

Several environmental exposures to a variety of neurotoxic chemicals have been suggested to explain the aetiology of these chronic effects, including to pyridostigmine bromide (used as a prophylactic drug for nerve gas poisoning), organophosphates, insect repellants and other chemicals. However, expert committees concluded that there is inadequate or insufficient evidence to determine whether an association exists between exposures to drugs and chemicals and the observed effects.200

**Key points**

- A neurotoxic disorder should be considered if a temporal association exists between toxin exposure and any manifestations of neurological dysfunction.
- The progression of a neurotoxic disorder is arrested by discontinuation of toxin exposure, but ‘coasting’ sometimes occurs, with mild progression continuing for a short interval after exposure is stopped.
- Any presumed neurotoxic disorder must be biologically plausible, based on known toxicity or effects of the toxin on biological systems.
- When comparing exposed workers with control subjects using quantitative testing techniques, the selected control subjects must be appropriate.

**Note Added in Proof at Authors’ Request**

This chapter was delivered on time in December 2007. As publication has been delayed for reasons unconnected with the authors, more recent material is not included.
ACKNOWLEDGEMENT

Hepatotoxic effects of workplace exposure

THOMAS W WARNES AND ALEXANDER SMITH

INTRODUCTION

A variety of classifications of hepatotoxic agents exists in the medical and toxicological literature based variously on the source and chemical nature of the toxicant,1–3 the type of liver pathology produced4,5 or on the toxic mechanisms involved.6,7

The liver is the first organ after the gut exposed to ingested chemicals, toxins and drugs, and its rich blood supply ensures that agents absorbed through the lungs and skin also reach the liver quickly and at high concentrations. It is thus easily injured by direct exposure to these agents. In addition, many xenobiotic compounds are actively removed from the bloodstream by the liver and detoxified by hepatic metabolic processes. However, in the course of detoxification, some are metabolized into even more toxic substances,7 including free radicals.8

Due to increased awareness by workers, employers and physicians, traditionally recognized occupational hepatotoxins are now encountered much less frequently. However, a recent update to the Pocket guide to chemical hazards lists 228 industrial chemicals capable of causing liver injury.9,10 Exposure is usually by inhalation or skin absorption. Occupational liver disease may occasionally present after an acute incident at work, and in these circumstances, diagnosis and identification of the toxic agent is relatively straightforward. In general, however, the diagnosis of occupational liver disease is rare in clinical practice and likely to be difficult. The patient may present with general symptoms of liver dysfunction or alternatively, an individual health check or routine workplace screen may have provided the initial clue to liver disease. However, the large functional reserve of the liver allows most cases of occupational liver injury to go undetected during many years of chronic exposure or until long after exposure has ceased and thus advanced liver disease may already be present and the occupational aetiology may be missed. Even when an occupational cause is suspected, it is usually difficult to quantify the level of exposure to a specific toxin, particularly when, with routine safety measures in place, exposure may have occurred in unpredictable ways, such as in machinery breakdown, during cleaning and maintenance, or as a result of accidental leakage.

It should be appreciated, furthermore, that abnormal liver function tests are found quite commonly in the general population not exposed to industrial chemicals.11 The most common cause of abnormal liver function tests in the general population of Western countries is hepatic steatosis associated with obesity.12,13 Gilbert’s syndrome is present in 5 per cent of the population14 and is diagnosed by the finding of indirect hyperbilirubinaemia in the absence of haemolysis. Serum gamma glutamyl transpeptidase (GGTP) may be a sensitive indicator of hepatotoxicity since it is a marker, among other things, of liver microsomal enzyme induction, but it is essentially non-specific.11

Following the initial detection of an abnormality in liver function, a non-invasive screen should be carried out, including ultrasound scan of the liver, together with appropriate blood tests (Table 88.1 and Figure 88.1). These should permit diagnosis of metabolic, autoimmune and viral liver disorders, and if these have been excluded, then workplace exposure to chemicals needs to be carefully considered and liver biopsy may be required.

Chemicals and toxins can produce a wide spectrum of clinical presentations ranging from mildly abnormal liver function tests in asymptomatic patients, to fulminant liver...
failure. The liver has only a limited number of ways of responding to chemical insults: these include steatosis, acute or chronic hepatitis, hepatocellular necrosis, cirrhosis, veno-occlusive disease, non-cirrhotic portal hypertension and hepatic neoplasia. Chemical compounds may have both hepatotoxic and carcinogenic potential. No classification of chemically induced hepatotoxicity is entirely satisfactory, since the response of the liver depends upon the dose, duration and route of the exposure, as well as on differing sensitivities of individuals to the particular chemical. Alcohol and drugs, such as anti-epileptics, as well as other chemicals such as dichlorodiphenyltrichloroethane (DDT), all increase hepatic microsomal enzyme activity and are degraded by specific cytochrome P450 isoforms. These agents can therefore increase the damage produced by hepatotoxins, such as carbon tetrachloride, which are activated by the cytochrome P450 system, with secondary effects on the metabolism of chemical hepatotoxins. Phenothiazines (chlorpromazine, promazine and promethazine) have also been shown to inhibit the effect of CCl4, possibly by membrane stabilization.

The physician must therefore have a high index of suspicion regarding chemicals and toxins in the genesis of liver dysfunction and must be aware of the occupations which present a risk in this respect (Table 88.2), together with the wide range of industrial chemicals, elements and toxins which have been reported to produce hepatotoxicity (Table 88.3). This list is not exhaustive, but serves to indicate the wide range of substances which must be considered.

Patterns of toxic liver injury

Elevation of alkaline phosphatase (ALP), are consistent with cytotoxic injury. Hepatomegaly may be present, but clinical signs of acute liver injury may be marginal, or similar to those found in symptomatic viral hepatitis. Clinically, cholestasis presents with pruritus, jaundice and elevation of the serum ALP and GGTP, with a much less impressive elevation of serum transaminase levels. The morphological findings are those of intracellular accumulation of bile or of canalicular bile deposits. Mixed hepatocellular and cholestatic forms of liver injury may be found, for example, that produced by exposure to methylene dianiline (4,4′-diaminodiphenylmethane18) a compound used in industry as an epoxy resin hardener, in the preparation of isocyanates, in the production of polyurethane and as an antioxidant in latex rubber. It was first identified as a liver toxin during an epidemic outbreak of jaundice in 84 inhabitants of the English town of Epping, who had eaten bread which had been made with flour that was inadvertently contaminated with methylene diamine during its transport to the bakery.19 Jaundice was accompanied by elevation of serum ALP and transaminase levels. Needle biopsies showed cholestasis and hepatocellular damage. Recovery was rapid in most patients and none died. Re-exposure to methylene dianiline may cause recurrence of hepatitis, but the mechanism of action has not been extensively studied.20

Acute cytotoxic injury is indicated by steatosis and necrosis and these are often encountered together, for instance after intoxication with carbon tetrachloride (CCl4). Yellow phosphorus steatosis may be microvesicular, macrovesicular,21 or mixed; the type of steatosis is frequently characteristic for a number of chemicals. The chemical injury can also be classified according to its localization, since zonal damage often occurs in parallel with the activity of enzymes which mediate the metabolic activation of the chemical to the toxic metabolite. Thus, CCl4 and dimethylnitrosamine produce centrilobular necrosis because cytochrome P450 is more abundant in Rappaport zone 3 (the centrizonal area).22 It has been suggested that yellow phosphorus may produce periportal fibrosis,23 but this claim has not been substantiated.

Acute liver injury may result in hepatic failure and death. However, if the patient recovers from the acute attack, the prognosis is good since complete recovery usually occurs.

</table>
Chronic injury

Occasionally, long-term sequelae of acute intoxication eventually result in chronic liver disease, although this is much more commonly found after repeated or long-term exposure to chemicals. Chronicity is manifest by the presence of fibrosis in the liver. This is a consequence of the activation and transformation of hepatic stellate (Ito) cells into collagen-producing myofibroblasts. This activation can be induced by a number of factors, such as free radicals and cytokines. Cirrhosis is frequently the end result with fibrous tissue disrupting the functional anatomy of the organ. The cirrhotic patient may be asymptomatic, or may present with hepatic decompensation associated with bleeding varices, ascites or encephalopathy. Cirrhosis has been reported after chronic exposure to arsenical pesticides and to halogenated alkanes, such as carbon tetrachloride and chloroform.

Vascular lesions

Non-cirrhotic portal hypertension has been reported after exposure to vinyl chloride and inorganic arsenicals and usually presents with bleeding from gastric or oesophageal varices. Liver function tests may be normal or minimally disturbed. Splenomegaly, if present, is detected clinically and confirmed on ultrasound. The wedged hepatic vein pressure in such cases is either normal or only slightly raised, while the splenic pulp pressure is markedly elevated, indicating presinusoidal portal hypertension.

The histology shows enlargement and thickening of the portal vein branches with perisinusoidal fibrosis. In some cases, activation and proliferation of sinusoidal cells is seen. The liver histology closely resembles that found in idiopathic portal hypertension (Banti’s syndrome) suggesting that this syndrome may sometimes result from unrecognized toxic injury. Occasionally, peliosis hepatis is seen in chemical liver injury, particularly with vinyl chloride. Both peliosis hepatis and non-cirrhotic portal hypertension can progress to hepatic angiosarcoma and this progression is well documented in vinyl chloride workers.

Malignant change

A wide range of chemicals has been shown to induce primary liver tumours in animal studies, but in humans, a causal relationship between primary liver tumours and previous exposure to a specific chemical has been shown convincingly for only a few compounds. Primary liver cancer is seen in association with arsenic and vinyl chloride exposure, but less commonly than angiosarcoma. Such tumours may present with right upper quadrant pain and weight loss. The diagnosis is made on abdominal ultrasound scan and confirmed on computed tomography (CT) scan, hepatic angiography and ultrasound-guided liver biopsy. Serum alphafetoprotein levels may be normal or raised. Dioxin has been shown to be a potent hepatocarcinogen in animal studies and it has also been implicated in man, although firm evidence is difficult to obtain.

Disturbances in porphyrin metabolism

Porphyrias can be acquired or can result from inborn metabolic errors of haem synthesis and they are characterized by increased urinary excretion of porphyrins or their precursors. Porphyria cutanea tarda (PCT) usually presents with photosensitive skin lesions, including bullae, hypertrichosis and hyperpigmentation, together with increased uroporphyrin excretion in the urine. Constitutional PCT is inherited in an autosomal dominant fashion and is characterized by a deficiency of uroporphyrinogen decarboxylase (UROD) in the liver, erythrocytes and other tissues, with a secondary
elevation of aminolaevulinic acid synthetase (ALAS). Clinical presentation is precipitated by liver cell damage most often due to alcohol, oestrogens or hepatitis C; iron deposition in the liver is an important cofactor.

Acquired PCT occurs when UROD, particularly the liver enzyme, is inhibited by ingested agents. An outbreak of PCT in Turkey between 1956 and 1960 followed ingestion of bread contaminated with the fungicide hexachlorobenzene. Between 3000 and 4000 people from several distinct genetic populations were affected, suggesting that there was no inherent predisposition. The time interval from ingestion to initial symptoms was about six months; these included weakness, loss of appetite and sensitivity to sunlight. A small number of patients were treated with EDTA, a heavy metal chelator, with reversal of skin symptoms and signs. Exposure to vinyl chloride, methyl chloride, hexabromobenzene and polybrominated and polychlorinated biphenyls may also cause acquired PCT. In animal studies, tetrachlorodibenzo-pterodrin (TCDD), is the most porphyrinogenic substance known. Following an explosion at a chemical plant near Seveso in Italy in 1976, the nearby population were exposed to TCDD. A brother and sister who were exposed to low levels developed overt PCT. They were part of a large family of 66 members who were also exposed, but showed no evidence of PCT. PCT in these two siblings developed on the background of a predisposing genetic defect resulting in UROD deficiency in erythrocytes and thus increased susceptibility to porphyria. Thirteen of 60 other exposed individuals (22 per cent), not of the same family, developed coproporphyrinuria; UROD levels in other exposed individuals (22 per cent), not of the same family, developed coproporphyrinuria; UROD levels in erythrocytes were not decreased. In the two patients with PCT, treatment with chloroquine resulted in remission of symptoms.

Diagnosis of PCT depends on the finding of a characteristic isomeric distribution of porphyrins in the urine, stool and to a lesser extent plasma. Analyses are best performed in a specialized laboratory using the sensitive and specific technique of high pressure liquid chromatography (HPLC). Normal urine porphyrin content is 70 per cent coproporphyrin (70 per cent of which is isomer III), and 15 per cent uroporphyrin (90 per cent isomer I) with the remainder being 5-, 6- and 7-carboxylate porphyrins (all mostly isomer III). In PCT, urine contains mostly uroporphyrin (predominantly isomer I) and 7-carboxylate porphyrin (isomer III); 6-carboxylate porphyrin is mostly type III, while 5-carboxylate porphyrin and coproporphyrins are present as equal amounts of isomers I and III. These proportions hold for both familial and acquired PCT, although with hexachlorobenzene, more uroporphyrin III is present. Porphyrin excretion in faeces is increased, particularly isocoproporphyrin, and consists predominantly of type III isomers. The profile of porphyrins in plasma is similar to that in the urine. Total urinary porphyrins in patients exposed to chlorinated hydrocarbons without overt disease show no increase compared to controls, but the pattern of porphyrin distribution may be abnormal, indicating subclinical disease (PCT type A).

Conventional treatment for porphyria is venesection. UROD inhibition by TCDD is prevented by an iron deficiency state. Venesection should be continued until urinary porphyrin concentration falls below 0.5 mg/L.

### TREATMENT

Early identification of, and removal of the patient from, the offending chemical is the most important measure in treatment of acute hepatotoxicity since continued exposure to the toxic agent, especially if jaundice has appeared, may lead to acute liver failure. However, if the patient presents with symptoms of chronic liver injury, it is unlikely that exposure has been continuous and it may have been many years in the past.

Specific treatments or antidotes to hepatotoxins encountered in the workplace have been proposed, but they are largely experimental and none has been evaluated in controlled trials (Figure 88.2). Patients who develop acute liver failure, or complications of chronic liver disease, should be referred for specialized care on a Liver Unit. Management will generally be supportive and is aimed at detecting and addressing specific problems as they arise. Liver transplantation is an option for both acute or chronic liver disease, including malignancy, which is refractory to medical therapy.

### MECHANISMS OF LIVER TOXICITY IN MODEL HEPATOXINS

The different processes resulting in hepatotoxicity can be illustrated by considering hepatotoxic mechanisms for four agents which are relatively well understood: carbon tetrachloride, vinyl chloride, hexachlorobenzene and dioxin (TCDD). While the dangers of these particular agents are now well appreciated and their use has been restricted and stringent controls applied, patients exposed in the past may still present with chronic problems. An understanding of the mechanisms established for these agents may also help in understanding how other established and novel hepatotoxins produce their effects.

#### Carbon tetrachloride

The various mechanisms resulting in CCl₄ hepatotoxicity have been extensively studied in the experimental animal (Figure 88.3). Initially, direct lipid solvent injury to the hepatocyte and mitochondrial membranes produces altered cellular function. In adipose tissue, solvent effects lead to increased mobilization of triglyceride stores which then contributes to fat accumulation within the liver (steatosis).

Liver transplantation

Figure 88.2 Treatment of occupational liver diseases. TIPS, transjugular intrahepatic portal-systemic shunt.

Figure 88.3 Mechanisms of carbon tetrachloride hepatotoxicity. ER, endoplasmic reticulum; ROS, reactive oxygen species.
A secondary effect, occurring after three hours of exposure to \( \text{CCl}_4 \), involves metabolic activation of \( \text{CCl}_4 \) by the cytochrome \( \text{P}^{450} \) system to the trichlorethyl radical (•CCl\(_3\)) and then to the trichloromethylperoxy radical (•OOCCl\(_3\)) in the presence of molecular oxygen. The initial liver injury is centrilobular, due to the location of the cytochrome \( \text{P}^{450} \) enzyme. These free radicals derived from carbon tetrachloride initiate a chain reaction of lipid peroxidation within the endoplasmic reticulum by hydrogen abstraction from unsaturated fatty acids. Hepatic fibrogenesis leading to fibrosis and cirrhosis, may be triggered either directly by free radical-induced hepatocyte damage leading to Kupffer cell activation, and activation of stellate cells by cytokines or may be triggered by secondary activation of hepatic stellate cells by lipid peroxidation products, such as malondialdehyde or 4-hydroxy nonenal. Concomitant with and/or subsequent to lipid peroxidation, other destructive processes occur in the endoplasmic reticulum. Carbon tetrachloride acts as a suicide substrate for cytochrome \( \text{P}^{450} \) leading to loss of enzyme activity. Damage to the rough endoplasmic reticulum also leads to decreased protein synthetic activity. Fat accumulation leading to steatosis is partly due to this decrease in protein synthesis, especially reduced synthesis of very low density lipoproteins (VLDL), which leads to a failure of the lipid export mechanism.

Microsomal Ca\(^{2+}\)-ATPase, the pump responsible for sequestration of Ca\(^{2+}\) into the endoplasmic reticulum, is damaged by oxygen free radicals. Consequently, the intracellular free Ca\(^{2+}\) concentration is raised, thus activating a number of proteolytic enzymes, including phospholipases which are capable of propagating membrane disturbance at distant sites, and endonucleases which give rise to DNA strand breaks.

Experimental studies have shown that carbon tetrachloride produces upregulation of genes involved in extracellular transport and cell signalling, as well as changes in regulation of genes involved in regulation of stress response and cell cycle.

**Vinyl chloride**

Vinyl chloride metabolism occurs via different pathways depending on the level of exposure (Figure 88.4). At concentrations of less than 50 ppm, vinyl chloride monomer (VCM) is metabolized by alcohol dehydrogenase to produce chloroacetaldehyde and monochloroacetic acid, while at levels of more than 50 ppm, oxidation occurs by the peroxidase-catalase system to chloroacetaldehyde, and at concentrations of more than 250 ppm, it is metabolized by microsomal mixed function oxidase to chloroethylene oxide. Vinyl chloride and its reactive metabolites bind covalently to hepatic glutathione and are then hydrolysed and excreted in the urine as conjugates of cysteine. Both vinyl chloride and its metabolites produce hyperplasia of mesenchymal sinusoidal lining cells in the liver and spleen and also hyperplasia of hepatocytes. Hepatic stellate cell activation results in fibrosis and the end result is splenomegaly and portal hypertension; this fibrosis may be detectable by ultrasound scan. There is evidence that genetic polymorphism in the cytochrome \( \text{P}^{450,2E1} \) (CYP2E1) may be responsible for individual differences in

*Figure 88.4*  Mechanisms of vinyl chloride hepatotoxicity.
susceptibility to liver fibrosis associated with chronic VCM exposure and to variable susceptibility to the carcinogenic effects of VCM in exposed groups of workers. Liver ultrasonographic abnormalities increase as the cumulative exposure dose increases, although changes have been reported in VCM workers exposed within the current occupational health standards. Similarly, exposure to low or moderate levels of VCM and ethylene dichloride may be associated with raised serum AST and ALT, although others have found that only GGT is associated with current VCM exposure. In countries with a high incidence of viral hepatitis, there may be a synergistic effect of hepatitis B and C with occupational exposure to VCM and ethylene dichloride, in producing liver damage. The metabolite chloroethylene oxide damages DNA bases and is thought to play a key role in the development of angiosarcoma. Female Chinese workers are at increased risk of chromosomal damage induced by VCM compared to males.

Hexachlorobenzene

Hexachlorobenzene provides an excellent illustration of the mechanisms by which hepatic toxins may disturb haem synthesis and thereby produce acquired porphyria (Figure 88.5). This compound inhibits hepatic uroporphyrinogen decarboxylase and coproporphyrinogen oxidase and causes secondary coproporphyrinuria which may progress to uroporphyrinuria and to porphyria cutanea tarda. The •O₂ radical may be involved in inhibition of uroporphyrinogen decarboxylase.

Dioxin

2,3,7,8 Tetrachlorodibenzo-p-dioxin (TCDD) is the most fully investigated member of the very large polychlorinated dibenzo-p-dioxin family and is the most toxic synthetic compound known. These compounds do not occur naturally, but are now ubiquitous in the environment. They are produced as contaminants during a variety of industrial synthetic reactions, such as the production of chlorinated phenols, during incineration of municipal and hospital wastes, from petrol and other fossil fuel combustion and during a host of other industrial processes. Dioxins are lipophilic and therefore accumulate in adipose tissue, skin, liver and breast milk in mammals, and have an extremely long half-life of between five and eight years in man. TCDD is immunotoxic and teratogenic and affects the gut, liver, skin and kidneys. Acute toxicity produces chloracne and death following a period of wasting. In chronic low-dose studies (as low as 0.1 μg/kg per day) TCDD acts as a potent carcinogen in many organs, including the liver.

A great deal is known about the mechanisms of TCDD toxicity, but many aspects remain uncertain. TCDD, on entering the cell, binds to a specific aryl hydrocarbon (dioxin) receptor (AhR) (Figure 88.6). Binding of dioxin releases heat-shock protein 90 (HSP90) from the complex which can then bind an AhR nuclear translocator protein (Arnt). This allows the complex to enter the nucleus and interact with dioxin response elements (DREs), specific base sequences in the cell genome. Binding to these sequences triggers expression of a number of genes including several cytochrome P₄₅₀ genes and other enzymes.
The mechanisms by which activation of these gene products result in the clinical problems associated with dioxin toxicity is still poorly understood, although effects on intracellular calcium levels, cytokine expression, and effects on oestrogen expression have all been proposed. Differences in the affinity of the AhR for dioxin in different species probably account for the enormous range (3000-fold) of sensitivity to dioxin in different species.

In laboratory animals, it is well established that dioxin is a potent hepatocarcinogen, which can both initiate and promote carcinogenesis and produce cancers with exposures as low as 0.001 μg/kg per day. While TCDD does not itself modify DNA, it is a very effective tumour promoter, increasing cell turnover and fixing DNA defects which clonally expand to tumours. Initiation may arise following Ca^{2+}-triggered endonuclease DNA damage or alternatively, free radical-induced DNA damage.

World concern over dioxin contamination was triggered by the Seveso incident in July 1976 when an explosion in an Italian chemical factory heavily contaminated the surrounding countryside and population. Bird and animal life in the area died. Human problems initially appeared to be limited to chloracne, but long-term follow-up studies have suggested an increased incidence of a variety of cancers, including hepatocellular carcinoma and cholangiocarcinoma. However, no demonstrable hepatic injury or predisposition to liver cancer has been found in soldiers exposed to dioxin-contaminated herbicide (Agent Orange) used during the Vietnam war.

SPECIFIC OCCUPATIONAL HEPATOTOXINS

The solvent controversy

Most industrial plants and businesses use solvents in some form or another. Evidence regarding their hepatotoxicity is conflicting. Abnormalities in liver function tests and histology have been reported in chemical industry workers and painters exposed to solvents, but these studies lacked controls. The situation is further complicated by the fact that workers may be exposed to multiple agents. Laboratory testing that is commonly used by clinicians (routine liver function tests) to detect liver toxicity may not be sensitive enough to detect early liver damage from industrial solvents and new methodologies are being developed in the diagnosis of solvent hepatotoxicity. Furthermore, clinical assessment must take account of synergism between the solvent or mixture of solvents concerned with medications, drugs of use and abuse, alcohol, nutrition and age of the individual concerned.

Haloalkanes

CARBON TETRACHLORIDE (CCl₄, TETRACHLOROMETHANE)

Industrial accidents account for most cases of CCl₄ poisoning, the usual mechanism being the inhalation of fumes in a poorly ventilated environment. As little as 5 mL can produce the typical histological changes of hepatic necrosis and steatosis in zone 3. Within hours of an acute exposure, initial symptoms of headache, dizziness, confusion and blurred vision are found and these are followed by nausea, vomiting and diarrhoea. Evidence of liver damage occurs 24–48 hours after exposure with tender hepatomegaly, increasing jaundice and a bleeding diathesis. In severe cases, ascites and coma can result. Death due to liver disease usually occurs within ten days of the onset of symptoms. The liver disease can last for three weeks, before recovery occurs, which in survivors, is rapid. The laboratory findings include marked elevation of the serum transaminase levels. Serum bilirubin rapidly rises, due to hepatocyte necrosis, haemolysis, destruction of the cytochrome P₄₅₀ enzymes and decreased renal excretion of bilirubin. Liver histology shows centrilobular necrosis and steatosis. CCl₄ is no longer produced on a large scale in Western Europe or the United States and occupational
exposure typically only occurs in countries that still allow its use.\textsuperscript{44,64,66} Treatment is supportive. In the experimental animal, carbon dioxide-induced hyperventilation has been shown to increase the pulmonary elimination of volatile hydrocarbons and to prevent CC\textsubscript{4} toxicity. Prostacycline (prostaglandin I\textsubscript{2}) is hepato-protective, even when given 24 hours after intoxication.\textsuperscript{67} The mortality rate from CC\textsubscript{4} poisoning is 10–25 per cent, most deaths occurring from renal failure. Hepatic causes of death account for one-quarter of the total, and occur in the first week after intoxication. If the patient survives, recovery is usually complete, but hepatic fibrosis and cirrhosis can ensue.

**TRICHLOROMETHANE (CHLOROFORM)**

This chemical was used in the community as a spot cleaning agent and formerly as an anaesthetic when death due to hepatic necrosis was occasionally reported.\textsuperscript{68} Exposure is by inhalation. In acute chloroform poisoning, hepatotoxicity is associated with elevation of enzymes and in severe cases with coma. Empirical treatment with haemoperfusion, activated charcoal and N-acetylcysteine has been employed.\textsuperscript{69} Some workers exposed daily for 12–48 months to moderately high levels of trichloromethane developed liver disorders. Subjects with pre-existing liver disease may be more sensitive to the effect of trichloromethane. Possible clinical presentations include jaundice, hepatomegaly and ‘transaminitis’ and cirrhosis is a possible sequela.

**TRICHLOROETHANE**

The most important isomer is 1,1,1-trichloroethane (methylchloroform) which is used extensively as an industrial degreasing agent. Experimental hepatotoxicity has been demonstrated in mice.\textsuperscript{70} There are a number of isolated case reports of acute and chronic liver disease probably associated with exposure to this industrial solvent.\textsuperscript{71–73} In man, presentation may be with ascites and N-acetyltransferase. While the liver biopsy may show fibrosis, perivenular sclerosis of the central veins and subacute hepatic necrosis,\textsuperscript{74} occupational exposure has been associated with fatty liver and cirrhosis.\textsuperscript{75} Patients with pre-existing chronic liver disease may be more sensitive to liver injury following exposure to very high levels of trichloroethane.

**TETRACHLOROETHANE**

This chlorinated hydrocarbon solvent is no longer used because of its hepatotoxicity, which was identified as a result of heavy exposures to workers in the First World War when it was used as ‘dope’ in aeroplane manufacture.\textsuperscript{5} Absorption was mostly by inhalation, although occasionally ingestion and skin absorption occurred. Low-grade exposure produced hepatomegaly and a few patients became jaundiced. If the patient is removed from the contaminated environment, the liver recovers rapidly, but continued exposure can produce jaundice, hepatomegaly and ascites together with fulminant hepatic failure and subacute hepatic necrosis, both of which may be fatal.\textsuperscript{76} The overall mortality rate was approximately 17 per cent. The histology is similar to that found with carbon tetrachloride and includes centrilobular necrosis, steatosis and bile duct proliferation. If exposure is prolonged, the patient may die of subacute hepatic necrosis often followed by post-necrotic fibrosis.\textsuperscript{78}

**TRICHLOROETHYLENE**

Trichloroethylene was used in dry cleaning and as a degreasing agent in industry, but it has been replaced by less toxic chemicals. It is structurally similar to vinyl chloride. Severe liver injury can be seen in individuals who have sniffed solvents; they may develop raised serum transaminase levels associated with acute hepatic and renal failure.\textsuperscript{77} Liver disease is rarely caused by occupational exposure, although fatal addiction at work may occur, and acute hepatic failure has been described with degreasing. The liver histological changes include fatty liver, fibrosis and centrilobular necrosis, many of which have the potential for recovery after withdrawal from exposure. Trichloroethylene has been implicated as a probable cause of non-alcoholic steatohepatitis (NASH) in a patient suffering from chronic hepatitis C.\textsuperscript{79}

**TETRACHLOROETHYLENE (PERCHLOROETHYLENE)**

This is probably the least hepatotoxic of the chlorinated hydrocarbons used as dry cleaning agents. Accidental exposure can produce central nervous system (CNS) depression, followed by hepatic and renal damage. Serum bilirubin, transaminases and ALP may be elevated; a variety of liver lesions has been described, including acute hepatitis and centrilobular necrosis.\textsuperscript{80–82} Diagnosis is dependent on the history, supported by a chloroform-like odour of the solvent, which may be detected on the patient’s breath for several hours after exposure. Repeated vapour exposures to high concentrations of tetrachloroethylene have produced hepatitis in experimental animals. Mild to moderate hepatic parenchymal changes were found on ultrasound scan in two-thirds of dry cleaners exposed to tetrachloroethylene, but only 19 per cent had a raised serum transaminase (ALT) level.\textsuperscript{83}

**N-Substituted amides**

**DIMETHYL ACETAMIDE**

Acute toxicity of this solvent leads to raised serum transaminases and hepatomegaly, with focal necrosis on liver biopsy. More prolonged exposures are associated with
microvesicular steatosis. Recovery after removal from the
toxin may be incomplete.84,85

DIMETHYL FORMAMIDE

Acute exposure to dimethyl formamide (DMF) may be
associated with raised AST and ALT levels and chronic
exposure with microvesicular steatosis, while in severe
cases hepatic necrosis can occur.86,87 This widely used
industrial solvent was incriminated in an outbreak of liver
disease in workers coating fabric in poorly ventilated areas
without appropriate skin protection: 62 per cent of work-
ers tested had a raised serum AST or ALT and histology
compatible with toxic hepatitis was found in the small
number of patients biopsied.88

Nitro-paraffins

Nitromethane, nitroethane, 1-nitropropane and 2-nitro-
propane are used extensively in industry as solvents.
Hepatotoxic effects may be underdiagnosed because
2-nitropropane (2-NP) is rarely used alone as a solvent and
any toxicity is usually blamed on other chemicals. This
chemical can produce acute liver failure.89 Histology shows
centrilobular necrosis, bile duct proliferation, cholestasis,
steatosis and a mild inflammatory infiltrate in the peri-
portal areas.90 In one report,91 two construction workers
applied epoxy-resin coating to a water main in an under-
ventilated underground vault; no protection was provided
for their respiratory tracts or skin. One patient died of
fulminant hepatic failure, while the other survived. 2-NP
is also a hepatocarcinogen.

Acute liver damage produced by 2-NP in the experi-
mental animal can be reduced by treatment with the anti-
oxidant diphenyl diselenide.92 The hepatotoxicity of this
chemical is associated with lipid peroxidation and in the
experimental animal at least, it can be reduced by pre-
treatment with either melatonin93 or green tea infusion in
drinking water.94

Toluene

Acute hepatocellular injury, with reversible renal failure, has
been reported in a glue sniffer.95 However, in a controlled
study of car painters exposed to toluene, no increased
hepatotoxicity was seen compared to controls.96 2,4,6-
Trinitrotoluene (TNT) (see under Trinitrotoluene) is an
important occupational and environmental pollutant which
may be associated with toxic hepatitis, hepatomegaly and
hepatocellular carcinoma. A recent study of TNT workers
in an ammunition factory in China showed evidence of uri-
nary mutagenicity and chromosomal abnormalities and
monitoring of certain biomarkers may be of more value in
assessing toxicity than chemical measurements of TNT
metabolites in the air or on the skin.97 The enormous pro-
duction of munitions over the past century has led to large-
scale discharge into the environment of water containing
explosives and nitrated organic byproducts.98

Chlorinated napthalenes

A number of cases of acute yellow atrophy of the liver have
occurred in workshops in which chlorinated napthalenes
were used to impregnate electrical equipment. The average
time of exposure varied from four to six months. The presen-
tation is with general malaise followed by jaundice, asso-
ciated with anorexia, dizziness, weight loss, vomiting and
upper abdominal pain. Liver changes include necrosis,
fibrosis and regeneration, which may be associated with
acute enterocolitis together with pancreatitis. Hepatic
decompensation was revealed by the presence of jaundice,
ascites and oedema. Many patients who survived the acute
insult developed subacute hepatic necrosis or macronodu-
lar cirrhosis.99,100 Polychlorinated napthalenes induce the
cytochrome P450 system and produce lipid peroxidation in
the liver.101 A study of workers in an electrical capacitor
manufacturing plant, where chlorinated napthalenes were
used with polychlorinated biphenyls (PCBs) and other
chemicals, has shown a significantly increased mortality
for liver and biliary tract cancer.102

Nitroaromatics

TRINITROTOLUENE

Trinitrotoluene (TNT) produced a considerable amount
of hepatotoxicity in munitions workers in the First and
Second World Wars, with an incidence of hepatotoxicity
ranging from <0.01 to 5 per cent.103 Since this time, the
incidence of liver damage has been markedly decreased
by improvement in industrial techniques. Absorption is
largely through the skin, but inhalation, ingestion or
mucus membrane exposure, may also result in significant
absorption. The mechanism is unclear, but may be
related to the production of a toxic intermediate. There
appears to be a marked individual difference in suscepti-
bility to the hepatotoxic effects of TNT. After a latent
period of two to four months during the exposure period,
the patient develops anorexia, weakness, nausea, vomit-
ing and abdominal pain with hepatomegaly and jaundice.
Some patients go on to develop fulminant hepatic failure,
which may be fatal in up to 25 per cent. Others develop
subacute hepatic failure with ascites and portal hyperten-
sion. These symptoms may be accompanied by extra-
hepatic manifestations, including rash, aplastic anaemia
and methaemoglobinaemia. Some patients who survive
chronic exposure may go on to develop macronodular
cirrhosis.104,105
NITROBENZOATE

Nitrobenzoate has been used as a hepatotoxin in the experimental animal. Rare cases of liver damage have occurred in humans exposed to inhalation of toxic fumes during the production of aniline. It is also a potential human carcinogen.10

DINITROPHENOL

Dinitrophenol is used in the dye industry and in the manufacture of photographic developers, and workers may be exposed by inhalation or dermal contact. Rarely, it may cause cholestatic or necrotic liver injury.106

Aromatic hydrocarbon mixtures

Coke oven and byproduct workers may be exposed to emissions composed of polycyclic aromatic hydrocarbons and volatile organic compounds. Some of these are hepatotoxins. Workers most heavily exposed to coke oven emissions exhibit altered aminotransferase levels.107

Solvents and non-alcoholic steatohepatitis

In 1980, Ludwig et al.108 described a series of patients who lacked a history of significant alcohol intake but in whom the liver histology resembled that of alcoholic liver disease. They termed this condition ‘non-alcoholic steatohepatitis’. The main features on liver biopsy are steatosis (fatty liver), lobular inflammation, balloon degeneration of hepatocytes and Mallory bodies, with or without fibrosis.

It is recognized that NASH is the most common type of liver disease in affluent societies, affecting between 1 and 8 per cent of the population. Typically, it is asymptomatic, but in up to 16 per cent of cases, NASH may progress to advanced hepatic fibrosis and cirrhosis, sometimes associated with hepatic decompensation, and hepatocellular carcinoma may occasionally occur.109

Typically, NASH is associated with obesity, diabetes mellitus and hypertriglyceridaemia and recent studies from Brazil have clearly implicated solvents as a cause of NASH in petrochemical workers who lacked any alternative risk factors.110 These Brazilian petrochemical workers were selected for study on the basis of having serum transaminase and/or GGTP levels at least 1.5 times the upper limit of normal in three or more determinations. They had been potentially exposed to a wide range of petrochemical products including acrylonitrile, acetylene, benzene, carbon tetrachloride, chloroform, chloroethyl vinyl ether, dimethyl formamide, ethane, ethylene, hexane, methanol, toluene, trinitrotoluene, tetrachloroethane, vinyl chloride, styrene, xylene and hydrocarbon mists. The period of exposure was for at least five years. Improvement in liver enzyme tests occurred in workers removed from the industrial area. Further studies comparing such workers lacking alternative risk factors for NASH, with first, other workers exposed to petrochemicals who also presented with obesity, hyperlipidaemia or diabetes, and second, with NASH occurring in patients with risk factors other than petrochemicals, have characterized ‘petrochemical NASH’ as typically occurring in men younger than non-exposed individuals and histological evidence of cholestasis was more frequent. All exposed workers with NASH were asymptomatic. All subjects had elevated ALT, AST and GGTP levels and ultrasound scan showed steatosis. The mean time of work in the petrochemical industry was 15 ± 5.4 years. The liver histology characteristically showed relatively mild changes of steatohepatitis and fibrosis, but the long-term evolution of these changes has yet to be reported.110–112 A lesion similar to NASH was reported from Spain in victims who had inadvertently consumed adulterated cooking oil113 in the toxic oil syndrome epidemic in 1981.

STYRENE

Workers exposed to styrene when working with fibreglass-reinforced plastics, or boat and tank fabricators, may exhibit raised levels of direct-reacting bilirubin, alkaline phosphatase, ALT and AST, suggesting mild hepatic injury.114

SOLVENT MIXTURES

Workers are typically exposed to a single solvent, but mixtures of solvents are occasionally encountered, and sometimes in unusual environments. Thus, a study of asymptomatic craftsmen repairing shoes demonstrated abnormal liver function tests and it was suggested that periodic liver screening may be appropriate.115 In car painters exposed to solvent mixtures in Brazil, measurement of serum bile acids appeared to be the most reliable measure of subclinical hepatotoxicity,116 since elevated serum GGTP levels are often associated with obesity and alcohol consumption rather than occupational solvent exposure.117,118

MEDIQUELAL ASPECTS OF SOLVENT HEPATOTOXICITY

While the liver biopsy appearances in individuals acutely exposed to high concentrations of solvents may be highly suggestive of toxic exposure, the more normal context is of chronic low-grade exposure and here the situation, from a medicolegal viewpoint, is much more complex. The liver has only a limited number of ways of responding to injurious agents, whether chemical, drug, viral, metabolic or autoimmune and the patterns of liver injury observed with these differing insults may overlap. The most common histological pattern with chronic, low-grade exposure to
solvents appears to be NASH, which is undistinguishable from NASH due to other causes. Since the risk factors associated with NASH, such as overweight and obesity, hypertension, hyperlipidaemia and diabetes are so common and since the biopsy appearances in NASH may be similar to those seen in alcoholic liver disease, attribution of NASH to solvent exposure in a court of law is difficult. A successful outcome for the plaintiff is more likely if other causes of chronic liver disease can be excluded by the non-invasive liver screen (Table 88.1) and if the histology is compatible with NASH, especially if no other risk factors for NASH are present. The case is strengthened if it can be shown that suitable precautions and appropriate workplace environmental recommendations have not been followed. It is also likely that low level solvent exposure below recommended limits may act synergistically with other risk factors, such as alcohol consumption, overweight, hypertension and raised serum lipids or blood sugar, to cause NASH. However, while the synergism (the ‘two-hit hypothesis’\textsuperscript{119}) is very likely from a medical point of view, it may be difficult to establish a causal link to liver damage in a court of law, due to the lack of a clear association between symptoms and liver damage (established by raised liver enzymes and liver biopsy) and also due to the lack of published information concerning the duration and levels of exposure to solvents required to produce NASH. However, this difficulty may be addressed by the new DNA microarray technology, in which samples of DNA from healthy persons are exposed to the chemical in question to determine which genes are affected (i.e. upregulated or downregulated). This is then used as a blueprint against which a claimant’s DNA can be compared. This technique has already been used in courts in the United States in more than 20 cases involving chemicals as diverse as benzene and hexavalent chromium.\textsuperscript{120,121}

### Metals and metalloids

#### COPPER

With acute poisoning, jaundice as a result of liver injury and haemolysis occurs on the second or third day in about a quarter of patients. Elevated transaminases and hepatomegaly are also features.

Liver granulomas containing copper have been found in vineyard workers exposed to an antifungal spray called Bordeaux mixture which contained a 1–2 per cent aqueous copper sulphate solution.\textsuperscript{122} The most common hepatic abnormality was a raised serum ALP; hepatomegaly was present in 40 per cent and one of seven patients biopsied had hepatic granuloma. Other features described in chronic occupational copper toxicity in vineyard sprayers include Kupffer cell proliferation, fibrosis, cirrhosis, portal hypertension and one case of angiosarcoma. While copper can be demonstrated in the liver histochemically, the gold standard for the diagnosis of liver disorders associated with increased hepatic copper is direct biochemical estimation by neutron activation analysis. Copper-induced hepatotoxicity is a multifactorial process involving the generation of reactive oxygen species that can affect biomolecules directly, with a consequent enhancement in membrane lipid peroxidation, DNA damage and protein oxidation.\textsuperscript{123}

Acute copper toxicity is managed by gastric lavage to remove copper. Although penicillamine, a heavy metal chelator, is extremely effective in Wilson’s disease,\textsuperscript{124} there is no evidence that it is of benefit in acute copper poisoning.

#### ARSENIC

An outbreak of arsenic-induced liver disease in beer drinkers was reported from Manchester, England in 1900,\textsuperscript{125} where the severity of the liver disease was proportional to the amount of arsenic in the beer. However, occupational exposure to arsenic has been most common in the production and use of pesticides. Up to 1942, when the use of these insecticides was banned, there was a significant incidence of cirrhosis in grape workers and vintners.\textsuperscript{23} Exposure was in the form of oral ingestion via insecticide sprays and dust, which also led to high levels of residual arsenic in the wine. Occupational and environmentally induced liver disease secondary to arsenic exposure is exclusively chronic. Associated clinical features include pigmentmentation with spotty melanosis of the skin and hyperkeratoses of the palms of the hands and soles of the feet with tumours of the skin and other sites.\textsuperscript{126}

Both organic and inorganic arsenicals cause necrosis of hepatocytes, injure sinusoidal and endothelial cells, and may cause obliteration and thrombosis of intrahepatic portal vein radicals. Although the number of cases of chronic liver disease in German vintners declined after 1942, the incidence of arsenical cirrhosis at autopsy continued to rise until the early 1950s due to the persistent effect of arsenic in the tissues, though alcoholism was likely to be a compounding factor in many cases.\textsuperscript{23} Four patients with severe liver damage due to arsenic poisoning in the Mosel vintners died of cirrhosis, but milder forms of arsenic liver damage underwent healing with some degree of periportal scarring.\textsuperscript{23} Chronic arsenic exposure can produce a variety of different patterns of liver injury, including steatosis, cirrhosis, non-cirrhotic portal hypertension, angiosarcoma and primary liver cancer.\textsuperscript{127} A recent study of patients exposed to environmental arsenic for up to ten years, and noted to have hepatomegaly showed chronic inflammation, vacuolation and focal necrosis on liver biopsy, while cDNA microarray studies showed changed expression of genes involved in cell-cycle regulation, apoptosis and DNA damage response.\textsuperscript{125} Similar studies have clarified the mechanism of arsenic-induced carcinogenicity.\textsuperscript{129} The liver function tests in liver damage due to chronic arsenic poisoning are frequently normal, although bromosulphophthalein (BSP) retention may be present. Scalp hair arsenic levels may be raised and skin biopsy sometimes shows marked hyperkeratoses typical of chronic
arsenic poisoning. On the other hand, analysis of tumour, liver, hair and other organs and tissues in a patient dying of haemangio-endothelial sarcoma due to arsenic poisoning showed no significant traces of arsenic. In one case of non-cirrhotic portal hypertension, arsenic content on percutaneous liver biopsy, measured by neutron activation analysis, was markedly increased at 28 μg/g (normal being <0.25 μg/g dry liver). The value of treatment with dimercaprol, a heavy metal chelator, is uncertain.

Environmental arsenic poisoning has reached massive proportions in recent years in West Bengal and Bangladesh. In an effort to supply clean drinking water to rural villages, thousands of tube wells have been sunk to allow use of subsurface water. Unfortunately, natural arsenic concentrations in this groundwater can reach very high levels and it is reported that over 220,000 people are now suffering from arsenic-related diseases. It is estimated that up to 90 million people in these areas are at risk. However, susceptibility to arsenic-induced liver diseases differs greatly between individuals, probably due to interindividual variations in arsenic metabolism. Arsenite is an important cancer chemotherapeutic, but hepatotoxicity may limit its therapeutic value. Recent studies suggest that nitric oxide releasing prodrugs may reduce this hepatotoxicity.

BERYLLIUM

Beryllium poisoning can produce a spectrum of hepatic abnormalities, including hepatomegaly, focal or centrilobular necrosis, and granulomata which mimic those found in sarcoidosis, and contain beryllium. In the past, exposures were primarily by inhalation; only rare case reports now occur due to significant improvements in industrial hygiene.

PHOSPHORUS

Acute poisoning is usually from suicidal intent, but hepatotoxicity from the manufacture of firecrackers has been reported. Histological changes include microvesicular steatosis and necrosis, while in the long term fibrosis may develop. Diagnosis depends on the detection of characteristic garlic odour on the breath, with phosphorescence of the stool.

CADMIUM

A wide spectrum of hepatotoxic effects, ranging from minor abnormality in liver function tests to necrosis or cirrhosis are found. Increased hepatic cadmium concentrations have been implicated in the pathogenesis of cryptogenic liver disease in Japan. Occupational hepatotoxicity has been reported in gold smelting. In the experimental animal, cadmium damages hepatic mitochondria, increases lipid peroxidation, induces apoptosis, damages endothelial cells, activates Kupffer cells and induces collagen gene expression. Some of these pathological processes are prevented or modified by treatment with putrescine or antioxidants, such as vitamin E or N-acetylcycteine.

SELENIUM

At low concentrations, selenium is an essential trace element. At higher concentrations, acute hepatotoxicity can occur from accidental ingestion or inhalation of selenium dioxide or hydrogen selenide, resulting in steatosis. In large quantities, and with chronic exposure, selenium can produce cirrhosis and, possibly, hepatic neoplasia. In contrast, low plasma selenium levels are found in alcoholic liver disease possibly resulting in oxidant stress, since glutathione peroxidase, an important factor in antioxidant defence, requires selenium as a cofactor.

CHROMIUM

The cytotoxic and genotoxic effects of chromium compounds depend on their valency and solubility. In vitro, kidney epithelial cells are ten times more sensitive towards Cr(VI) treatment than liver (Hep G2) epithelial cells, which explains the nephrotoxicity of this compound in vivo. However, chronic occupational exposure has been reported to produce hepatotoxicity in a chromium plating factory. Toxic hepatitis was accompanied by mild to moderate abnormalities in liver function tests.

LEAD

Lead exposure occurs in workers involved in lead smelting and the manufacture of batteries, car radiators and pigments. Before 1977, when the lead content of paint was regulated, some construction workers had significant exposures. Lead inhibit enzymes involved in haem synthesis, interferes with certain energy and transport systems and may affect nucleic acid metabolism. While acute lead hepatotoxicity has not been reported, high blood levels (>75 mg/dL) were associated with liver injury in a series from Spain. Liver biopsies showed centrilobular hepatitis with steatosis. Withdrawal from lead exposure led to rapid resolution of the liver dysfunction. In addition, chelation therapy appears to be of value.

Pesticides and herbicides

This section includes herbicides, insecticides and fungicides which have different chemical structures and toxicities. Although the effects of acute pesticide poisoning are well known for the pesticides most commonly used, few data exist on the hepatic effects after long-term, low-dose exposure. Agricultural workers studied during the course of a spraying season in Spain showed mild elevations of serum AST levels, but no clinically significant hepatotoxicity. The common pesticides associated with experimental
hepatotoxicity are DDT, methoxychlor, chlordane, heptachlor, aldrin, dieldrin, lindane and chlordcone, but the evidence that they are hepatotoxic or hepatocarcinogenic in humans is conflicting. Acute hepatotoxicity has been reported after rare accidental ingestion of large amounts of DDT, while centrilobular necrosis and hepatic failure after a single dose of 6g of DDT has occurred. However, despite massive production, there is little evidence from the literature of poisoning in workers. Only minor elevations of AST and reductions in BSP excretion have been recorded. There has been no report of liver injury in the United States, despite exposure for 20 years with absorption of 500 times the daily ingestion of the average adult. DDT induces hepatic mixed function oxidase which may result in production of hepatotoxic and hepatocarcinogenic metabolites from parent chemicals or drugs already in the environment or body. Carcinogenicity in humans has been debated for years. However, no study has shown a definite risk of cancer in humans and the carcinogenic role of pesticides in the experimental animal is also disputed.

CHLORDECONE (KEPONE)

In the 1970s, chlordcone was detected in high concentrations in samples of blood, adipose tissue and liver from highly exposed factory workers at a kepone manufacturing plant in Virginia. Many of the exposed factory workers had hepatomegaly and some had splenomegaly. Liver function tests were mostly normal and liver biopsy showed only non-specific changes. Two or three years after exposure ceased, there was no pesticide in the tissues, the liver and spleen were of normal size and the liver histology was normal. There is evidence of potentiation of carbon tetrachloride hepatotoxicity by chlordcone in rats, which is both age and sex dependent. Animals exposed to chlordcone develop liver cell injury and neoplastic changes, but the ultimate effects of exposure in humans are unknown. Cohn et al. reported on the use of cholestyramine to accelerate elimination of chlordcone following industrial exposure and toxicity. Chlordcone is no longer manufactured.

CHLOROPHENOXY HERBICIDES

In experimental animals, there is only minor evidence of hepatotoxicity and the major effect on the liver appears to be induction of mixed function oxidases of the hepatic microsomes. Hepatotoxic effects have been attributed to 2,4,5-trichlorophenoxy acetic acid, but this toxicity is probably due to contamination with 2,3,7,8-tetrachlorodibenzo-p-dioxin. A major concern is a possible synergistic hepatotoxicity from two or more synthetic chemicals. Despite concurrent exposure to multiple organochlorine compounds, workers engaged in the manufacture or handling of mixtures of pesticides seldom manifest hepatotoxic effects.

paraquat

Paraquat (1,1’-dimethyl 4,4’-dipyridylidium dichloride) is a powerful herbicide and toxicity is occasionally seen in manufacturers and gardeners. Accidental ingestion of as little as 2g can produce shock, renal failure, pulmonary oedema and jaundice. Toxicity may occur as a result of skin exposure or ingestion. Liver histology shows congestion with centrilobular necrosis, acidophilic bodies, steatosis, injury to the interlobular bile ducts and cholestasis. There may be two phases of hepatotoxicity; first, hepatocellular injury and then after two days, cholangiocellular damage. Biochemical findings include raised serum bilirubin, transaminases and ALP. Paraquat induces hepatic lipid peroxidation and atypical necrosis (aponecrosis) and these processes, together with their high associated mortality rates, can be reduced in the experimental animal by pretreatment with vitamin E and selenium.

Polychlorinated biphenyls

The manufacture of PCBs was banned in the 1970s due to their persistence in animal and human tissues and in the environment, but the liquids had become widely used as coolants and insulators in electrical systems. Skin absorption of PCBs in workers in the electrical manufacturing industry is followed by hepatic metabolism resulting in induction of the cytochrome P450 system and amino laevulinic acid (ALA) synthetase, which may lead to porphyria (Figure 88.3). Abnormal liver function tests have been reported in workers exposed to PCBs, but these reports have been poorly controlled and lack histology. Raised GGTP levels in serum may persist for up to two years after handling PCBs. In general, raised enzyme levels correlate with serum PCB concentrations. PCBs can produce hepatocellular carcinoma in animals. It is not clear whether they are direct carcinogens or whether carcinogenicity is associated with the metabolites, produced by cytochrome P450. Two cases of hepatoma have been reported in autopsy examinations of patients from the Yusho epidemic in Japan in 1968, in which about 10000 people were affected by consuming rice oil accidentally contaminated in the factory. The Taiwan epidemic of acute PCB toxicity known as Yucheng in 1979 also occurred after ingestion of contaminated rice oil. In both cases, the major features were chloracne, conjunctivitis, neuropathy and oedema of the eyelids, while jaundice developed in 11 per cent. Porphyria has also been reported. Although elevated mortality from liver disease may occur in the short term, more recent studies have attributed the hepatotoxicity to contaminating dibenzofurans. Epidemiological studies of the long-term effects of PCBs in humans have failed to show a significant increase in deaths from cirrhosis or hepatoma, but the long-term consequences of exposure are not known.
Vinyl chloride

This halogenated aliphatic hydrocarbon is structurally similar to trichloroethylene. Despite its known toxicity, it is still a vital component of the plastics industry in the manufacture of the widely used plastic polyvinyl chloride (PVC). Hepatotoxicity used to occur primarily by inhalation of vinyl chloride monomer (VCM) gas in workers manufacturing this chemical. Hepatic fibrosis, hepatosplenomegaly, non-cirrhotic portal hypertension, angiosarcoma and hepatocellular carcinoma have all been reported. Severe acute exposure in laboratory animals (more than 8000 ppm) produces hepatic necrosis 24–48 hours after exposure, associated with raised serum transaminases and GGTP levels. Recovery is usually rapid and fulminant hepatic necrosis is rare. Histology shows isolated necrosis of hepatocytes with occasional polymorph infiltrate. In chronic exposure in workers, liver biopsy findings may be unremarkable, but in other patients, hepatic fibrosis is more marked, with extensive capsular and subcapsular fibrosis and portal fibrosis extending into the parenchyma and into the wall of portal vein branches. Peliosis hepatis is occasionally seen. Non-cirrhotic portal hypertension, including nodular regenerative hyperplasia, has been reported and may be a precursor to angiosarcoma (ASL), a rare liver tumour in the general population. With the introduction of industrial measures designed to drastically reduce exposure in the United States, the United Kingdom and other European countries in 1974–75, when the toxicity of VCM became apparent, no cases of workers developing this tumour employed after that date are expected. By 1993, 173 cases had been documented in 14 countries and the trend in UK experience was found to be less reliable in detecting the presence and extent of these infections as judged by raised serum aminotransferase activity. However, others reported that while relatively low levels of ethylene dichloride and VCM increase the risk of liver damage as demonstrated by raised serum ALT levels, GGTP was not associated with exposure to these chemicals. Exposure to PVC or VCM may have a synergistic effect with chronic viral hepatitis B and C on liver damage produced by these viruses in high incidence countries for these infections as judged by raised serum aminotransferase activity. However, liver function tests may fail to detect VCM-induced liver damage, while being of more value in suggesting steatosis or fibrosis due to non-occupational factors, such as alcohol intake, obesity and hyperlipidaemia. Ultrasound examination of the liver is of value in detecting steatosis, but is generally considered to be less reliable in detecting the presence and extent of hepatic fibrosis. It has been employed, in conjunction with liver function tests, to screen VCM workers for liver damage and in a large recent study was found to be of value in screening VCM workers; those exposed to 200 ppm for at least one year had a four-fold increased risk of periportal fibrosis. Other screening tests advocated have included determination of fasting serum bile acids or low-dose indocyanine green clearance and measurement of urinary coproporphyrin excretion; however, none of these is widely used.
Methyl bromide

This is known to be hepatotoxic in both humans and animals. In one report, intoxication simulated Reye’s syndrome, but the liver histology merely showed hepatocyte swelling and sinusoidal congestion.

Cytotoxic drugs

Over 20 years ago, before the hazard became fully recognized, when tight exposure controls became instituted in hospitals, personnel working in oncology units or hospital pharmacies were at risk of developing insidious liver disease after chronic handling of cytotoxic drugs, including neomycin, vincristine, cyclophosphamide, doxorubicin, 5-fluorouracil and methotrexate. Absorption is percutaneous or by inhalation. A free-radical based mechanism for the formation of active metabolites may explain the hepatotoxicity of some of these agents. Nurses handling these drugs can develop raised levels of gamma GT and ALP, while liver histology may show portal hepatitis, fibrosis and steatosis. Increased mutagenicity in the urine of nurses handling these drugs has also been demonstrated.

Phthalate esters

Both dioctyl phthalate and its isomer di-(2-ethyl hexyl) phthalate (DEHP) are plasticizers, which may be hepatotoxic and hepatocarcinogenic in the animal model. Dibutyl-phthalate is extensively used in industry and there is a high potential for human exposure in the workplace. In rats, it may cause hepatomegaly and cholestasis with elevated serum alkaline phosphatase levels. However, there is no conclusive evidence for hepatotoxicity in humans.

CONCLUSIONS

It is now well established that oxidant stress plays an important pathogenic role in chronic liver disease in general and in chemically induced liver disease in particular. In clinical practice, overt liver disease due to workplace exposure to hepatotoxins is nowadays rare, but is probably underdiagnosed and may be significantly more common than generally reported. The most important development in this area over the past few years has been the recognition that in patients with the histological appearance of NASH, but no evidence for the normally associated risk factors, certain solvent exposures can produce potentially serious chronic liver disease; in addition, synergistic interactions between solvent exposure and recognized risk factors for NASH such as obesity, hypertension, hyperlipidaemia and diabetes may increase the risk of liver damage.

However, exposure is often hard to quantify, and may occur some time prior to presentation of the liver disease. Furthermore, multiple agents may be implicated, making the actual toxic substance difficult to identify. Multiple agents which are themselves minimally toxic may act synergistically to produce injury. Safety procedures should be in place in the work environment which implies that reports of toxicity only occur when these measures break down and exposure becomes uncontrolled.

A number of difficulties complicate the diagnosis of occupational liver disease. The finding of abnormal liver function tests is relatively common in the general population, and elevations of serum GGTP are non-specific, while the interpretation of abnormal results can be complicated by the fact that alcoholism and drug ingestion may be denied. It has recently been shown that dramatically or intermittently elevated ALT levels may be of purely nutritional origin; especially when found in the absence of hepatic steatosis. Elevated ALT levels after a short over-indulgent holiday can be caused not only by alcohol ingestion, but also by a higher than normal caloric intake than usual, particularly when this is associated with ‘fast foods’ combined with sedentary behaviour. In addition, liver histology may be suggestive, but is never diagnostic, of occupational exposure to hepatotoxins.

Finally, proof of hepatotoxicity, even following acute exposure, is difficult to obtain. It would require (1) liver biopsy following the insult to characterize the damage; (2) the demonstration of recovery following removal of the hepatotoxin; and (3) most difficult, the demonstration (preferably including re-biopsy), of recurrence following re-exposure. In practice, these requirements are rarely, if ever, fulfilled.

In chronic liver disease, even when known causes are excluded, perhaps around 20 per cent of cases remain cryptogenic. In these, we are left to consider the possibilities of a novel, currently undiagnosable virus or occupational exposure to a hepatotoxin. Clearly, the latter is only likely to be diagnosed by a well-informed clinician who maintains a high index of suspicion, and who is aware of the new techniques, such as DNA microarray technology, now becoming available to clarify these issues.

Key points

- Diagnosis of occupational hepatotoxicity requires a high index of suspicion in the treating physician and a detailed history of possible exposure.
- Although hepatotoxicity may occur after an acute exposure, it more commonly presents after chronic exposure or many years after exposure has ceased.
- The liver only has a limited number of mechanisms to deal with hepatotoxins and the
response of the liver will depend on the agent, duration and route of exposure.
- The hepatic response to hepatotoxins varies with genetic phenotype, with concurrent or subsequent exposure to prescribed drugs and alcohol and with the presence of other conditions, such as obesity and diabetes.
- Although routine workplace exposure to hepatotoxins in the developed world is now much less frequent due to increased awareness and health and safety legislation, exposure can still occur in less well-regulated industries, during accidental spills or escapes and particularly in the developing world.

ACKNOWLEDGEMENTS

We wish to acknowledge the assistance of Dr PM Smith and the late Dr FI Lee for their helpful discussions on the hepatotoxicity of vinyl chloride and for their permission to reproduce a figure from their paper (reproduced as Figure 88.7). We also wish to acknowledge the assistance of Dr R Ede, of Hope Hospital, Manchester, for his advice on aspects of porphyrin metabolism and analysis. Finally, we would like to acknowledge the work of Dr Sanjiv Jain as a co-author of the earlier version of this chapter which appeared in the ninth edition of this textbook.

REFERENCES

Workplace exposures and reproductive health

JENS PETER BONDE

INTRODUCTION

Reproductive hazards in the workplace become an issue for the general practitioner, the obstetrician and the occupational health professional when pregnant women ask for advice on how to safely carry on their work. Similarly, infertility and adverse pregnancy outcomes are rather common, but causes are most often hard to identify. Infertile couples and affected families may be concerned about occupational exposures. There are several well-known examples of infertility, birth defects and other adverse reproductive outcomes that are caused by noxious exposures at the workplace. Therefore, there is a need for proper professional counselling. The purpose of this chapter is to help the reader undertake appropriate risk assessment as a basis for advising patients, families and workplaces.

THE RANGE OF ADVERSE REPRODUCTIVE OUTCOMES

The reproductive cycle can be divided into four phases, all of which are susceptible to disruption from occupational exposures: (1) gametogenesis and the sexual act in adult men and women; (2) prenatal development from fertilization through implantation, embryogenesis and fetal growth; (3) lactation and weaning; and (4) the prepubertal growth and development and sexual maturation. While direct occupational exposures are only likely in the first three reproductive phases, the adverse effects may be manifested in all four phases (Figure 89.1). Some effects are seen immediately as miscarriage related to intoxication with organic solvents, other effects may take months to develop as, for instance, reduced sperm count and infertility due to pesticide exposure and yet other effects may be latent for years as, for example, minor cognitive disturbances in school-age children following exposure to inorganic lead in the prenatal and early years of life.

Some biological processes of the reproductive cycle are more sensitive to environmental disruption as meiotic cell divisions and embryogenesis. In the following, the adverse reproductive end points are presented with a description of occurrence, mechanisms of action and occupational risk factors, while general approaches to clinical examination and risk assessment are outlined in concluding paragraphs.

INFERTILITY

Epidemiology

In the clinical setting, infertility is defined as the inability to become pregnant within one year of regular intercourse. This limit is of course arbitrary. In healthy young couples not using contraception, the probability to obtain a clinical recognized pregnancy within one menstrual cycle, the fecundability, is about 25 per cent.¹ The chance that healthy couples with normal fecundity do not become pregnant within one year because of bad luck is 3 per cent [(1–0.25)¹²]. In contrast, subfertile couples may become pregnant within one year because of good luck. If, for instance, the fecundability is reduced to 50 per cent of the average, then (1−(1−0.125)¹²) = 80 per cent will become pregnant within the first year of trying.
The prevalence of infertility is in the range of 15–20 per cent in affluent countries and some 6 per cent of children are conceived by artificial fertilization techniques. Clinical series indicate that female factors are involved in about 50 per cent of infertile cases and male factors in about 30 per cent. The fecundity decreases substantially after 30 years of age among women, while male fecundity only declines moderately after 50 years of age. Tobacco smoking is known to reduce the fecundability among women with an average 30 per cent, but effects in adult men are limited. Emerging evidence indicates that the male fetal gonad is highly sensitive to maternal smoking resulting in low sperm count after puberty.

Several reports indicate that sperm counts have declined in some regions during past decades. Increasing incidence of testicular cancer and possibly cryptorchidism and hypospadias parallels this trend. Since it is well established that testicular cancer has fetal origins, it has been hypothesized that all these conditions share a common prenatal aetiology. Recent prospective studies demonstrate that the fecundability starts declining when sperm count gets lower than 40 million/mL (Figure 89.2). Several surveys from various parts of Europe in the past ten years show that a sizeable proportion of men of fertile age have a sperm count below this limit (Figure 89.3). Due to a lack of appropriate biological indices of female fecundity, little is known about regional or temporal shifts of fertility in women.

**Mechanisms**

Occupational exposures can adversely affect the male and the female reproductive systems at several levels that may
cause inability to obtain fertilization or carry a fertilized ovum to a clinical pregnancy.

Spermatogenesis lasts 74 days in humans and can be damaged at any stage of differentiation resulting in impairment of number, structure, mobility and viability of sperm and causing loss of chromatin integrity and DNA damage (Figure 89.4). Exposure in the early stages of spermatogenesis most likely causes long-term effects while interference with the epididymal function results in transient effects if exposure is discontinued. The Sertoli cells of the testis are essential for proliferation and maturation of sperm and therefore Sertoli cell toxicants may cause severe impairment of semen quality. Other sites of action of the male reproductive system include neuro-endocrine control at the pituitary or testicular level (Leydig cells) and interference with epididymal and accessory sex gland function.

Dysfunction of the female reproductive system may be caused by disruption of the endocrine regulation of the menstrual cycle and impaired ovulation, tubular transport of the fertilized egg or implantation. The number of primordial gonocytes in the fetal gonad counts some two million at birth – a number that is reduced to 400,000 at puberty. It is often assumed that the oogenesis is less susceptible than the spermatogenesis to toxicants because oocytes are dormant and well protected in the ovary until the last few weeks before ovulation. However, it is known that polyaromatic hydrocarbons arising from combustion processes may cause destruction of oocytes in the ovarian stroma. Depletion of the pool of follicles may cause premature menopause.

**Occupational risk of infertility**

In 1977, it was incidentally discovered that the nematocide dibromochloropropane (DBCP) was causing severe oligospermia and a permanent inability to have children in some men. So far, DBCP is the most well-established human reproductive toxicant conferred by occupational exposures. The compound is highly toxic to stem cells of the human seminiferous tubule and reproductive toxicity has also been seen in mice, rats and rabbits. The DBCP incident initiated heightened interest in reproductive hazards and during the past 30 years more than 100 occupational studies of semen quality and couple fertility have been undertaken. In general, cross-sectional semen studies have methodological limitations. Participation is most often low and selection bias may be introduced because control subjects seem to participate more often than exposed if they have experienced infertility.

The time-to-pregnancy approach to studies of couple fertility has become popular, but results needs cautious interpretation – first of all, because sexual behaviour and use of contraception has a strong impact on the end point and may vary between different occupational groups. Examples of occupations and exposures that have been associated with subfertility in epidemiological studies are given in Table 89.1. In the following, certain selected exposures that may interfere with fertility are briefly reviewed.

**IONIZING RADIATION**

Healthcare and nuclear plant personnel, laboratory technicians, welding operators and radar technicians may be exposed to ionizing radiation at the workplace. The gonads are among the most radiosensitive tissues of the body. A temporary reduction in sperm count occurs after a radiation dose of 0.15 Gy, while single exposures above 2 Gy may cause permanent azoospermia. Workplace exposure to gamma radiation is easy to monitor, while exposure to alpha and beta radiation by inhalation or ingestion of particles may easily escape recognition. However, at current occupational standards in industrial and research laboratories, exposure levels are far below the background radiation. If the usual exposure threshold of 15 mSv/year is not exceeded, reproductive effects seem unlikely.
study may result from radiant heat associated with HHF exposure. The significance of reduced semen quality observed in military radar equipment operators in the United States and Denmark is uncertain. The effects observed in the small human populations are not seen in animal studies.

EXTREMELY LOW FREQUENCY ELECTROMAGNETIC RADIATION

There has been a tremendous increase in the population exposure to extremely low frequency electromagnetic radiation from household electrical equipment and power cables. Clues as to the possible significance for reproductive health may be obtained from occupational studies. Metal welders are among the highest exposed professionals because of the close proximity to power cables during electric arc welding. Comprehensive studies with full shift monitoring of electromagnetic fields provide no evidence that the endocrine profile or conventional semen characteristics are influenced by exposure to such fields. Moreover, there is a paucity of experimental evidence indicating that we should expect any effects.

HEAT AND SEDENTARY BODY POSTURE

It is well known that elevation of the testis temperature impairs spermatogenesis. Work in hot occupational environments and exposure to radiant heat among welders, foundry workers, ceramic workers and bakers may cause reduced sperm count. Disruption of testicular heat regulation may cause delayed conception in taxi drivers. Men sitting at work for eight hours a day have on average 0.7°C higher scrotal temperature during the day in comparison with employees with less than eight hours in the sedentary body position. An increase of scrotal temperature of this order of magnitude may be sufficient to impair spermatogenesis, but reduced sperm count seems not related to sedentary work.

ORGANIC SOLVENTS AND GLYCOL ETHERS

Among the widely used volatile industrial organic solvents, it seems that carbon disulphide carries a risk to the male reproductive system. This solvent is used in the viscose-rayon industry. High-level exposure in the workplace may cause reduced semen quality and disruption of endocrine homeostasis. Styrene is used in the manufacturing of reinforced plastic products as used in windmills and yachts. Manual laminating procedures often involve high exposure levels. There is limited evidence that inhalation of styrene may impair semen quality, but not time taken to conceive. Animal as well as human data on reproductive effects of other widely used solvents such as toluene, xylene, benzene, carbon tetrachloride and trichlorethylene are limited.

Glycol ethers are solvents with low volatility, which increasingly have been used as substitutes for the highly volatile hydrocarbons in paints, adhesives, thinners, printing ink and anti-icing fluids. It has been estimated that two million workers are exposed to eight different glycol ethers

Occupational exposures that have been associated with reduced fertility or effects on biological indicators of reproductive function as semen quality or endocrine disruption. Substantial evidence of causal effects are indicated by an * and circumstantial evidence by (+). References to original work are provided in reviews.

### HIGH FREQUENCY ELECTROMAGNETIC RADIATION

Exposure to high frequency electromagnetic radiation (HHF, 200 kHz–300 mHz, short waves or microwaves) is increasing because of widespread use of cellular phones. Occupational exposure occurs among military radar equipment operators and employees working with thermal plastic sealing, glue hardening, physiotherapy and telecommunication equipment. The apparent effect on semen quality of microwaves (100–300 000 mHz) reported in an earlier East European
in the United States, including females in the semiconductor industry. Unequivocal reproductive toxicity of some of these compounds has been documented in laboratory rodents and a number of studies indicate reproductive effects in humans as well. The solvent 2-bromopropane has specific effect on rat spermatogonia. A small Korean study of electronic company workers exposed to this compound reported severely reduced sperm count. Clearly, attention should be paid to this particular organic solvent for workers in the electronics industry.

INORGANIC LEAD

The reproductive toxicity of lead has been known for a long time. Several occupational surveys have linked exposure to inorganic lead in the exposure range of blood lead above 40–50 μg/dL to reduced sperm count and other signs of male reproductive toxicity, although the literature is not entirely consistent. The evidence in humans is supported by compelling evidence in mice, rabbits and some rodent industry. Unequivocal reproductive toxicity of inorganic lead in the United States, including females in the semiconductor industry. Unequivocal reproductive toxicity of some of these compounds has been documented in laboratory rodents and a number of studies indicate reproductive effects in humans as well. The solvent 2-bromopropane has specific effect on rat spermatogonia. A small Korean study of electronic company workers exposed to this compound reported severely reduced sperm count. Clearly, attention should be paid to this particular organic solvent for workers in the electronics industry.

Metal welders

Several studies have demonstrated impaired semen quality, delayed time to conception and reduced fertility rate in metal welders, but more recent studies have not corroborated earlier findings. These apparent inconsistencies may be due to changing exposure levels. The risk is not related to welding stainless steel. Infertility of unknown etiology in a welder exposed to high levels of welding fume particulates above 5–10 mg/m³ should prompt further evaluation of occupational risk.

PESTICIDES

Several pesticides have been studied in occupational settings after the reproductive toxicity of DBCP was recognized in 1977. European studies of wine yard workers, organic and conventional farmers and greenhouse workers exposed to low levels of a wide range of pesticides have not revealed an effect on fertility, except in greenhouse workers. Other studies have found associations between pesticide exposure and fertility which may be explained by different exposure profiles and levels. For the clinician, only limited information can be obtained from the epidemiological studies with poorly characterized exposures. In the individual case, emphasis must be on work history, exposure to specific chemicals and laboratory evidence (Box 89.1). Unfortunately, only few pesticides can routinely be measured in blood, urine or semen.

Male-mediated developmental toxicity

Animal studies have demonstrated how paternal exposure to mutagens and carcinogens before mating are capable of introducing heritable genomic changes. This can result in reproductive failures, such as miscarriage, congenital malformations and cancer in the offspring. By 1985, it was shown that exposure of male rats to cyclophosphamide causes post-implantation loss without interfering with fertility. Aneuploid sperm is not a hereditary risk if they are disadvantaged at fertilization with respect to normal sperm cells. However, elegant studies demonstrated the absence of selection against aneuploid mouse sperm at fertilization. Thus, the question about consequences of paternal exposures for pregnancy outcomes seems highly relevant, and since 1985 several synthetic chemicals have been found to induce genetic damage, that is transmitted to the offspring. In humans, treatment with cytotoxic drugs and tobacco smoking have been associated with increased frequency of aneuploidy in sperm cells, but so far there is no clear evidence that developmental anomalies can be attributed to paternal smoking in spite of several findings suggesting such effects. Many epidemiologic studies indicate an association between certain paternal occupational exposures and adverse pregnancy outcomes. In most cases, positive findings obtained in one study have not been confirmed in other studies. However, a recent meta-analysis based on 14 studies selected by rigorous quality criteria concluded that occupational exposure to organic solvents is associated with an increased risk for neural tube defects, while associations with spontaneous abortion was less likely. Inorganic lead has also been associated with male-mediated toxicity.
### Box 89.1 Extrapolation of animal data to human scenarios

Counselling of subfertile couples and pregnant women with regard to reproductive chemical hazards in the workplace is heavily reliant on reproductive toxicity testing in rodents because epidemiologic data are scanty or too crude to be useful. Therefore, the issue of extrapolation from animal studies to the human situation is important and briefly commented on here.

Reproductive toxicity testing was developed after the thalidomide catastrophe and includes single-generation and multiple-generation studies. The single-generation studies use the highest dose not causing maternal toxicity to detect teratogens and fetotoxic effects, while the costly multigeneration studies use low doses over long time periods.

In general, the similarities between rodents and humans are much stronger than the differences. It is therefore reasonable to assume that a reproductive effect that is observed in rodents will be seen in humans if exposure levels are relevant and toxicokinetics and mechanisms of actions are not irrelevant for humans. In particular, this is true for teratogens and compounds that directly interfere with spermatogenesis. When a compound increases the frequency of specific structural abnormalities following administration of doses that are not causing general toxicity of the mother animal (no signs of intoxication, intake of water and food and weight gain as in the reference group), structural defects are also likely to occur in humans, although the specific nature of the defects may differ from species to species. In particular, this is true if the structural defects are rare in the rodent species. For example, cleft palate is common in mice due to high cortisol levels in stress conditions, while such effects are not seen in humans. Resorptions, delayed ossifications, reduced fetal weight gain and increased occurrence of minor skeletal malformations are common in experimental animals following high doses that are associated with toxic effects in the mother animal. The importance of similar effects at dose levels that are not associated with maternal toxicity is uncertain and difficult to extrapolate to humans.

All known human teratogens cause structural abnormalities in at least one and most often several rodent species. On the other hand, there are several animal teratogens with unproven teratogenic effects in humans because data are lacking. One exception is acetylsalicylic acid, which is a teratogen in rodents but not in humans. Similarly, compounds disrupting specific steps of the spermatogenic cycle in rodents are also likely to produce similar effects in humans. Effects in humans have been observed at 2–10 per cent of the effective dose in rodents. Therefore, a safety factor of at least 100 is warranted.

It should be acknowledged that there are no appropriate animal models to predict subtle cognitive or behavioural effects following disruption of central nervous system development and likewise effects of physical strain, work postures and psychosocial strain cannot be predicted from animal studies.

Overall, it remains a prudent approach to regard any effect found in animals as likely to occur in humans until additional evidence might indicate otherwise.

---

**ADVERSE PREGNANCY OUTCOMES**

**Spontaneous abortion**

It is estimated that up to 75 per cent of all fertilizations are lost and that 10–20 per cent of recognized pregnancies are terminated in spontaneous abortion (see p. 381 in Ref. 54). The probability of embryonal loss decreases with increasing gestational age (Figure 89.6). At least 30 per cent of recognized spontaneous abortions are chromosomally abnormal compared to 6 per cent in stillbirths and 0.6 per cent in live births (see p. 382 in Ref. 54). Chromosomal anomalies arise either before conception in male or female germ cells or at the time of fertilization, but are not caused by exposures taking place after this time. Maternal age above 30–35 years increases the risk of both chromosomally normal and abnormal spontaneous abortions. Other indisputable known risk factors are surprisingly few and include earlier abortion, maternal smoking and use of intrauterine device (IUD).

Most epidemiological studies of occupational risk of spontaneous abortion are constrained by methodological limitations, which may explain that few hazards have been identified in spite of a quite large number of studies these
Occupational exposures conferred during pregnancy associated with adverse pregnancy outcomes.

past 25 years. Spontaneous abortion is a heterogeneous outcome and it is seldom possible to examine the risk of specific types of abortions – as, for instance, chromosomally normal or abnormal embryos. The risk of a specific type of fetal loss conferred by an occupational exposure must therefore be observed on top of the high frequency of background losses. Moreover, the observed frequency of spontaneous abortion is heavily dependent on whether or not early losses are ascertained and this may vary between occupational groups that are compared. In addition, many studies are difficult to interpret because of lacking information about type, level and time of exposure. These methodological limitations should be taken into account when considering Table 89.2 which lists a number of occupational exposures that have been associated with increased risk of spontaneous abortion and other adverse outcomes in several studies.

Birth defects

Congenital malformation occurs in 3–5 per cent of births. Causes are known in one-third of cases. Genetic defects account for 20 per cent, chromosomal aberrations for 5 per cent and diseases, lifestyle and environmental factors for 10 per cent of cases.55 According to current knowledge, less than 1 per cent of birth defects are thought to be attributable to man-made chemicals (Tables 89.3 and 89.4).56

Teratogen refers to any agent that causes a structural abnormality following fetal exposure. Teratogens have seldom been identified by systematic epidemiologic studies. Most often, an increased occurrence of a particular malformation leads to the discovery of a teratogenic agent. For instance, Minamata disease, an encephalopathy that mimics cerebral palsy, was first recognized in villages surrounding Minamata Bay in Japan. This localized area of increased prevalence led to an investigation that pointed to methyl mercury as the offending agent. This compound was discharged into the bay by a local factory. Ingestion of contaminated fish during pregnancy was the primary cause for this devastating condition. Similar results followed the ingestion of grain laced with methyl mercury, which was used as a fungicide in Iraq.57

The sudden appearance of several cases of a rare disorder can also raise suspicions of teratogenicity. Cases of phocomelia in the early 1960s in Germany and Australia

</table>
led to the identification of thalidomide as a human teratogen. Thalidomide was used to treat morning sickness, resulting in exposure at the stage in development when the embryo is most vulnerable, the first trimester.

Effects of teratogens follow an exposure–response relationship. There is a threshold below which no effect will be observed and both severity and frequency of malformations increase as the level of exposure increases. Additionally, the time of exposure is important since certain stages of embryonic and fetal development are more vulnerable than others (Figure 89.7). Insults occurring from fertilization to early post-implantation most often result in an all-or-none response. Either the agent affects so many cells that the embryo is lost or so few cells that full repair from omnipotent remaining cells takes place. Otherwise, the embryonic stage (first trimester) is more vulnerable than the fetal period (second and third trimesters). Some malformations occur following exposure over a broad range of time as in microcephalia following ionizing radiation, while other malformations such as specific limb defects only occur after exposure during a narrow time period. Most teratogens are associated with a confined group of malformations that result after exposure during a critical period of embryonic development.

### Growth retardation and preterm birth

The birth weight is a function of intrauterine growth, gestational age and genetic factors. Low birth weight is strongly related to perinatal mortality (Figure 89.8). The prevalence of children born before the 37th week of gestation is round 5–6 per cent in western countries and the prevalence of children with intrauterine growth retardation (IUGR, birth weight below the tenth percentile at the given gestational week) is slightly lower (3–5 per cent).

### Occupational risk for adverse pregnancy outcomes

Women in gainful employment do not have less beneficial pregnancy outcomes than women with home employment. An overview of the most common work-related reproductive hazards for the pregnant woman is given in Table 89.2. Table 89.3 provides an overview and comments on reproductive hazards in selected occupations. Epidemiologic research to date has not convincingly established any workplace exposure as a human teratogen. However, in the aggregate, many studies suggest that some organic solvents, heavy metals and pesticides may cause malformations of several organ systems. A more detailed description is provided below.
ANAESTHETIC GASES

A number of studies suggest that the risk of spontaneous abortion may be elevated among women exposed to anaesthetic gases. A meta-analysis based on 19 studies concluded that exposure to anaesthetic gases a few decades ago was associated with a moderately elevated risk of spontaneous abortion. However, reproductive toxicity has not been seen in animal studies using low-level exposure corresponding to concentrations measured in operating rooms. Working in modern operating theatres with closed anaesthetic systems and efficient exhaust ventilation, exposure to anaesthetic gases does not entail a risk if the equipment is properly maintained and exposure levels are controlled. This is contrary to mask anaesthesia in dental practice and among midwives and veterinarians, where high peak exposures to nitrous oxide can be encountered and deleterious effects in the first trimester cannot be excluded. Nitrous oxide is teratogenic in rats above 1000 ppm. Moreover, an increased risk of miscarriage was found in a large study of dental assistants that worked with nitrous oxide at least three hours per week without use of local exhaustion. Precautions to protect midwives, nurses, dentists and dental assistants against exposure to nitrous oxide during pregnancy are warranted. This includes sufficient ventilation in post-operative care units where anaesthetic gas exposure from patient exhalations can result in ambient air concentrations exceeding threshold limit values.

PHARMACEUTICALS

Several pharmaceuticals including reproductive hormones, antineoplastic agents and certain immunosuppressive, antiviral and anti-inflammatory drugs exhibit reproductive toxicity in rodent studies. Antineoplastic drugs have received the most attention because mixing and intravenous administration may cause considerable exposure. A number of studies have reported increased risk of spontaneous abortion in nurses handling antineoplastic drugs. Given the well-established effects on cell growth by a variety of mechanisms, precautions must be taken to prevent skin contact or aerosol exposure to these agents. If it is not possible to comply with occupational safety standards, pregnant women should not handle antineoplastic drugs for other than oral administration. Results of studies performed in recent years in the Netherlands indicate that the risk for adverse pregnancy outcomes has not been eliminated.

CLEANING AGENTS AND DISINFECTANTS

Soaps and ethanol solutions used for ordinary cleaning tasks are not considered a reproductive hazard, while high exposure to very reactive chemicals used to sterilize objects and surfaces, such as ethylene oxide, formaldehyde and glutaraldehyde have been associated with an increased risk of fetal loss in a few studies. The limited evidence precludes comprehensive risk assessment, but the available data and the reactive nature of the chemicals indicate that precautions should be taken to prevent overexposure of pregnant women.

ORGANIC SOLVENTS

Aliphatic and aromatic organic solvents readily pass the blood-placenta barrier. The concentration in fetal tissues may be the same or even higher than in maternal tissues. Several large and well-conducted studies indicate that high-level exposure to organic solvents during early pregnancy carries a risk for spontaneous abortion. For instance, a Finnish study reported a nine-fold higher risk following first-trimester exposure to toluene in the shoe industry, where high exposure levels are known to occur. Other data indicate that risk of miscarriage may be increased at exposure levels close to United States Occupational Safety and Health Administration (OSHA) permissible levels for toluene, xylene and formaldehyde.

In several studies, birth defects have also been linked to organic solvent exposure during pregnancy. A study of women who received counselling because of concern about occupational solvent exposure reported a strongly elevated risk of subsequent birth defects. This disturbing finding has not been corroborated in independent studies.

In general, data on magnitude of risk, exposure-response relations, no-effect levels, specificity of effects according to type of solvents and other details have not been clarified. Moreover, effects in humans are not strongly supported by studies in rodents. Reviews considering data on specific solvents, such as styrene, toluene, xylene and trichloroethylene have not been conclusive. Considering the established neurotoxicity of organic solvents, it is remarkable that there is no evidence on neurobehavioural effects in children exposed during fetal life. High solvent exposure has also been linked to gestational hypertension and low birth weight.

Exposure during pregnancy should be kept at the lowest possible levels during the entire pregnancy. It should be kept in mind that permissible exposure levels for organic solvents are most often based upon irritant or neurotoxic effects that cannot be expected to provide sufficient protection against adverse pregnancy outcomes.

GLYCOL ETHERS AND THE SEMICONDUCTOR INDUSTRY

The reproductive toxicity of some ethylene glycol ethers has been well documented in animal studies. Increased risk of miscarriage has been observed in US semiconductor industries (see, for example, Ref. 74), but findings have not been corroborated by a British study. Monomethyl and ethyl ethers have caused malformations in many organs in several rodent species, but the epidemiological evidence is limited and is insufficient to allow conclusions with respect to risk for malformations in humans.
INORGANIC LEAD

Maternal blood lead levels above 10 µg/dL have been linked to increased risk of gestational hypertension, spontaneous abortion and delayed cognitive capabilities in children. A prospective study of spontaneous abortion in Mexico used incidence-density analyses in order to achieve comparable opportunity for the outcome to occur among exposed and controls and observed a striking exposure–response relation between blood lead and spontaneous abortion at low exposure levels.7 Blood lead levels in this range are far lower than permissible biological threshold values. Higher levels have been associated with reduced fetal growth. An increased risk of congenital malformations has also been suggested, but there is uncertainty with respect to specific malformations and exposure–response relationship.78 Precautions to protect pregnant women from even low-level exposure are strongly justified by available evidence. Workplaces putting women of fertile age at risk from exposure to inorganic lead should develop practices to prevent exposure from the very early stages of pregnancy.

MERCURY AND OTHER METALS

Organic mercury causes severe disruption of fetal development of the brain as tragically encountered in Minamata Bay in Japan and other places in the 1950s. Exposure to methyl mercury is not usual in the occupational environment and there are no consistent indications that inorganic or metallic mercury are teratogens in humans.79,80 Several studies among dental assistants with low-level elemental mercury exposure do not provide consistent data to indicate reproductive toxicity at these exposure levels. Other metals, such as nickel, arsenic, manganese and cadmium, have also been associated with reproductive toxicity in epidemiological studies, but the evidence is limited.81

PESTICIDES

Pesticides denote a large and heterogeneous group of chemicals that has toxicity to living organisms in common. Industrial workers engaged in manufacture and formulation of pesticides may be exposed through multiple pathways, while the predominant route of exposure among applicators in greenhouses and agriculture is through the skin. Spraying of pesticides also confers exposure through inhalation, unless the worker is adequately protected. Thousands of deaths are reported annually following acute intoxication in developing countries and high-level exposure in the occupational setting, as well as long-term low-level exposure of the general population continues to be of concern. A large body of evidence in laboratory rodents suggests reproductive toxicity of some pesticides when given at exposure doses that are higher than those obtained from occupational exposure. In spite of numerous studies of birth defects in agricultural workers, the evidence is still inadequate to conclude whether some of these highly diverse compounds impose a risk for birth defects in humans.82,83 Some pesticides have weak hormonal activity in in vitro and in vivo systems. In recent years, the hypothesis that endocrine disruption during fetal development may cause hypospadias and cryptorchidism attracted much attention.84 Emerging evidence from environmental studies indicate that biopersistent organochlorines, such as dichlorodiphenyl- trichloroethane (DDT) and its main metabolite dichlorodiphenyl-dichloroethane (p,p’-DDE) may cause intrauterine growth retardation and miscarriage.85,86

HAIR DYES AND SPRAYS

Hairdressers, barbers and cosmetologists are exposed to a complex chemical environment of permanent and temporary hair dyes, hair sprays, shampoos, permanent-wave solutions and perfumes. Some constituents of dyes, such as toluene- and phenylenediamines, exhibit reproductive toxicity in laboratory animals. However, according to a 1993 IARC evaluation, no teratogenic effects were seen in rodents that were exposed by application of a number of hair dye formulations on the skin.87 In general, ambient air measurements of volatile solvents as indicators of overall exposure have been very low (less than 10 ppm ethanol, acetone or dichlormethane), but high peak exposure may occur and small amounts of toluenediamines have been measured in urine samples, which documents systemic uptake. A number of reproductive studies in the past two decades have reported slightly increased risk of miscarriage and birth defects, but findings are not entirely consistent.88 Based upon a small number of cases, two studies indicated an increased risk of cleft palate89 and thus there is need for additional research. However, potential hazards can be minimized by use of general and local exhaust ventilation and use of gloves to prevent skin absorption. With these precautions, job replacement is seldom needed.

OFFICE WORK

In the 1980s, video display terminals were suspected of causing adverse reproductive outcomes because of exposure to electromagnetic fields, but several large-scale epidemiological studies did not find an increased risk of spontaneous abortion nor any of an array of congenital defects.90 This is a good example of how comprehensive reproductive epidemiology may help resolve widespread concern and fear related to introduction of new technologies.

IONIZING AND NON-IONIZING RADIATION

Genetic effects of ionizing radiation on male and female gametes before fertilization are mainly stochastic effects, while intrauterine effects in terms of miscarriage, stillbirth and birth defects are mainly deterministic effects.58 A total dose during pregnancy of less than 1 mSv is not associated with increased risk of adverse pregnancy outcomes, but exposures should be kept as low as possible to protect the fetal gonads from
stochastic genetic effects. For comparison, the average background exposure is in the range of 4 mSv/year. Exposures of hospital nurses above 0.5 mSv/year are unlikely if working conditions comply with current safety regulations.

Ultrasound and microwaves induce tissue damage because of hyperthermia at high exposure levels. Epidemiological studies have shown associations with miscarriage and changed sex ratio. Pregnant women should be protected from high exposures at the workplace. Very low frequency electromagnetic fields (video display terminals, welding, electric equipment) do not emit high enough energy to induce hyperthermia and biological effects have so far not been demonstrated.

NOISE

The fetal ear is sensitive to noise-induced damage from the 20th week of gestation. Uterus and fetal fluids attenuate the sound level, but less so at low frequencies where resonance phenomena may even reinforce the sound pressure. Pregnant women should avoid very high exposure levels above 110 dB over eight hours and low frequency noise should be avoided at even lower exposure levels. In several studies, noise has been associated with miscarriage, preterm birth and growth retardation which has been attributed to high circulating cortisol levels related to continuous activation of the hypothalamic–pituitary–adrenal (HPA) axis. Noise exposure is, however, often correlated with several other risk factors, such as physical and mental strenuous work, which may confound observed associations.

PHYSICAL WORKLOAD

Strenuous work conditions have long been suspected to be associated with adverse pregnancy outcomes, in particular premature birth and intrauterine growth retardation. The metabolic demands of pregnancy and fetal growth may be in conflict with demands for blood flow, oxygen and nutrients needed in heavy physical work. Blood flow to the placenta and uterus may be redistributed and thus reduce oxygen and carbohydrate delivery resulting in restricted fetal growth and increased uterine contractility causing preterm birth. It is remarkable, however, that exercise in pregnancy is considered to be safe in healthy and well-nourished women. An early review of epidemiological studies in the occupational setting found limited evidence for adverse pregnancy outcomes related to a number of individual ergonomic factors, such as prolonged standing, physical exertion and long work hours, while women exposed to several risk factors seemed at increased risk for giving preterm birth. More recent meta-analysis of a large number of studies addressing occupational risk for adverse pregnancy outcomes indicated an elevated risk of preterm delivery related to physically demanding work and prolonged standing (Figure 89.9). This result, however, conflicts with the most recent findings. More advanced assessment and ascertainment of exposure will probably be needed to get more exact knowledge and to establish exposure–response relations, if any. At present, the evidence does not allow for highly specific or restrictive recommendations with respect to physical work conditions during pregnancy. In general, healthy and fit women are able to comply with physical work demands throughout pregnancy without posing a risk to the fetus. However, prolonged strenuous physical exertions, awkward postures and prolonged standing should be avoided and sufficient rest periods for the pregnant woman is warranted – in particular in the third trimester and in the presence of earlier pregnancy failures or if pregnancy complications develop.

MENTAL STRAIN

Indications that psychosocial factors at the workplace have a bearing on adverse pregnancy outcomes are few. However, severe emotional stress related to an unexpected loss of a child has been associated with an eight-fold increased risk of neural crest malformations if the event happened in the first trimester of pregnancy. This finding indicates that stressful events, if sufficiently severe, may cause congenital malformations. Whether less severe psychosocial stressors put the pregnancy and fetus at risk seems plausible, but remains to be established.

SHIFT WORK

A large number of epidemiological studies have not demonstrated consistent associations between adverse pregnancy outcomes and rotating shift work or irregular work hours.
across different occupations and countries. Nevertheless, several studies indicate that some forms of shift work are related to increased risk of spontaneous abortion, preterm birth and fetal growth retardation. Lack of consistency may be related to varying definitions of work schedules. At present, the strongest and most convincing evidence from a limited number of studies indicate that working a fixed night shift is associated with increased risk of spontaneous abortion. The mechanisms involved may be related to disruption of circadian endogenous rhythm, but this explanation provides few clues on appropriate advice or whether monitoring of fetal growth is feasible if fixed night work cannot be avoided.

INFECTIONS

Several infectious diseases are severe reproductive hazards if infection takes place during the first trimester of pregnancy. However, immunization by natural infection or vaccination programmes and adherence to infection control procedures at hospitals and other workplaces strongly limit the occupational risk. Parvovirus B19 infection is of concern because only about two-thirds of women of fertile age are immune and infection in pregnancy is related to an increased risk of late fetal death. The annual seroconversion rate among susceptible women is about 10–15 per cent during epidemic periods and nursery school teachers have a three-fold increased risk for acquiring acute parvovirus B19 infection. Since the risk of stillbirth following gestational infection is not negligible (1–5 per cent), susceptible nursery school teachers and day care workers should be replaced when pregnant – at least during periods with epidemics. Prenatal infections with rubella, varicella, morbilli, hepatitis B, cytomegalovirus, immunodeficiency virus and toxoplasmosis are associated with severe developmental toxicity, but infections are seldom work-related.

DEVELOPMENTAL TOXICITY

Several prospective follow-up studies consistently indicate that exposure to inorganic lead during prenatal life cause subtle changes of behaviour and reduced learning capability that persists at least to school age. Although studies of behaviour and cognitive function are expected to be highly sensitive to confounding by socioeconomic factors, the replication of findings in several well-defined independent studies have – together with biological plausibility of the findings – convinced the scientific community at large. Effects have been observed at low environmental exposures to lead in the blood lead range of 10–20 µg/dL – far lower than levels often encountered in industry. There is emerging evidence that polychlorinated biphenyls through interaction with thyroid function in prenatal life may cause delayed effects on cognitive function. Whether occupational exposure to organic solvents during pregnancy has a bearing on cerebral and cognitive development in the offspring is a question that surprisingly has never been addressed by reproductive epidemiology.

In follow-up studies of pregnant women who survived the A-bombing in Hiroshima and Nagasaki, it has been shown that ionizing radiation in weeks 8–15 is associated with increased risk of mental retardation.

CHILDHOOD CANCER

The incidence of childhood cancer has been increasing in the United States. Two in 1000 children develop malignant disease before 16 years of age, the most common cancers being leukaemia, brain tumours (medulloblastoma and glioblastoma), kidney tumours (Wilms tumour) and retinoblastoma. The discovery that the synthetic oestrogenic drug diethylstilbestrol (DES) causes the extremely rare vaginal carcinoma in girls after puberty proves the concept of ‘transplacental carcinogenesis’. Likewise, testis tumours having their peak incidence at 30 years of age are derived from precursors that originate in prenatal life. Thus far, no parental occupational exposure has consistently been linked to malignant disease occurring in childhood or early adulthood. There are, however, indications of increased risk of childhood leukaemia and nervous system cancer following maternal and paternal exposure to organic solvents, paints and pesticides.

RISK ASSESSMENT AND CLINICAL COUNSELLING

General and occupational health practitioners may be asked to provide an assessment of reproductive hazards and clinical advice in a variety of situations spanning couples planning a pregnancy, infertile couples and pregnant women during pregnancy. In follow-up studies of pregnant women who survived the A-bombing in Hiroshima and Nagasaki, it has been shown that ionizing radiation in weeks 8–15 is associated with increased risk of mental retardation.

Established reproductive hazards include those for which substantial data in humans indicate reproductive effects at exposure levels occurring at the workplace or in the environment. Some compounds affect the fetus only at dose levels that approach maternal toxicity (for instance, metal mercury), while others cause adverse effects at otherwise subtoxic exposure levels (for instance, DBCP, PCB, inorganic lead). Suspect hazards include those for which human data are limited, but animal data are substantial. The majority of chemicals in industrial use have not been thoroughly evaluated for reproductive toxicity.

The pregnant woman

The first step in the risk assessment is to delineate and specify potential harmful workplace exposures by taking
occupational histories to assess the type, route, timing and level of the exposure. On many occasions, material safety data sheets (MSDS) and product labels may help to identify agents and ingredients of chemical products precisely. The MSDS may also provide information on human or experimental data suggestive of reproductive hazards, but most often fail to do so. However, practitioners can retrieve online reproductive toxicity data through one or more databases. Once the occupational history together with information from MSDS and reproductive toxicity databases indicate that the worker is exposed to an established or suspected reproductive hazard, the next step is to estimate exposure levels. The presence of a toxic agent in the workplace is not equivalent with exposures that imply absorption into the body and distribution to the target organ. An appropriate occupational history is of importance, but sometimes inspection of the workplace or even hygiene measurements may be needed to carry out a reliable estimate of exposure levels. Working with volatile organic solvents under a fume hood may reduce airborne exposure to very low levels, while the same work task on an unventilated bench could cause significant exposure. When accessing exposure levels, it should be kept in mind that the occupational exposure limits are not designed to protect specifically against reproductive risk. Thus, the risk assessment should be based upon no-observed effect levels in appropriate animal studies with appropriate safety factors of, for instance, 100 rather than on threshold limit values. A safety factor of 100 is based upon the fact that adverse effects have been observed in humans at 2–10 per cent of exposure levels in rodents and that variations of susceptibility within humans may be spanning one order of magnitude.

With the exception of inorganic lead, measurements of agents in blood or other tissues are seldom useful because of a lack of reference values for reproductive effects.

Sonographic imaging of fetal development is indicated if pregnant women have been exposed to teratogens or chemicals associated with fetal growth retardation in the relevant time period of gestation.

The subfertile couple

In infertile couples, the ovulatory function can be investigated by measurement of basal body temperature, pre-ovulatory luteinizing hormone and surge in urine of midluteal serum progesterone levels. In addition, male reproductive function can be evaluated by semen analysis. When interpreting results of a semen analysis, the large day-to-day and week-to-week variation and the strong impact of sexual abstinence on sperm counts should be kept in mind. Sperm counts increase with duration of sexual abstinence up to six to eight days and then level off, but the period of abstinence only explains a minor part of the intra-individual variation which is also heavily influenced by factors related to semen collection. Determination of gonadotrophins in blood may help to discriminate between dysfunction of the testis (high gonadotrophin levels and low inhibin-B), insufficient function of the hypothalamus or pituitary (low gonadotrophins and inhibin-B) and androgen insensitive tissues (high LH and high testosterone). If the occupational history raises suspicion that one or more exposures at the workplace contribute to low semen quality, temporary replacement for three to six months can be associated with improvement of semen quality depending on type of insult (Box 89.3).

### Box 89.3 Databases on reproductive toxicity

- IPCS/INCHEM ([www.inchem.org](http://www.inchem.org)). Toxicological monographs (criteria documents) from IPCS, WHO, IARC and ILO. Free online access to exhaustive information on exposures and compounds, but without any specific focus on reproductive toxicity.
- Reprorisk® system of reproductive toxicity databases ([www.micromedex.com/products/reprorisk](http://www.micromedex.com/products/reprorisk)).
- Reprotext: Reviews of 850 chemicals
- Reprotox ([www.reprotox.org](http://www.reprotox.org)). Reviews of the scientific literature with interpretation of animal and human data.
- Catalogue of teratogenic agents: 2900 drugs original data, but no interpretation.
- Teris teratogenic effects of 1100 drugs.
- General information on exposure can be found in toxicological databases, such as TOXNET ([www.toxnet.nlm.nih.gov](http://www.toxnet.nlm.nih.gov)).

### RISK MANAGEMENT

The objectives of risk management are to eliminate existing risks, to reassure if no risk is anticipated and to ensure that no misleading statements may lead to harm.113

If the risk assessment is suggestive of a reproductive risk, this should be carefully communicated to the pregnant woman or the infertile couple. Appropriate actions include technical adjustments to reduce or eliminate exposure (for instance, closed artificial ventilation systems in operating theatres), use of protective devices (as gloves in hairdressers using dyes or greenhouse workers handling pesticide-treated cultures), change of job content so that specific tasks are avoided (as, for instance, use of acrylamide in the laboratory) or transfer to other jobs or departments. In a few countries, including Canada, Finland and Denmark, it is possible to obtain compensated pregnancy leave if a documented or suspected risk to the pregnancy or the fetus cannot be eliminated and...
replacement is not possible or feasible. Nevertheless, when
a risk is clearly demonstrated, employees are in most coun-
tries obliged by law to undertake preventive measures or to
offer other job tasks, replacement or leave. However, when
the risk is less obvious because toxicity data are inadequate
or exposure levels are low, employers may not be obliged
to accommodate worker requests. In these instances, the
risk communication is of particular importance so the
decision finally made by the pregnant woman is as well
informed as possible.

Agreed important principles for communication include
honest and truthful answers to questions. However, it is
also good practice to avoid to do harm by inappropriate
information and to be aware of professional competence
and limitations. Highly categorical advice is seldom
justified.

Recommendation to terminate a pregnancy because of
workplace exposures are almost never warranted – except
perhaps accidental exposure to ionizing radiation above
0.3 Gy, rubella infection in the first trimester or severe
anoxia.

Reduction of exposure to chemicals is clearly warranted
when regulatory limits are exceeded or for even moderate
exposure to agents known or suspected to be developmen-
tal hazards.

Rational advice to couples planning to become preg-
nant would be to ensure that blood lead levels are normal-
ized before conception.

## Key points

- Noxious exposures at the workplace are
  acknowledged risk factors for a range of
  adverse reproductive outcomes, including poor
  semen quality, menstrual disturbances, sexual
dysfunction, infertility, spontaneous abortion,
genital malformation, preterm birth, fetal
growth retardation, childhood cancer and
impaired cognitive development during
childhood.
- Occupational hazards include a wide range
  of toxicants, as well as physical, microbiological,
eronomic, night work and possibly psychosocial
  factors.
- The four reproductive cycles including
  gametogenesis, embryogenesis and fetal growth, lactation and prepubertal development are all
susceptible to reproductive toxicants.
- Risk assessment should be based upon no-
observed effect levels or benchmark doses in
appropriate animal studies with appropriate
safety factors because only few occupational
exposure limits are designed to protect
specifically against reproductive risks.

INTRODUCTION

The haemopoietic system is characterized by the proliferation and differentiation of cells which govern the delivery of oxygen to the tissues, the body’s defence against infection and the maintenance of haemostasis. It is a system with a key physiological role and a high cell turnover which makes it sensitive to the influence of toxic agents which interfere with DNA replication and repair. In developed countries, many of the well-recognized causes of occupationally related disease, such as lead, benzene and ionizing radiation, are declining in incidence. However, in an increasingly complex globalized economy, with a migratory workforce operating in countries which have differing legislative controls, such diseases may still occur and it is important that an awareness of the effect of these exposures is maintained. Furthermore, the advent of new industries and processes carries the potential for producing substances with hitherto unrecognized haemopoietic effects.

In recent years, there have been extraordinary advances in the understanding of the molecular and genetic triggers of haematological diseases and these have allowed diagnoses to become more precise and treatments more focused. Treatment outcomes have improved and more patients, including those with occupational exposures, now have the option of returning to work. There is a need therefore to understand the issues concerning the long-term effects of some treatments and their impact on fitness for work. For all of these reasons the haemopoietic effects of workplace exposures are considered in this chapter as a distinct group.

STRUCTURE AND FUNCTION OF THE HAEMOPOIETIC SYSTEM

Stem cells and progenitor cells

The bone marrow stem cell has the capacity to renew itself as well as to produce progeny which proliferate and differentiate into mature cells. Stem cells are pluripotent which means that they are capable of forming colonies of progenitor cells (colony-forming units, CFU) which are multilineage (Figure 90.1), able to differentiate into red blood cells (erythrocytes), granulocytes and monocytes or platelets depending upon regulatory influences within the marrow. The stem cells also give rise to the cells of...
the immune system. As a consequence, it is not surprising that such a complex and rapidly proliferating system is sensitive to toxic effects at various stages. For example, inorganic lead and benzene exert their haematotoxic effects on erythropoiesis and progenitors, respectively, while ionizing radiation has the ability not only to damage dividing cells, but also resting cells including stem cells.

**Regulation of haemopoiesis**

As the bone marrow precursor cells (stem cells and progenitors) mature, they lose the capacity for self-renewal but increase their degree of differentiation before each cell division. It has been estimated that there are approximately 20 cell divisions in the maturation pathway and that one stem cell division is capable of producing one million mature blood cells. This is controlled by a complex array of interacting auxiliary cells, growth factors and extracellular matrix within the bone marrow stroma. The haemopoietic growth factors are glycoproteins which regulate the proliferation, differentiation and function of the blood cells. They act only at specific phases of cell maturation and either singly or in combination control the direction and rate of precursor cell differentiation. Many of them have now been cloned and are available for clinical use.

**Circulating blood cells**

The main circulating cells are the red blood cells (RBC), white blood cells including granulocytes, monocytes and lymphocytes, and platelets (thrombocytes). Red blood cells have a life span of 120 days. Granulocytes and monocytes have a short period in the circulation (about eight hours) before entering the tissues. Platelets have a life span of about ten days. The different life spans mean that toxic agents which acutely compromise cell production lead to a rapid fall in granulocytes and platelets, but anaemia may develop more slowly. Lymphocytes may survive and multiply in the circulation for prolonged periods and may reveal evidence of toxic damage after many years.

**Red blood cells**

Red blood cells (erythrocytes) transport oxygen from the lungs to the tissues and carbon dioxide in the opposite direction. To fulfil these functions, the erythrocyte is a deformable, biconcave disc, devoid of a nucleus and mitochondria, and contains functional haemoglobin (Hb) in high concentration. In order to maintain these characteristics, sources of energy and of reducing power are needed. Energy is generated as adenosine triphosphate (ATP) by the anaerobic glycolytic (Embden–Meyerhof, EM) pathway, 2 mol of ATP being produced from each mol of
glucose (Figure 90.2). Reducing power, as reduced nicotinamide-adenine dinucleotide (NADH), is produced by the same pathway and as reduced nicotinamide-adenine dinucleotide phosphate (NADPH) by the hexose monophosphate (HMP) shunt (Figure 90.2). The role of the erythrocyte in oxygen carriage continuously exposes it to the risk of oxidative injury from endogenous substances (e.g. hydrogen peroxide, \( \text{H}_2\text{O}_2 \)) often produced in response to infection, and exogenous oxidant drugs and chemicals. To counteract oxidant stress, the red cell has an array of protective antioxidants and redox defence mechanisms. These are largely a group of enzymes and co-factors catalysing reduction steps.

Haemoglobin is readily oxidized to methaemoglobin in which the ferrous iron (Fe\(^{2+}\)) is converted to the ferric state (Fe\(^{3+}\)) rendering the molecule incapable of oxygen transport. Methaemoglobin is mostly reduced by NADH: methaemoglobin reductase (cytochrome \( b_5 \) reductase) utilizing NADH derived from the EM pathway. Methaemoglobin-generating chemicals, such as aniline dyes and nitrobenzene, have a tendency to overwhelm even the normal erythrocyte’s ability to reduce methaemoglobin to haemoglobin (Figure 90.2).

NADPH is a co-factor for glutathione reductase which maintains protein function by reduction of protein sulphydryl (-SH) groups, including those of haemoglobin, enzymes and the membrane. Glucose-6-phosphate dehydrogenase (G6PD) catalysing the first step in the HMP shunt is the only source of NADPH in red cells (Figure 90.2). Deficiency of NADPH results in the inefficient recycling of glutathione and, therefore, suboptimal protection against peroxides and slow reduction of disulphides. The red cells are therefore susceptible to added stress imposed by oxidant chemicals.

As molecular oxygen undergoes successive reductions, a number of reactive species, e.g. superoxide, hydrogen peroxide and hydroxyl radicals are generated. These have strong oxidizing potential and unless they are scavenged by enzymes in the red cells, such as superoxide dismutase, catalase and glutathione reductase, they may cause oxidative denaturation of haemoglobin, enzymes and other proteins, as well as membrane damage through lipid

**Figure 90.2** Principal reactions in the erythrocyte for the reduction of oxidized compounds. GHS, reduced glutathione; GSSG, oxidized glutathione; NADPH, reduced nicotinamide adenine dinucleotide phosphate; \( \text{O}_2^- \), superoxide.
peroxidation. Which of these is the most important in damaging erythrocyte function depends on the type and origin of the oxidant stress and on the nature of the failure in reducing antioxidant protective mechanisms.

All of these defences against oxidant damage can be compromised by either congenital deficiency or impaired function of the relevant enzymes. Strong oxidizing agents, including some drugs and chemicals, however, may easily overwhelm these mechanisms resulting in oxidative haemolysis.

**CLINICAL EVALUATION**

**History**

An occupational history, as well as an accurate drug history, is part of the clinical evaluation of any patient presenting with a haematological disorder, but is particularly important in bone marrow failure syndromes, including aplastic anaemia, myelodysplastic syndrome and acute leukaemias. The latent interval between the onset of exposure and the clinical expression of disease may be many years, in which case a causal relation might well be overlooked. In these disorders, it is important that the occupational history encompasses both current and all previous employments, although the great majority of cases are not related to occupational exposure to potentially toxic substances. Anaemia, particularly haemolytic anaemia, may have a more rapid onset and potentially causative occupational exposure be more readily identified – providing such a possibility is thought about at the time.

Exposure dose, duration, peak levels as well as total, are each important but can be difficult to quantify. Dose determination may require particular techniques and expertise. Information on the use of personal protection (equipment and clothing) and general environmental control measures is essential in establishing whether a causal relation exists or not. Non-occupational environmental factors, such as the domestic or recreational use of pesticides and metals and the abuse or misuse of solvents, may also be relevant and should be recorded. Smoking history is important in cases of methaemoglobinemia and carbon monoxide toxicity.

Inherited disorders may increase susceptibility to occupational risks so family and previous haematological histories are important. Drug records, both current and previous, are essential in establishing a possible occupational role. Particularly in bone marrow failure, multiple drug exposure may confound attempts to establish a precise causation. There are no tests which can be used to prove a particular causation, so aetiology is based on a number of circumstantial criteria; was the patient exposed to the potential cause, has the association been described before, and was the temporal relationship between exposure and presentation as expected in the causation of the disease?

**Symptoms and signs**

Symptoms of blood diseases relate mainly to deficiency of functioning blood cells. Anaemia is associated with fatigue, pallor and breathlessness on exertion. Slowly developing anaemia may be well tolerated down to very low levels of haemoglobin, whereas more acute anaemias produce effects early. Lack of granulocytes increases the risk of infection, but the susceptibility only becomes apparent at low levels (neutrophils <0.5 × 10⁹/L). Where occupational exposure is a potential risk to blood cell production, screening blood counts may be needed to identify problems before serious consequences arise. Easy bruising and haemorrhages are features of platelet deficiency, but again arise usually when there has been a marked reduction in number. Haemolytic anaemias due to increased RBC destruction present with mild acholic jaundice with or without anaemia, depending on the rate of onset and destruction and the ability of the bone marrow to compensate for the increased loss. Obvious jaundice, particularly with bile in the urine, is suggestive of hepatic or biliary disease.

The bone marrow, spleen and the lymphatic system are the main organs associated with the haemopoietic system. Slight enlargement of the spleen, often detected only by ultrasound, is a feature of many anaemias including haemolytic anaemias when the spleen may be discovered on palpation. More marked enlargement, down to or below the umbilicus, is suggestive of lymphoma or myeloproliferative disorders such as myelofibrosis or chronic granulocytic leukaemia. Palpable lymph nodes raise the possibility of lymphoma. Systemic symptoms, such as fever and weight loss, are more usually features of leukaemia or lymphoma rather than aplastic anaemia or other types of marrow failure. It is important to elucidate all symptoms and signs involving other systems since many, if not all potentially toxic agents may affect other organs than the blood. Abdominal symptoms, neuropathies and liver abnormalities should be particularly examined.

**Physical examination**

Physical examination is important, but the signs of haematological disorders are often non-specific. Pallor may be noticed, but detection of anaemia by examination is notoriously difficult. Mouth ulcers and buccal haemorrhages may indicate low neutrophil counts or platelet levels, respectively. Petechial haemorrhages and more extensive bruising are also signs of thrombocytopenia. Jaundice, which may be mild, is suggestive of haemolysis. Certain occupational exposures may give rise to more specific physical signs, the detection of which should suggest the underlying diagnosis. These include central cyanosis caused by methaemoglobinemia (nitrobenzene, aniline, aromatic amines); a blue line on the gingival margins (lead); peripheral neuropathy (arsenic, lead); plantar-palmar
hyperkeratosis and transverse lines (Mee’s lines) in the nail bed (arsenic); and acneiform eruptions (organochlorine compounds).

**Laboratory investigation**

Haematological diagnosis requires a full blood count with RBC indices and white blood cell differential, examination of the stained blood film and, where bone marrow damage is suspected, bone marrow aspirate and trephine. As with anaemias in general, those caused by workplace exposures, may be microcytic, normocytic or macrocytic. Lead poisoning characteristically produces a mild microcytic or normochromic anaemia, while haemolytic anaemias can be either normocytic or slightly macrocytic depending on the degree of reticulocytosis. Aplastic and myelodysplastic anaemias usually show a degree of macrocytosis. In general, the reticulocyte count should increase in response to anaemia and do so in proportion to its severity. This is particularly so when erythroid hyperplasia has had time to develop, as in chronic haemolysis. Failure of the reticulocyte count to increase in response to anaemia indicates impaired erythropoiesis. Investigation of haematological disorders is not discussed in detail, but examination of the blood film might reveal abnormalities which provide a clue to the underlying cause. Basophilic stippling of red cells (Figure 90.3) can be evidence of lead exposure, although the degree of stippling does not correlate with the body burden of lead. Heinz bodies (Figure 90.4) and other red cell inclusions are seen in haemolytic states associated with oxidant chemicals (aniline, naphthalene, nitrobenzene, nitrates and chlorates). These inclusions represent intracellular deposits of denatured globin and are also found in inherited haemoglobinopathies. Methaemoglobin is detected by changes in the Hb absorption spectra. Examination of the bone marrow requires not only histological review of the aspirate and trephine for dysplastic changes, but also cytogenetic analysis to look for acquired somatic mutations.

**ANAEMIA**

Anaemia is very common in many populations. It may be produced by dietary deficiency or malabsorption of iron, vitamin B<sub>12</sub> or folic acid, chronic blood loss or an increased destruction of red blood cells – haemolytic anaemia. Occupational anaemias are mostly haemolytic.

**Haemolytic anaemias**

Haemolysis may be defined as that condition where the rate of red cell destruction is accelerated. The bone marrow normally responds to this change by increasing red cell production (erythroid hyperplasia), and theoretically this response can compensate for the excessive red cell destruction, even when the lifespan of the circulating cells is reduced from the normal 120 days to as few as 15–20 days. Anaemia develops when this compensatory mechanism fails to match the rate of haemolysis. Haemolytic anaemias may be due to intracellular defects of the membrane, haemoglobin or metabolic pathways or to extracellular events acting on the circulating red blood cells. The former are mainly inherited disorders, the latter acquired through many inherited disorders increase susceptibility to extracellular events. The excess destruction may take place in the reticuloendothelial system (extravascular haemolysis) or within the circulation (intravascular haemolysis).
Where haemolysis is attributable to occupational exposures, the clinical features are dependent on the agent and the route, duration and dose of the exposure. Anaemia may develop insidiously over a period of weeks or months, in which case pallor and mild jaundice may be the first indication of illness. Methaemoglobinaemia presents as central cyanosis. Acute intravascular haemolysis may occur following excessive oxidant stress and be accompanied by circulatory collapse, oliguria, haemoglobinuria, dyspnoea and generalized aching pains, especially in the loins and limbs.

Mechanisms of haemolysis

The most common mechanism of red cell damage in occupational medicine is oxidative attack which can be directed at the membrane of the red cell, the globin chains of the haemoglobin molecule or the haem group. The chemical may act as an oxidizing agent itself or it may interact with oxygen to form free radicals or peroxides. These are capable of oxidizing haem-bound ferrous iron to ferric iron with the formation of methaemoglobin which cannot serve as an oxygen carrier. This is a potentially reversible step, but if the oxidant stress is severe, the globin chains may denature and precipitate as inclusions known as Heinz bodies (Figure 90.4). These inclusions have an affinity with the red cell membrane which becomes damaged. Lipid peroxidation may also disrupt the integrity of the membrane. The damaged cells are then destroyed or fragmented in the reticuloendothelial system by the process of extravascular haemolysis. If the oxidant stress is greater there may be rapid red cell destruction with the clinical picture of intravascular haemolysis.

Acute intravascular haemolysis with methaemoglobinemia is known to follow exposure to arsine, a highly toxic gas produced by the contact of acid with metals containing arsenic. Chlorate also produces acute intravascular haemolysis, usually with acute renal failure. Treatment for both arsine and chlorate poisoning is by red cell exchange transfusion.

INHERITED DISORDERS AFFECTED BY OCCUPATIONAL EXPOSURES

Glucose-6-phosphate dehydrogenase deficiency

Individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency have an increased susceptibility to oxidant chemicals. G6PD deficiency is an X-linked disorder common in much of Africa, Mediterranean countries and much of Southeast Asia, countries where falciparum malaria flourished. This diagnosis should be sought in any patient with acute haemolysis or recurrent haemolysis and especially where there is the likelihood of occupational exposure to oxidizing agents. Such individuals must avoid further exposure to oxidant chemicals, even though the exposure might be well within the relevant occupational exposure control values. Naphtha and naphthalene products produce acute intravascular haemolysis in G6PD-deficient subjects.

Sickle cell disease

Sickle cell disease is common in parts of Africa, some parts of the Middle East around the Persian Gulf and occurs in small pockets in Greece. It is the result of inheriting the gene for HbS either in the homozygous state (HbS/S) or in combination with genes which deplete the normal HbA chains (HbS/β Thal; HbS/C). Patients suffer from recurrent painful crises and a number of other serious problems caused by the Hb in the red cells forming rigid structures which lead to non-deformable red cells and ischaemia. The process is aggravated by dehydration, fever, infection and cold. Hypoxia increases the precipitation of the Hb, so sufferers should avoid situations such as flying in unpressurized aircraft. Heterozygotes (HbS/A) may have problems if hypoxia is severe.

Methaemoglobinemia

Hereditary homozygous deficiency of the enzyme NADPH:methaemoglobin reductase is associated with benign congenital methaemoglobinemia often with striking cyanosis. It is rare, but heterozygotes are asymptomatic unless exposed to oxidizing drugs or chemicals when cyanosis becomes apparent at much lower concentration of the agent than normal. Substances with the ability to induce the oxidation of the haem group leading to the formation of methaemoglobin include the aniline dyes, aromatic amines, nitro-substituted benzene compounds, and organic and inorganic nitrites and nitrates (see Chapter 42, Organic chemicals). Methaemoglobin formation by itself does not necessarily lead to premature red cell destruction as shown by the absence of haemolysis in patients with methaemoglobinemia induced by nitrites.

Some chemicals which produce methaemoglobinemia have additional toxic effects which dominate the clinical presentation, for example methaemoglobinemia produced by paraquat is almost trivial in comparison with its effects on the lungs and other organ systems.

LEAD AND ANAEMIA

Chronic exposure to inorganic lead primarily affects erythropoiesis producing a combination of anaemia and bone marrow erythroid hyperplasia, an association best described by the term ‘ineffective erythropoiesis’. The anaemia
can be either microcytic or normochromic or mixed. Polychromasia may be noted on the blood film associated with slight elevation in the reticulocyte count and red cell survival is shortened. These are all features of haemolysis and reflect the inhibitory effect of lead on erythrocyte maturation and damage to the red cell membrane. The severity of the anaemia is poorly correlated with the degree of lead exposure, but is rarely seen at blood lead levels below 60 μg/100 mL in occupationally exposed groups. The anaemia of chronic lead exposure is characteristically persistent, unlike that of acute lead poisoning (see Chapter 23, Lead).

The bone marrow usually shows erythroid hyperplasia and may also be sideroblastic (ineffective erythropoiesis with typical ringed sideroblasts), but erythroid hypoplasia is also occasionally described.

Basophilic stippling (Figure 90.3) of red cells may be prominent, but it is not always found and correlates poorly with blood lead levels, haemoglobin and clinical symptoms. It is unusual when blood lead levels are below 80–100 μg/100 mL. With improved controls of current occupational exposures, this marker of lead poisoning is now a rare feature in the peripheral blood. In general, haematological parameters are neither sensitive nor specific in relation to blood lead levels, although there is a correlation between lead and Hb levels in environmentally exposed populations. The mechanism of lead-induced anaemia involves reduced red cell production (ineffective erythropoiesis), as well as reduced red cell survival (haemolysis) (see Chapter 23, Lead). The pathogenesis of the ineffective erythropoiesis is complex and not completely understood.

5-Aminolaevulinic acid (ALA) dehydratase is the enzyme most affected by lead, but the majority of the enzyme steps in the human biosynthetic pathway are inhibited by lead to some degree. The haemolytic component is due to both lead-induced structural alterations in the red cell membrane and impaired erythrocyte pyrimidine 5’-nucleotidase activity. Under normal conditions, this enzyme plays a prominent role in the cleavage of residual nucleotide chains that persist in the cell after nuclear extrusion. Deficiency, whether in the acquired or the congenital form, is usually associated with the presence of basophilic stippling which has been shown to result from the deposition of aggregates of ribosomal RNA. The accumulation of nucleotides inhibits the HMP shunt and this accelerates the rate of haemolysis. Lead may also impair globin chain synthesis. In view of its multiplicity of effects on the red cell, it is interesting that anaemia is a late sign of lead intoxication. Biological effect monitoring techniques utilize the increase in substrate concentrations, such as urinary ALA and erythrocyte protoporphyrin, to screen for exposure. The general reduction in occupational exposures to the metal in developed countries has meant that patients with lead toxicity now more commonly present with non-haematological manifestations.

**BONE MARROW FAILURE**

In a number of disorders, failure of the bone marrow stem cells to produce adequate numbers or functional progenitors leads to inadequate circulating functional blood cells with consequent anaemia, risk of infection and defects of haemostasis. The disorders which may be generated by occupational exposures are aplastic anaemia, myelodysplastic syndromes (MDS) and acute myeloid leukaemia (AML).

**Aplastic anaemia**

Aplastic anaemia is a rare disease (1–2 × 10^6 population/year in the West), defined by the presence of a peripheral blood pancytopenia and a hypocellular marrow. Remaining blood cells have more or less normal morphology (Figure 90.5a,b). The cause of the bone marrow failure lies in the pluripotent stem cells, but in some cases and at certain stages of the disease one of the cell lines may be more severely affected than the others. About 15 per cent of cases are thought to be triggered by exposure to drugs or chemicals, about 10 per cent follow a hepatitic illness and the great majority are idiopathic. Among the chemical and physical agents associated with aplastic anaemia are those which invariably cause aplasia given a sufficient dose (benzene, ionizing radiation) and those which only do so occasionally (arsenicals, gamma-benzene hexachloride and other insecticides, glycol ethers, carbon tetrachloride). Hair dye containing paratoluenediamine and closely related compounds have been linked to several case reports of aplastic anaemia in non-occupationally exposed individuals having used the dye two to three weeks before the onset of symptoms. In such case studies, it is difficult to be certain whether the dye was the aetiological factor. Where a drug, chemical or virus has been identified as a likely cause of the marrow damage, the exposure is usually some 3–24 months before the effects of the pancytopenia become apparent. This is the idiosyncratic form of aplastic anaemia. Recurrent subclinical exposure to a myelotoxic agent, such as benzene, is associated with a much longer latent period. Cytopathetic abnormalities are uncommon and the disease may remain stable for years or may evolve to a more malignant phase of myelodysplastic syndrome and/or acute myeloid leukaemia with the emergence of clonal cytogenetic abnormalities. Any age group may be affected, but there are peaks in young adults and in those over 50. In severe cases (neutrophils <0.5 × 10^9/L, platelets <20 × 10^12/L and reticulocytes <20 × 10^12/L), the prognosis was very poor before the introduction of specific treatment with immunosuppression or stem cell transplantation. Five year survival following either treatment is of the order of 70 per cent, but patients treated with immunosuppression continue to have a high risk of developing abnormal clones, including MDS and AML.
Myelodysplastic syndrome

Myelodysplasia implies abnormal morphology of blood cell progenitors in the marrow. MDS is a collection of bone marrow failure disorders with various abnormalities of some or all progenitor cell lines, often with cytogenetic abnormalities and variable cytopenias, and functional abnormalities in peripheral blood cells. The syndrome becomes more common with increasing age. At one end of the spectrum, the syndrome overlaps with aplastic anaemia with a hypocellular marrow, at the other end it merges with AML. There have been various classifications of the syndrome, the most recent being the WHO classification and an International Prognostic Scoring System (IPSS) provides an important means of risk assessment for individual patients. Cyogenetic abnormalities, cytopenias and the presence of leukaemic blasts are poor prognostic factors. MDS may arise some years after chemotherapy for other malignant haematological diseases, secondary MDS having a poor prognosis usually evolving into AML.

Acute myeloid leukaemia

This is not the place for a detailed discussion of AML. The disease may be stratified into good-, standard- and poor-risk groups according to a number of molecular and cytogenetic findings. AML may arise de novo, secondary to idiopathic MDS or aplastic anaemia or following chemotherapy and/or radiotherapy (treatment-associated AML (tAML)). Particular cytogenetic abnormalities are found in tAML following specific treatment schedules. Alkylating agents, such as melphalan and cyclophosphamide, are associated with abnormalities of chromosome 5 and 7; topoisomerase inhibitors, etoposide and doxorubicin, cause leukaemias with translocation at 11q23. Other anomalies are found with other therapeutic agents.

BENZENE AND BONE MARROW FAILURE

Benzene is volatile and readily absorbed by inhalation or through dermal contact. It was formerly used as a solvent in a wide variety of manufacturing processes involving leather, rubber, paint spraying and removing, dry cleaning, printing, batteries, linoleum and metal plating (see Chapter 42, Organic chemicals). Benzene itself is no longer used as a commercial solvent having been replaced by non-aromatic organic solvents, but it is still used in some chemical processes and is present in coal derivatives and petroleum fractions and distillates. Insecticides are often applied in petroleum-based media and in these cases the precise component which is causative in the development of aplastic anaemia (the insecticide or solvent) is often unclear.

The haematological effects of benzene exposure vary widely between individuals. An early stage of benzene toxicity is leukopenia, particularly lymphopenia, which is reversible when exposure is withdrawn. More persistent exposure may lead to irreversible marrow damage though often with a latent period of 5–20 years. It is thought that metabolites of benzene are critical for its toxicity and variation in the metabolic pathway between individuals may account for some of the marked disparity in susceptibility to benzene in workers exposed to similar levels in the workplace.
**Aplastic anaemia**

The association of benzene with aplastic anaemia has been known about for nearly a century, but in countries where there are strict controls and substitution for other solvents has occurred, this is now rarely seen (see Chapter 42, Organic chemicals). Cases may still occur in developing countries and studies on exposed workers in China have been particularly illuminating for the epidemiology of benzene toxicity. The incidence of aplastic anaemia in the general population is 1–2 per 10^6 per year: a six-fold increase was observed in one study on exposed Chinese workers and as high as 15-fold in Italian shoe workers exposed to particularly high levels.

**Acute myeloid leukaemia and myelodysplastic syndrome**

Malignant clonal disorders may arise after benzene exposure with or without an aplastic or intermediate phase. The incidence increases with the dose and duration of exposure. Chronic exposure is more likely than acute poisoning to promote leukaemogenesis. Analysis of epidemiological studies suggests that there has to be a critical concentration of benzene, with exposure for several years (more than six years) before the increased risk of acquiring acute myeloid leukaemia becomes evident. Frequent short-term exposures at high levels (>100 ppm) may result in transient blood changes (leukocytosis, polymorphocytosis) with no apparent long-term effects. In contrast, repeated low-dose exposure above 20 ppm results in cytopenias (anaemia, leukopenia and thrombocytopenia). The role of occasional high exposures in addition to long-term chronic exposures in the risk of developing acute myeloid leukaemia is a difficult area to explore given the lack of detail in historical occupational history data. Although removal of such exposed individuals from a benzene-containing environment usually results in the disappearance of such peripheral blood abnormalities over a period of months, the long-term risk of aplasia or leukaemia is not known.

Since the first suggestion in 1928 that benzene may be associated with leukaemia, several epidemiology studies have established that there is a specific causal relationship between the development of acute myeloid leukaemia and chronic exposure to benzene (see Chapter 42, Organic chemicals). The metabolism of benzene is complicated and gives rise to several reactive metabolites both in man and experimental animals which interact with a number of highly complex biological processes. The profile of benzene metabolites produced is the result of a subtle interplay of oxidation and conjugation pathways and distribution of enzyme systems in the liver and other organs, as well as relative rates of perfusion in different organs and different species. Experimental studies in vivo and in vitro suggest that the timing, duration and concentration of exposure to benzene metabolites (hydroquinone, catechol and muconaldehyde) are important independent factors in predicting potential leukaemogenic effects. Furthermore, it has been shown that a greater number of these metabolites result from short-duration, high-level rather than from long-duration, low-level exposures.

The metabolites can cause chromosomal aberrations or deletions that can alter the regulation and function of gene expression and cell proliferation in the marrow. It is speculated that such effects may also play a role in the acute myeloid leukaemia induced by benzene in humans. The relationship of AML to benzene exposure bears some similarity to therapy-induced or secondary leukaemias in clinical practice and may indicate similar mechanisms of causation. Chromosomal aberrations involving chromosomes 5 and 7, either alone or in combination with other changes, are found in most patients with therapy-related myelodysplastic syndrome prior to the development of overt acute myeloid leukaemia and similar characteristic chromosomal aberrations have been found in some patients with benzene-induced leukaemia that were cytogenetically monitored from shortly after the onset of symptoms through a pre-leukaemic phase and until death. A cytogenetic analysis of therapy-related myelodysplasia/acute myeloid leukaemia, de novo acute myeloid leukaemia and refractory anaemia patients has revealed a critical region at band (5q31) that was deleted in all patients. However, there does not appear to be a unique set of chromosome anomalies caused by benzene exposure different from that seen in de novo leukaemias.

Epidemiological studies suggest that benzene concentrations of at least 20–25 ppm experienced over years, are necessary for the appearance of acute myeloid leukaemia in exposed individuals. In the past, refinery workers have been a target population for such effects, but recent studies have shown no consistently elevated risks in relation to acute myeloid leukaemia. This may be explained by lower levels of exposure.

**Non-Hodgkin's lymphoma and other haematological malignancies**

While experimental and epidemiological evidence is very strong for the association of benzene with aplastic anaemia, MDS and AML, that for non-Hodgkin’s lymphoma (NHL) is less certain. Cytogenetic mutations in circulating lymphocytes may be present for years following benzene exposure. Case–control studies have produced conflicting results, a finding reflected in review articles on benzene and NHL. Some studies suggest that organic solvents, including chlorinated hydrocarbons, may increase the risk of some types of NHL but not aromatic solvents such as benzene. On the other hand, an Italian study did find such an association. One difficulty is that NHL is a disparate collection of subtypes which may have very different triggers. Nonetheless, an occupational history
should be obtained from patients with NHL particularly to identify heavy exposure.

OTHER AGENTS AND APLASTIC ANAEMIA

There have been several case reports implicating the organochlorine lindane as a cause of aplastic anaemia, agranulocytosis or bone marrow hypoplasia.\textsuperscript{42–44} However, lindane exposure was only confirmed in two of the cases. There have been no reported cases following therapeutic use where dermal absorption was documented. Early epidemiological studies did not show an association.\textsuperscript{45} A more recent case–control study did show an association for woodworm treatment and aplastic anaemia.\textsuperscript{46} Many other agents involved in pesticides and organic solvents have been incriminated in aplastic anaemia cases. The difficulty is that there are no tests which can conclusively demonstrate such causality in individual cases and even in the rare disease only about 2–6 per cent have a potential association with these agents.\textsuperscript{13}

IONIZING RADIATION

This is radiation that penetrates tissues and generates secondary ionizations. It includes neutrons, a-particles, electrons, x-rays and g-rays. It may be further classified into particles with high linear energy transfer which do not penetrate deeply, but generate relatively high levels of ionization and waves with low linear energy transfer, such as x-rays and \(\gamma\)-rays, which penetrate more deeply but generate less ionization (see Chapter 53, Ionizing radiations). Bone marrow is the most sensitive tissue to radiation exposure and with increasing doses thereafter the gastrointestinal tract, skin, lungs and other tissues become affected.

BONE MARROW FAILURE

Pancytopenia with an aplastic marrow is a prompt but reversible response to therapeutic doses of radiation. This is mainly caused by damage and apoptosis in the rapidly dividing progenitor cell pool, sensitive to radiation. Larger doses produce damage to the stem cell pool with delayed onset of pancytopenia and increased risk of malignant change. The severity of the injury is dependent on the type, quality, dose, dose rate and tissue distribution of the radiation. Radiation-induced bone marrow aplasia is now an uncommon occupational hazard owing to stringent controls of exposure and health surveillance procedures in the nuclear industry and in radiological medicine. Accidental exposure does, however, still occur.

Uniform whole-body irradiation with 1–10 Gy of low linear energy transfer radiation produces pancytopenia predisposing the recipient to infections and bleeding usually two to four weeks after the exposure. In human bone marrow, the total number of nucleated cells is reduced at day 1 by 10–20 per cent after 1–2 Gy, by 25–30 per cent after 3–4 Gy, by 50–60 per cent after 5–7 Gy and by a maximum of 80–85 per cent after 8–10 Gy. Whole body irradiation up to 10 Gy is administered under carefully determined conditions in haemopoietic stem cell transplants for acute leukemias and other malignant disorders where the transplant rescues the patient from the irreversible stem cell loss. Resistant cells such as macrophages, stromal cells, vascular endothelium and some mature granulocytes and eosinophils remain.\textsuperscript{47} Doses exceeding 30 Gy damage the marrow microenvironment such that it can no longer sustain haemopoiesis.

In radiation accidents, the exposure may be difficult or impossible to quantify, but such information is vital in planning management. Not only is the total dose difficult to estimate, but the variation of dose across the bone marrow may not be quantifiable. Stem cell transplantation is only rarely an option because an accidental whole body dose producing irreversible marrow damage is likely to be associated with lethal damage to non-haemopoietic organs. In an early attempt to rescue subjects exposed to accidental radiation exposure which rendered them severely pancytopenic, all five patients transplanted recovered their own marrow function.\textsuperscript{48} The behaviour of haematological parameters can be useful in dosimetry estimations. The peripheral blood lymphocyte count is the most sensitive index of radiation injury and its fall is directly related to the whole body radiation dose up to doses of about 3 Gy. Neutrophils show an initial increase over the first few days after irradiation, then a dose-related fall. Between 10 and 15 days after a dose of 2–5 Gy, there is a second rise due to recovering haemopoiesis from precursor cell populations, followed by a second decline to about day 25. The time-course for platelet loss is similar to that for granulocytes, but usually there is no second rise. The severity of the thrombocytopenia is also a measure of the exposure dose.

Figure 90.6 shows data from accident cases, depicting the average time-courses for suppression and recovery of neutrophils, lymphocytes and platelets in man following irradiation.
Approximately three weeks after irradiation, patients become symptomatic as a result of the reduction in blood cell components. Where the radiation dose is less than 4–5 Gy, it is possible to support the individual with the use of blood and platelet transfusions and to treat infection with antibiotics appropriate to the pathogens isolated or suspected. If recovery is possible, it may be accelerated by the use of haemopoietic growth factors. Despite these measures, most victims (as found following the explosion at the Chernobyl nuclear power plant) receiving more than 5 Gy will not survive long enough for marrow function to recover.\(^\text{59}\) This is not solely due to the marrow aplasia, but reflects the other injuries the patient may have suffered such as trauma, burns, inhalational effects, diarrhoea, and fluid and electrolyte depletion. Haemopoietic stem cell transplantation would seem the logical treatment for this group of patients, but is fraught with difficulties. These include the poor prognosis conferred by multiorgan damage, the inability to perform histocompatibility testing due to lymphocytopenia, the lack of compatible donors for most patients and the requirement for further immunosuppressive conditioning.

**Leukaemia and MDS**

The causal relationship between leukaemia and ionizing radiation is well documented and much of the risk estimates are based upon the incidence of acute myeloid leukaemia and myelodysplasia among the survivors of the Nagasaki and Hiroshima atomic bombs in 1945. There was also an increased incidence of chronic myeloid leukaemia with expression of the classical Philadelphia chromosome marker.\(^\text{50}\)

The association of low level occupational exposures was established in studies on pioneering radiologists and radiation scientists\(^\text{51}\) and led to changes in radiographic procedures (see Chapter 53, Ionizing radiations). Significant numbers of excess leukaemias – acute myeloid leukaemia, chronic myeloid leukaemia and acute lymphoblastic – have been reported in medical radiation workers in China during the period 1950–85.\(^\text{52}\) The possibility that leukaemia and lymphoma could result from low level exposures to waste products from nuclear power plants has received extensive attention in the United Kingdom and elsewhere following the finding of geographic clusters of acute lymphoblastic leukaemia (ALL) around such plants.\(^\text{53,54}\) Careful case-control studies did not confirm any link with the radiation from the plant and similar clusters are found with no nearby nuclear plant.

**NON-IONIZING RADIATION**

There is considerable debate regarding the possibility that the very low frequency waves of electromagnetic fields, such as those around electricity power lines,\(^\text{55}\) household\(^\text{56}\) and workplace appliances,\(^\text{57}\) may have leukaemogenic effects. The profusion of population variables make such studies difficult to carry out and small effects may be present without being detectable. In addition, no clear distinction was made between the effects of electrical and magnetic fields. There is a view that while the risk may be small the populations at risk are large. Animal studies have not been helpful in elucidating any causative mechanisms and further studies are required (see Chapter 55, Extremely low frequency electric and magnetic fields).

**OTHER OCCUPATIONS AND OCCUPATIONAL AGENTS**

**Leukaemias**

There have been consistent reports of an increased risk of leukaemia in other occupational groups, such as electrical workers, printing workers and workers in the rubber industry. There is no indication of the agent that might be involved in these reports, but there is some speculation that benzene which was used as a solvent, especially in the rubber industry, might have been one of the factors.

**Hodgkin’s disease and non-Hodgkin’s lymphoma**

Several studies have indicated an increased risk of Hodgkin’s disease in woodworkers with tasks ranging from the manufacturing of furniture to the installing of fences.\(^\text{58,59}\) Eight of the studies showed an increased risk, although the studies involved different methods and were carried out in three countries. However, the consistency of the results would suggest that association is unlikely to be due to chance, but no specific factor in terms of causative agent linked the studies.

Studies in farmworkers have suggested an increased incidence of non-Hodgkin’s lymphoma.\(^\text{60}\) It has been speculated that possible farm risks would include elevated exposures to pesticides, agricultural chemicals, organic and inorganic dust, zoonotic pathogens and sunlight. The agricultural factor most prominently linked with non-Hodgkin’s lymphoma has been exposure to phenoxycetic acid herbicides\(^\text{61,62}\) or insecticides.\(^\text{63}\) Organophosphate pesticides are known to inhibit serine esterases, which are important in T cell and natural killer cell cytolytic activity and may play an important role in lymphomagenesis through an immunosuppressive mechanism.\(^\text{64,65}\)

Finally, fungicides and fumigants have also been associated with increased risks of non-Hodgkin’s lymphomas. One study\(^\text{66}\) strengthened the hypothesis in relation to exposure to phosphated insecticides by showing a dose–response relationship which was also suggested for stannates, carbamates, chlorinated compounds and for DDT. Exposures to such a variety of chemicals make the identification of a
A 56-year-old expatriate plant manager at an overseas petrochemical refinery had a routine executive medical examination. He was asymptomatic and physical examination was normal. The results of the full blood count were as follows: haemoglobin 12.8 g/dL, mean corpuscular volume (MCV): 100 fL, white cell count: 5.5, neutrophils: 1.5, lymphocytes: 2.0, monocytes: 1.5, eosinophils: 0.5 (all normal). The results of other secondary leukaemias, such as those following chemotherapy and dermal exposure was reported and no protective measures were taken. It would have been valuable to know whether any of the high exposures had any short-term effects on the haemopoietic system, such as pancytopenia or marrow hypoplasia, although the history was not suggestive of this.

The marrow showed evolution from myelodysplasia to acute myeloid leukaemia with characteristic biological and clinical features. These features are not diagnostic of benzene-related leukaemogenesis and are shared with other secondary leukaemias, such as those following chemotherapy. They are:

1. the long latent period lasting many years;
2. the complex chromosomal abnormalities particularly involving loss or interstitial deletions of chromosomes 5 and 7;
3. the low remission rate in response to chemotherapy;
4. the poor prognosis.

Case study 2: Haemolytic anaemia

During the summer vacation, a 23-year-old, final year medical student presented to his general practitioner on a Friday evening with vague flu-like symptoms, headaches and a dry cough. He was a keen athlete and had noticed a
decrease in his exercise tolerance over the previous week. Physical examination was unremarkable other than a comment in the general practitioner’s notes that he looked ‘pale and grey’.

The young man was told that it was probably a viral infection and was asked to return if there was no improvement in his symptoms. He felt better over the weekend, but the symptoms returned the following week and he noticed a consistent change in the colour of his urine. His partner, who was a nurse, thought that he looked slightly jaundiced, especially at the end of the day. He also felt increasingly tired and had several bouts of shivering.

The general practitioner confirmed the clinical impression of mild jaundice and requested a urine test and some haematological and biochemical investigations. The student continued with his studies and took an interest in its normal characteristics after ten days. The medical student asked the company revealed that the pilot plant was investigating a novel halogenated aniline compound. The health and safety data sheet revealed that the compound was likely to cause blood problems by inhalation or dermal exposure and warned of the specific risk of methaemoglobinemia and haemolysis.

**COMMENTARY**

This case highlights the importance of all personnel involved in the handling of toxic substances being fully informed of the risks and safety procedures. This includes not only regular employees who are directly involved with the primary handling, but also casual staff and those who may be involved in cleaning and disposal. While the substance was labelled as hazardous on the containers from the manufacturers and full-time employees were aware of the risks, health and safety checks had not identified the individual illustrated in this case in its risk assessment.

The blood tests showed the pattern of increased red cell destruction (hyperbilirubinaemia, increased urinary urobilinogen, reduced haptoglobins, polychromasia, reticulocytosis) with evidence of intravascular haemolysis (haemoglobinuria, haemosiderinuria). The direct antibody test excluded an immunological mechanism of the increased red cell destruction and the presence of methaemoglobinemia was consistent with oxidative haemolysis.

The patient’s symptoms recovered completely within four to five days and his haematology profile had resumed its normal characteristics after ten days. The medical student continued with his studies and took an interest in toxicology.

**Key points**

- The bone marrow and blood are targets of assault from a number of toxic agents to which workers may be exposed.
- The bone marrow is particularly susceptible to agents which interfere with proliferation and differentiation of rapidly dividing cells.
- Benzene and radiation are two examples where excessive exposure may result in bone marrow failure syndromes, including aplastic anaemia, myelodysplastic syndrome and acute leukaemia.
- The latency of emergence of bone marrow failure from exposure may be several years. A careful and extensive occupational history is required in assessing bone marrow failure syndromes.
- Circulating red blood cells are particularly susceptible to agents which cause oxidative stress which may cause acute haemolytic anaemia and/or methaemoglobinemia.

Shift work and extended hours of work

GIOVANNI COSTA, SIMON FOLKARD AND J MALCOLM HARRINGTON

INTRODUCTION

The arrangement of working hours has become a crucial factor in work organization, and may vary with the economic and social consequences that can arise at different periods in the worker’s life. Not only has the link between workplace and working times been broken (for example, through teleworking), but also the borders between working and leisure times are no longer fixed and rigidly determined by the normal working day. Working hours are extended to evening and night hours, as well as to the weekend, and hours of duty have become more and more variable (the ‘24-hour society’).

In this context, shift work is the most common form of working time and enables round-the-clock activities not only in relation to rigid technological conditions (e.g. the chemical and steel industry, power plants) and necessary social services (e.g. hospitals, transportation, electricity, telecommunications), but also to support productive and economic choices (e.g. textile, paper, food, mechanical industry, banking), as well as the wider use of leisure time (e.g. entertainment). Shift work includes any arrangement of daily working hours that differs from standard day work. It is aimed at extending the organization’s operational time from 8 hours up to 24 hours per day, by means of a succession of different teams of workers.

According to the results of the 3rd European Survey on Working Conditions outlined in Ref. 1, only 24 per cent of the working population (27 per cent of employed and 8 per cent of self-employed workers) were engaged in the so-called ‘normal’ or ‘standard’ day work, that is between 07.00–08.00 (7–8 a.m.) and 17.00–18.00 (5–6 p.m.), from Monday to Friday. This means that the vast majority of workers are engaged in ‘non-standard’ working hours, including shift and night work, part-time work, weekend work, compressed work week, extended working hours, split shifts, on-call work, etc.

Working schedules can vary widely, in particular (1) duration of duty period (i.e. from 6 to 12 hours); (2) presence and extension of night work (i.e. between 24.00 (12 p.m.) and 05.00–06.00 (5–6 a.m.)); (3) permanent or rotating shift schedules (i.e. people work regularly on one shift or alternate periodically on different shifts); (4) continuous or discontinuous shift systems (i.e. all days worked or interruption on weekend); (5) start and finish time of the duty periods (i.e. between 04.00 (4 a.m.) and 07.00 (7 a.m.) in the morning, between 20.00 (8 p.m.) and 24.00 (12 p.m.) at night); (6) number of workers/crews who alternate during the working day (i.e. two, three or four shifts); (7) speed (i.e. ‘fast’, every one–two or three days, or ‘slow’, every 15–30 days) and direction of shift rotation (i.e. ‘clockwise’, morning–afternoon–night, or ‘counter-clockwise’, afternoon–morning–night); (8) number and position of rest days between shifts; (9) length of shift cycle (i.e. from six to nine days up to six months or more); (10) regularity/irregularity of the shift schedules.

According to the 4th European Survey on Working Conditions, weekly working hours range from an average of 34 hours in the Netherlands to 55 hours in Turkey, and from a minimum of eight hours (as part-time work) to a maximum of 90 hours (as overtime work). Shift work, which includes night work, involves more than 17 per cent of the total working population, with large differences among the countries (from 6.4 per cent in Turkey to 33.5 per cent in Croatia).
In 2004, almost 15 percent of full-time salaried workers in the USA usually worked on alternating shifts including nights. In the United States, men were more likely than women to work such shifts (16.7 and 12.4 per cent, respectively); blacks were more likely than whites, Hispanics or Latinos, or Asians; and shift work decreased progressively with age.3

Extended working hours refers to working for longer than eight to nine hours per day, and 40 hours per week. According to the International Labour Organization, annual hours worked per person surpassed 1800 hours in 27 countries out of 52 monitored from 1996 to 2006, and 2200 hours in six Asian economies.4 In the United States, almost one-third of the workforce regularly works more than the standard 40-hour week and one-fifth more than 50 hours.5 In Europe, according to the 4th European Survey on Working Conditions, 16.9 per cent workers of the 27 EU member states worked 48 hours per week or more, ranging from 11.1 per cent in Luxembourg to 32.1 per cent in Turkey.2

Working irregular or extended hours may have negative consequences for health and well-being due to the stress derived from interference with psychophysiological functions and social life. The majority of the studies up to now have focused on shift work rather than on extended working hours since they are often confused. However, some recent studies have addressed this second aspect independently, with some contrasting results.5,6

BIOLOGICAL AND SOCIAL INTERFERENCE

Circadian rhythms and psychophysiological conditions

It is commonly accepted that work efficiency at night is not the same as during the day. Man is a diurnal creature, synchronized to the 24-hour light/dark cycle, who is naturally awake and active during daylight and consequently resting and sleeping at night. This behaviour is determined by the regular oscillation of bodily functions (‘circadian rhythms’). For example, core body temperature decreases during the night when people are asleep down to a minimum of 35.5–36.0°C in the early hours of the morning, and increases during the waking day to reach a maximum (acrophase) of about 37.0–37.3°C at around 17.00 (5 p.m.). This rhythmicity is controlled by a strong endogenous oscillator (or body clock), located in the suprachiasmatic nuclei, and is influenced by environmental factors (synchronizers), such as work, activity, sleep, meals and, in particular, light exposure.7–9

Night work forces the individual to change their normal sleep/wake cycle and to attempt to adjust to the nocturnal activity by a progressive phase shift of circadian rhythms that may be more or less complete depending on the number of successive night shifts. However, circadian rhythms very seldom show a complete inversion, rather there is a flattening of their amplitude and a dissociation between them due to differing rates of adjustment of the rhythms in the variables concerned. Indeed, even in permanent night workers, the vast majority show insufficient adjustment of their body clocks for it to be of any real benefit.10 The general lack of circadian adjustment is due both to the continuous rotation through the different shifts on most shift systems, and to the fact that most individuals try to maintain a normal, day-oriented, social and family life during their free time and on rest days.

These rhythmic disturbances may have negative effects on health and well-being. In the short term, people may suffer from symptoms similar to those of jet lag and characterized by feelings of fatigue, sleepiness, insomnia, digestive troubles, and reduced mental ability and performance efficiency. In the longer term, such rhythmic disturbances may, often in combination with other factors, eventually result in the manifestation of a wide range of complaints and illnesses (see under Effects on health).11–14

Performance efficiency

Human error is often cited as an important factor in work-related accidents and depends on sleep and sleep-related factors, as well as on circadian rhythms in alertness and performance capabilities. Alertness can be substantially reduced by irregular rest/activity patterns and by prolonged physical and mental effort. In general, performance efficiency appears to parallel the circadian rhythm in body temperature, but it can peak earlier or later in the day depending on the demands of the task (e.g. physical, cognitive or memory-loaded), on the length of time that has elapsed since the individual’s last proper sleep, and on their general level of arousal and motivation.

The dissociation of circadian rhythms in combination with the associated sleep deficit and fatigue may significantly impair work efficiency, in particular at night, making the worker more vulnerable to errors. This pattern has been reported for many groups of shift workers including train and truck drivers, nuclear power workers, nurses, switchboard operators and seamen. A ‘post-lunch dip’ has also been noted which appears to be only partially dependent on the meal itself, and which may also reflect 12-hour or shorter ‘ultradian’ rhythms in alertness and wakefulness superimposed on the 24-hour circadian cycle.15,16

In addition, sleepiness due to the truncation of sleep by an early start to the morning shift has been shown to cause a higher frequency of errors and accidents in train and bus drivers, while increased sleepiness and changes in electroencephalogram (EEG) ultradian rhythms (bursts of alpha and theta power density) have been recorded on the night shift, indicating a high propensity for the workers concerned to fall asleep ‘on the job’.17

Family and social life

People engaged in shift work or extended working hours can face greater difficulties in their social lives since most
Activities are arranged according to the day-oriented rhythms of the general population. In addition, weekend work may interfere with various social activities, such as sports events, religious ceremonies, travel and entertainment. Shift workers thus face more difficulties in combining their time budgets (work hours, commuting and leisure times) with the complex organization of social activities, particularly when these require regular contacts and involve a great many people. Hence, shift work can lead to social marginalization.

Shift work and extended working hours may also hinder the already complex coordination of family timetables, with the extent of any such hinderance depending on factors such as family composition and duties (e.g. marital status, number and age of children, housework, moonlighting and illnesses) and the organization of social services (e.g. school and shop hours and public transport). ‘Time pressure’ is a constant condition among those who have pressing family responsibilities (e.g. women with small children). These complaints may be further complicated when both partners have the same working conditions (i.e. as shift workers or with long working hours), and this can have negative effects on marital relationships, parental roles and children’s education. Complaints from shift workers about family and social difficulties are more frequent than those related to biological adjustment, and are often the main cause of shift work intolerance.

On the positive side, shift work can give more flexibility to those who enjoy solitary activities and to those who give a higher priority to family and domestic duties than to personal leisure. Consequently, shift work is sometimes popular since it provides greater opportunities to use daytime hours to meet particular needs (e.g. access to public offices), or simply allows longer spans of rest days between shift cycles. For this reason shift systems that include ‘quick off’ (working two shifts in one day) and compressed shift cycles. For this reason shift systems that include ‘quick returns’ (working two shifts in one day) and compressed working weeks (e.g. three or four days of 12 hours per day) are often preferred because of the longer spans of rest days, despite the clear negative effects of such systems on sleep and performance efficiency.

**EFFECTS ON HEALTH**

**Sleep, chronic fatigue and psychoneurotic troubles**

Sleep is the main function that is disrupted by shift work. Sleep duration is typically reduced before morning shifts, depending on their start time, and between night shifts because the individuals are trying to sleep when their body clocks expect them to be awake. People may have difficulty in falling asleep and remaining asleep during the day, while the environmental conditions (lighting and noise in particular) are also often far from ideal. Some interference occurs with the daytime sleeps between night shifts (in particular a reduction in stage 2 and rapid eye movement (REM) sleep, whereas slow wave sleep (SWS) sleep is unaffected, although irregularly distributed) and for the truncated night sleeps before morning shifts (again with a loss of stage 2 and REM sleep due to the early wake up).

The decreased length of main periods of sleep and early awakenings are strongly associated with increased sleepiness during the rest of the day and a higher recourse to napping. Naps may partially compensate for sleep deprivation and have a prophylactic effect in counteracting the fall in alertness if properly taken before or during the work shifts. The length of the nap seems less important (20 minutes and two hours may have the same value) than its temporal position in relation to the duty period.

Both homeostatic (time elapsed since prior sleep termination) and circadian (sleep/wake cycle) components interact in determining the extent of the reduction in alertness and psychophysical performance over the waking day, and even more so at night. This may be further aggravated by features of the work schedule, and in particular the number of night shifts in succession, the start time of morning shifts, and shorter rest periods between shifts (i.e. ‘quick returns’).

The disturbances of sleep can be both severe and long lasting, and may eventually lead to an increased incidence of symptoms of chronic fatigue, nervousness, persistent anxiety, and depression, which may require the administration of psychotropic drugs. This has been confirmed in both cross-sectional and longitudinal survey studies using standardized psychological health questionnaires. Rather fewer studies have reported the incidence of those clinically diagnosed as suffering from psychological health problems, and those that have suffer from problems of adequate, matched control groups. Nevertheless, stress-related symptoms are relatively common in people working extended hours, particularly if associated with high work loads or monotonous, repetitive jobs. There is also some evidence that these symptoms may act as a risk or aggravating factor for other psychosomatic complaints or diseases including symptoms of gastrointestinal and cardiovascular health.

**Digestive and metabolic disorders**

Many shift workers complain of digestive disorders, reflecting on both the irregularity of meal timing and the poor quality of the food consumed, namely an increased consumption of prepacked meals and caffeinated drinks. Studies carried out over the last 50 years have shown that 20–75 per cent of night and shift workers, compared to 10–25 per cent of day workers, complain of disturbances of appetite, irregular bowel movements, constipation, dyspepsia, heartburn, abdominal pains and flatulence. In the longer term, many workers also develop more serious disorders, such as chronic gastritis, gastroduodenitis and peptic ulcers. A review of epidemiological studies found a generally higher prevalence of such disorders (from two to
five times higher on average) amongst shift workers whose work schedule included night work.\(^{24}\) However, improved diagnostic methods (endoscopy), better aetiological definition of peptic ulcer (i.e. Helicobacter pylori) and more appropriate therapies have recently changed the course of the disease, and hence its prevalence, as well as allowing people to continue shift working without major problems.

In recent years, an increased prevalence of metabolic disturbances in shift workers has also been emphasized.\(^{25,26}\) It has been suggested that these may reflect several factors, and in particular (1) a mismatch of circadian rhythms of anabolic and catabolic phases; (2) changes in daily lifestyle (i.e. unbalanced diet, irregular timing of food intake, nibbling carbohydrates and increasing consumption of caffeinated or alcoholic drinks at night); and (3) disturbed sociotemporal patterns (i.e. time pressure, work–non-work conflicts) with consequent higher stress levels.\(^{27}\)

A higher prevalence of overweight and obesity and increased blood triglycerides levels has been found in several studies of both shift work\(^{26–29}\) and extended hours,\(^{30,31}\) whereas somewhat inconsistent findings have been reported for total and HDL cholesterol levels. With respect to glucose intolerance, a higher prevalence (two-fold) of type 2 diabetes in shift workers compared to day workers has been reported by two studies,\(^{32,33}\) while a single study has reported an increased risk (RR = 3.73) for type 2 diabetes associated with a >50 hour/week overtime.\(^{34}\)

### Cardiovascular diseases

A number of epidemiological studies have indicated an association between shift work and cardiovascular diseases. More specifically, there is (1) an increased prevalence of cardiovascular risk factors among shift workers; (2) a higher morbidity due to cardicirculatory and ischaemic heart diseases with increasing age and shift work experience; and (3) an increased relative risk of myocardial infarction in occupations with a high proportion of shift workers.\(^{25,35}\)

It is worth noting that several possible confounding factors may also act as mediators or modifiers of the effect, such as age, smoking, diet and social class. The conclusion of a review of 17 cohort and longitudinal studies of shift work was that shift workers have a 40 per cent excess risk for cardiovascular disease compared to day workers, but that in the age group of 45–55 years, the relative risk rises to 1.6 in men and 3.0 in women.\(^{36}\) Moreover, the relative risk for coronary heart disease increases to 2.3 when shift work is associated with obesity, and to 2.7 when associated with smoking (which alone has a RR of 1.6).\(^{37}\) Furthermore, since smoking is often increased in shift workers, it can be viewed not only as a confounding variable, but also as an intermediary between shift work and ischaemic heart disease.\(^{35,38}\)

With respect to extended hours, Japanese studies have indicated a two-fold increase of myocardial infarction in people working more than 60 hours per week\(^{39}\) or 11 hours per day,\(^{40}\) but the findings for hypertension have been inconsistent.\(^{31}\)

### Accidents

As mentioned under Biological and social interference (p. 1234), shift workers may be more prone to errors and work accidents due to reduced vigilance and performance capabilities, than their day-working counterparts. However, while some studies have reported a higher overall incidence of injuries and accidents on the night shift, others studies have found inconsistent effects.\(^{24}\) These inconsistencies reflect a large number of potentially confounding factors, such as differences in the work sector studied or jobs examined, which may influence the relative risk of accidents. The most important factors relate to the manner in which work is organized on the different shifts. For example, maintenance and supervision are often largely confined to the day shift(s), while long, 'easy', runs of a particular job may be saved for the night shift. Furthermore, the day shift may be 'augmented' by permanent day workers, thus increasing the likelihood of accidents on the day shift. It is noteworthy that in the studies in which the a priori risk appeared to be constant across the 24-hour day, industrial injuries were higher on the night shift, and also showed a bigger increase over successive night shifts than over successive day shifts.\(^{42–44}\)

Other studies have shown peaks in accidents at around 10.00–11.00 (10–11 a.m.) and 15.00–16.00 (3–4 p.m.) which probably reflect peaks in work activity since performance capabilities due to circadian rhythms should be relatively high at these times. There is, however, evidence that both long working hours and an early start time to the morning shift may be associated with an increased accident risk.\(^{45}\) It is clear that careful attention needs to be paid to the potential accident risk when considering work schedules and other organizational factors. Indeed, it is noteworthy that the nuclear incidents at Three Mile Island and Chernobyl, the Bophal disaster, and many air accidents including the Challenger space shuttle, all occurred at night. Furthermore, in each case, shift scheduling and fatigue due to sustained operation were cited as important contributory factors.\(^{46}\)

### Absenteeism

Despite inconsistencies, a number of authors have cited the influence of aspects of shift scheduling on absenteeism rates, including the speed of rotation, the amount of overtime, and the shift start and finish times.\(^{37,46}\) It should be noted that, in addition to the 'healthy worker effect', there are a number of reasons why shift workers may show lower absenteeism rates despite higher frequencies of complaints and illnesses. These may include (1) a higher solidarity with colleagues since an unexpected absence may cause more
problems for shift handovers than for normal day work; (2) a higher threshold in the reporting of complaints and symptoms since shift workers more often accept them as ‘part of the job’ (e.g. digestive and sleep disorders); and (3) a higher punctuality rate since shift workers are less likely to have to travel to work during rush hours and have fewer problems accessing public offices during working hours. Finally, data on absenteeism are also inconsistent for extended work hours, probably due to confounding factors, such as motivation, work pacing and type of job.41,49

Women’s reproductive function

There is good reason to assume that shift work may be a peculiar problem for women’s health. This follows both from the potential disruption of their hormonal cycles and from the increased stress caused by the conflict between their irregular working schedules and their domestic duties. Disorders of the menstrual cycle, reproductive function and pregnancy outcomes have been reported in many groups of women shift workers, including a higher incidence of menstrual pains and abortion and interference with fetal development, such as premature births and/or low birth-weight.50–53 A meta-analysis of six studies carried out between 1987 and 1997 also suggested a weak but significant (RR = 1.24) association between extended working hours and preterm birth.54 Women shift workers, especially those married with small children, may also have more difficulties in combining their irregular working schedules with their additional domestic duties, and may thus suffer more from sleep troubles and chronic fatigue than their male colleagues.20,55 Indeed, some national legislation protects shift working women, e.g. exemption from night work when pregnant, and the possibility to transfer to day work during the first two to three years of age of their children.

Toxicological risk

Shift workers may be particularly susceptible to xenobiotics due to (1) potential fluctuations in the environmental concentrations of pollutants and a concomitant increase in risk at certain times of day; (2) the reduced interval between shifts; (3) pronounced circadian rhythms in the metabolism and excretion of toxic substances; and (4) the potentially detrimental consequences of circadian disturbances. Experimental chronotoxicology studies have demonstrated circadian rhythmicity in the activity and effectiveness of some toxic compounds (i.e. mercurials, cyanides and organophosphate pesticides), as well as variations in susceptibility after changes to the light–dark regimen. Thus, the balance between the ‘biokinetics’ of the substance and the ‘chronoesthesy’ of the biological system is more likely to be unfavourable at night when metabolic function is slowing down. This was dramatically demonstrated by the Bhopal disaster when, surprisingly, none of the night workers died from the vapours of methyl isocyanate, but thousands of inhabitants of the near villages died in their sleep. At the same time, thousands of cattle died while nocturnally active rats were observed to be scurrying around the corpses and carcasses.56

Risk assessment and biological monitoring should take into account circadian fluctuations in physiological responses (in terms of absorption, metabolism and excretion) and the consequent severity of the toxic effect. This should be evaluated not only with reference to environmental threshold limit values (TLVs) and biological exposure indices (BEIs), but also for evening and night shifts, as has been suggested for prolonged, 12-hour shifts. Indeed, some studies have already shown a circadian excretion pattern of toxic substances or metabolites that can be used for better strategies in workers’ biomonitoring.57,58

Mortality

Apart from the first negative report in 1949 (cited in Ref. 59), there have been only three well-controlled studies that have examined the mortality rates of shift workers. The first study was of 1578 deaths in 8603 male British industrial workers from 1956 to 1968.60 The overall number of deaths was very close to that expected from national mortality rates, and no significant excess mortality was found in either the shift (722 versus 711.4) or ex-shift (120 versus 100.9) workers. Shift workers in some age groups had a significant excess (e.g. in those under 60 years old for atherosclerotic heart diseases), but this was not consistent across work organizations and types of shift work. However, a recent re-analysis of the mortality rate ratios, adjusted for age, showed that former shift workers had a slight, but significantly, increased mortality risk compared with day workers (RR = 1.24; 95 per cent CI, 1.03–1.51).61

The second, Danish, study followed 1123 shift workers and 4084 day workers over a 22-year period. The relative death risk was 1.1 (95 per cent CI, 0.9–1.3) for shift workers after adjustment for age and social class.62 The third study was based on a Swedish survey of 22 411 individuals between 1979 and 2000. The results, adjusted for age, stress, physical work load, disease at the outset of the study and smoking, showed no significant difference between shift and day workers in general, but an increased hazard ratio for female white-collar shift workers (HR = 2.61; 95 per cent CI, 1.26–5.41).58

With respect to extended hours, a Swedish survey of 2632 workers carried out from 1973 to 1996 reported that more than 5 hours/week overtime increased all-cause mortality in men (RR = 2.0) at 5-year follow up, and women (RR = 1.92) at 24-year follow up, when controlling for the other most important risk factors.63

Cancer and shift work

Several recent epidemiological studies have examined the association between cancer and shift work. A slightly
higher incidence of breast cancer in women engaged in shift work, including night work has been reported in four studies of nurses (OR or RR 1.36–2.21), in four studies of flight attendants (standardized incidence ratio between 1.42 and 2.0), and in one study of sea radio and telegraph operators (OR = 1.5). These studies controlled for several important confounding factors (i.e. age, menarche, parity, menopausal status, family history, body mass index (BMI), contraceptives) but were limited with respect to the quantification of the exposure (both in terms of the definition of night work and the characteristics of the shift schedules), and with respect to the potential exposure to other proven carcinogens, i.e. antineoplastics, x-rays, cosmic radiation and electromagnetic fields).64,65

Possible explanations for such an association are based on perturbations of melatonin secretion and changes in gonadotropin axis resulting from the disruption of both dark–light exposure and sleep–activity patterns, with a consequent deregulation of circadian genes involved in cancer-related pathways (i.e. inactivation of Per2 and inhibited expression of Period genes) and reduced immune defences (suppression of natural killer-cell activity and changes to the T-helper 1/T-helper 2 cytokine balance), such as has been found in rodents.66

The International Agency on Research on Cancer (IARC) recently classified ‘shift work that involves circadian disruption’ as ‘probably carcinogenic to humans’ (Group 2A) on the basis of ‘limited evidence in humans for the carcinogenicity of shift-work that involves nightwork’, and ‘sufficient evidence in experimental animals for the carcinogenicity of light during the daily dark period (biological night)’.67

Ageing and shift work

Ageing is associated with a decreased ability to adjust to night work and an increase in sleep disturbances, such that night work may become less and less bearable with advancing age.68 More difficulties have also been reported in changing from 8- to 12-hour shifts in those aged over 50 years.69,70 Moreover, as people grow older, they tend to become more ‘morning type’, making it both more difficult to sleep during the day after night work, and more difficult to maintain alertness during the waking period.71,72

In general, health deterioration with increasing age may be more pronounced in shift workers than in day workers due to sleep problems and chronic fatigue, with a consequent reduction in work ability, and an increase in sick leave, sleep disorders and gastrointestinal and cardiovascular diseases.73–76 Moreover, older people obviously suffer more health problems, quite independently of shift work, and these may hamper their adaptation and tolerance to irregular and/or extended hours. On the other hand, it should be noted that the greater experience of older workers may have resulted in their having better coping strategies and countermeasures. This is particularly true in terms of work commitment, regular life regimen, more satisfactory job positions, better housing conditions and fewer domestic constraints.

### FACTORS AFFECTING TOLERANCE TO SHIFT WORK AND EXTENDED WORKING HOURS

It has been estimated that about 15–20 per cent of workers do not like shift work and suffer from serious problems that force them to leave, mainly due to circadian disruption and severe sleep problems. In contrast, around 10 per cent have no complaints since they are able to satisfactorily combine their personal attitudes and behaviours to their peculiar demands. The majority (70–75 per cent) simply tolerate shift work, showing various levels of (in)tolerance, that may be more or less manifested at different times and with different severity. Indeed, it is abundantly clear that a number of moderating variables, including individual differences, situational factors and social conditions, may significantly influence both the short-term circadian adjustment to, and the longer-term tolerance of night and shift work.12,77,78

Individual characteristics have been widely investigated in an attempt to determine which psychological and physiological factors are associated with either adverse health effects or a better tolerance, and hence may have important practical applications. Individuals who have a small amplitude of their circadian rhythms may have a less stable circadian structure (i.e. show larger phase shifts on abnormal work schedules) and may be more prone to internal desynchronization, thus having more long-term problems.57,79 Morning types (‘larks’) and evening types (‘owls’) also differ in their circadian adjustment to night work: the former appear to be less tolerant to night work since they have an earlier phase of their circadian system, while the latter have a later circadian phase, face greater problems in waking up early in the morning, and may suffer from an even greater truncation of their night sleeps taken before morning shifts.

There are a number of other personality traits and/or behavioural characteristics, including neuroticism, locus of control, rigidity of sleeping habits and the ability to overcome drowsiness, that may influence the degree of circadian adjustment and hence have a potential impact on long-term tolerance. In addition, physical fitness can improve sleep, lessen fatigue and increase performance, and may thus improve tolerance to night work, as may a strong commitment to shift work, since this is associated with more stable sleep timings and other circadian behaviours.80–83

With respect to family and social conditions, marital status, number and age of children, living with old and/or ill people, housing location and comfort (e.g. rooms, protection from disturbing noises) have all been shown to influence tolerance to shift work.84–86 For women in particular, the partner’s job (whether a shift worker as well),
the presence of small children, the organization of social services (i.e. school timetables, shop hours, public transport) and family support, are factors that may be important. It is well documented that married women with small children suffer from shorter and more fragmented sleep and from cumulative fatigue, and that they are obliged to significantly reduce their social relations and leisure activities.\textsuperscript{55,87-89}

Absenteism, work accidents, fatigue and the disruption of social and family life, are certainly enhanced by local factors, such as low social support, a lack of basic services, and long and uncomfortable commuting hours. Support from family and friends at home, and from co-workers and supervisors at work have been proved to enhance shift work adaptability and tolerance.\textsuperscript{90,91} Indeed, many surveys in developing countries have shown that the effects of night work on health and safety are often aggravated by less than favourable social conditions (e.g. low nutrition, education and salary; poor housing, community services and social protection, labour market restrictions and discrimination), that are also often connected with poor working conditions (environmental pollution, heavy work) and long working hours.\textsuperscript{92-95}

Even on the same work schedule, the cultural background and the socioeconomic conditions of each country or community may make the impact on health, safety and well-being quite different. In industrialized countries with high immigration levels, minority ethnic groups are often engaged in jobs with low pay and poor working conditions, including more shift and night work, with consequent negative effects on social integration.\textsuperscript{96} Furthermore, the specific arrangement of shift schedules is of paramount importance (see under Preventive and compensatory measures). The problem of tolerance to shift work is therefore multifaceted, with a high interindividual variability in terms of both clinical and temporal manifestations, due to the various complex interactions between personal characteristics, working and social conditions.

It is also noteworthy that the health troubles reported by shift workers are predominantly psychosomatic disorders that are quite common in the general population and have a multifactorial origin. They reflect the influence of several risk factors including genetic and family heritage, psychological characteristics, life styles, social conditions and intervening illnesses. Furthermore, their chronic degenerative nature makes their manifestation more likely to occur after long-term exposure and with increasing age. In this context, shift work may act as a further stress factor or a trigger as it combines conflicts between endogenous rhythms and social synchronizers with demanding working conditions and interferences with family and social life.

Consequently, the process of maladaptation, or intolerance, to shift work is variable in its speed of onset and intensity, depending on the differences in personal, working and social circumstances. Thus, health problems and disorders may manifest themselves at different life periods, with different degrees of severity and duration, and sometimes in an alternating or fluctuating way, thus further increasing the interindividual and intraindividual variability.\textsuperscript{97,98}

It is, as yet, unclear as to the extent to which the disturbance of biological rhythms influences long-term tolerance. However, it is commonly presumed that circadian disturbances, including those of sleep, are the main causes of intolerance to night work in the first years of shift work, whereas longer-term intolerance may be more related to other personal, working and social circumstances. An important confounding factor in this respect, is the process of self-selection that occurs in shift workers. Most of the epidemiological studies in this field have been cross-sectional and have considered workforces in whom an unknown number of individuals may have previously left shift work because of illness or social problems. Indeed, longitudinal studies have found it virtually impossible to follow up the same sample of shift workers over a prolonged period, due to the fact that many other factors (i.e. job demands, workload and pacing, shift schedules, rest pauses, motivation, decision latitude, flexible times, commuting) may be confounded. This may underlie the conflicting findings that in some studies long working hours are not a problem, while in others they can have severe health effects, related to higher stress, sleep deficit and fatigue.\textsuperscript{5,6,41,99,100}

### Preventive and Compensatory Measures

Since shift and night work are risk factors for health and well-being, medical examinations should be carried out with the dual aims of giving the workers suggestions and guidelines on how best to cope with shift work, and of detecting the early signs of intolerance to night work.\textsuperscript{101} The importance of this has been emphasized recently in international directives and recommendations. Thus the ILO Night Work Convention No. 171 and Recommendation No. 178 concerning Night Work (1990)\textsuperscript{102,103} and the European Directive 2003/88/EC concerning ‘certain aspects of the organisation of working time’,\textsuperscript{104} cover a number of specific measures for night workers, including health assessments prior to assignment to night work, at regular intervals thereafter, and in the case of any health complaints. They also state that night workers found to be unfit for night work for health reasons should be transferred, whenever possible, to day work.
Medical examinations should ensure an appropriate screening of workers who are going to be engaged in shift work in the first place, and then ensure that regular assessments of their continued suitability for night and shift work are conducted. With regard to the former, it should be emphasized that the ability to cope with a ‘bad’ shift schedule should not be used to ‘select’ shift workers. The primary aim should be to design shift schedules that minimize the potentially harmful consequences and to develop appropriate compensative measures. In this manner, disturbances to circadian rhythms, accumulation of a sleep debt and any marked interference with family and social life should be avoided, such that most people should be able to tolerate shift work without significant health impairment.

It would be totally inappropriate to develop a medical surveillance programme for people obliged to work an unfavourable shift system, because adoption of a better shift schedule would reduce the health complaints and the need for medical control or intervention. The main guidelines for designing better shift systems according to ergonomic criteria are:

- Night work should be reduced as much as possible (i.e. diluting it among workers by increasing the number of crews).
- Night shifts should be carefully planned. The greater the number of night shifts in a row, the greater the circadian and sleep disturbance and the accumulation of fatigue.
- Rotating shifts are preferable to permanent night work. Although permanent shifts may reduce circadian disturbances they are not normally acceptable for social reasons. However, if safety is paramount, permanent night shifts may improve performance levels.
- Quickly rotating shift systems (that change every one, two or three days) are preferable to slowly rotating ones (changing every five or more days), since they minimize circadian disruption and any cumulative sleep debt.
- Clockwise rotation (morning–afternoon–night) is preferable to the counterclockwise (night–afternoon–morning) since it avoids ‘quick returns’ (e.g. morning and night shift on the same day). It also parallels the natural tendency of the circadian system to delay slightly.
- Duration of shifts should be set according to psychophysical demand, with a view to minimizing sleepiness and fatigue, particularly on the night shift, while proper rest pauses should be planned throughout the duty period.
- Early starts to the morning shifts should be avoided to reduce the truncation of the previous sleep and the consequent increase in sleepiness, fatigue, and the risk of errors and accidents.
- Extended work days (9–12 hours) should only be contemplated when the nature of the work, and the workload, are suitable (adequate breaks, no overtime) and the shift system is designed to minimize the accumulation of fatigue and the exposure to toxic substances.
- Shift system should be as regular as possible to allow people to better plan their family and social life, and their coping strategies.
- Rest days should follow night shifts to allow adequate recuperation, while continuous shift systems should include as many free weekends as possible, and allow at least two consecutive days off between shift cycles.
- It is also desirable, and advantageous in terms of health and well-being, to allow flexible working time arrangements, and to encourage workers’ participation in designing tailor-made shift systems according to their needs and preferences.

In addition to the ergonomic design of shift schedules, other countermeasures that can prove beneficial include the compensatory reduction of working hours for night work, the introduction of additional rest breaks (for meals and naps), the addition of supplementary rest-days or holidays, the improvement of canteen and transport facilities, the improvement of social services (i.e. child care facilities, extended school and shop hours), specific education and training courses for shift workers, financial support for improving housing condition (i.e. sleeping rooms), transfer to day work after a certain number of years on night work, and gradual or early retirement.

**MEDICAL SURVEILLANCE**

It is clear that some complaints or illnesses may be a contraindication for shift work, particularly when it is associated with other stress factors such as heavy work, heat, noise, monotony or high cognitive demands. Thus, the occupational health physician needs to carry out an evaluation of both the working conditions and the health status of the individuals before assigning people to shift and night work. In the light of various suggestions given by a number of authors and institutions, it appears reasonable to propose the following strategies for medical intervention:

1. Consider exempting from night work all those suffering from severe complaints and disorders that could be connected to, or worsened by, shift work such as:
   a. chronic sleep disturbances;
   b. severe gastrointestinal diseases (e.g. peptic ulcer, chronic hepatic and pancreatic diseases, Crohn’s disease);
   c. chronic heart diseases (e.g. myocardial infarction up to 12 months or with impaired heart function,
angina pectoris, hyperkinetic syndromes and severe hypertension);

d. brain injuries with sequelae and severe nervous disorders, and in particular chronic anxiety and depression;

e. epilepsy requiring medication since seizures can be encouraged by sleep deficit and the efficacy of the treatment can be hampered by irregular wake–rest schedules;

f. spasmophily (i.e. chronic idiopathic or constitutional tetany), as temporal changes can be a promoting factor of tetanic crisis;

g. insulin–dependent diabetes, thyroid (thyrotoxicosis and thyroidectomy) and suprarenal pathologies, since they require regular drug treatment that is strictly connected to the activity/rest periods;

h. chronic renal impairment, since the disruption of circadian rhythms can further impair renal functioning;

i. immunological disorders and cancers, to avoid further stress and facilitate medical treatment;

j. pregnancy, particularly if there is a known risk of miscarriage.

2. Evaluate carefully before assigning to night work people who are or who have:

a. over 45–50 years of age, as it becomes more difficult to sleep at irregular hours;

b. digestive troubles or chronic respiratory diseases (asthma and chronic obstructive bronchitis);

c. alcoholism or other drug addictions;

d. marked hemeralopia or visual impairment, which can make night work difficult or dangerous in case of reduced illumination;

e. women with small children (under six years);

f. long distance commuters.

Particular attention should also be also paid to those who score highly on scales of neuroticism, morningness or rigidity of sleeping habits. In contrast, some individual characteristics and preferences could be considered to pre-dispose people towards shift work (see under Factors affecting tolerance to shift work and extended working hours, p. 1238).

Regular health checks should be aimed at detecting early signs of intolerance to night work which may require prompt organizational (e.g. change the shift schedule) and/or individual (e.g. improve coping strategies or transfer to day work) intervention. Such checks should focus primarily on sleeping times and troubles, eating and digestive problems, psychosomatic complaints, drug consumption, housing and commuting problems, workload, and out of job activities, preferably using standardized questionnaires or check lists in order to facilitate a comparison of the worker’s health over the years. Furthermore, the use of sleep logs, diaries of daily activities, some rhythmometric recordings (e.g. body temperature, performance) or hormonal dosages (e.g. cortisol, melatonin) may be helpful in evaluating the level of an individual’s (mal)adjustment.

Physicians should also bear in mind that shift work may worsen some disorders (e.g. sleep, digestive or nervous complaints) and hence hamper the efficacy of their pharmacological control, particularly when this requires a precisely timed administration and/or a stable life regimen, as is the case for diabetes, hypertension, asthma, hormonal pathologies, epilepsy and depression. In addition, people affected by seasonal affective disorders may encounter more difficulties in coping with night work, due to the lower exposure to bright light.

The frequency of medical examinations should be set by the occupational physician and take into account factors concerning both the working conditions (e.g. shifts rotas, environmental conditions, workload, etc.) and aspects of the individual (e.g. age and health condition). Many authors have emphasized the importance of careful monitoring during the first year of assignment to night work, since it may be critical for the development of effective coping strategies. At each periodical check the individual’s fitness for shift work should be re-evaluated if they complain of sleep, gastrointestinal, psychological or other related problems, or if they contracted any other illnesses that might hamper their psychophysical equilibrium and working capacity. Temporary exemption from night work should be considered in the case of transient health impairment or severe difficulties with family or social life.

It is also necessary to pay particular attention to older workers, for whom some specific recommendations can be given, such as the need to limit night work after 50 years of age, give such workers priority for transfer to their preferred shift (e.g. morning shifts), reduce work load (supplement crews), shorten working hours, increase rest pauses and increase the frequency of health checks (at least every two years). In addition, long-term medical surveillance (e.g. over five years) should be organized for any individual who leaves night or shift work for health reasons since there is evidence that these individuals may have a higher prevalence of sleep, gastrointestinal and cardiovascular disorders for several years after leaving shift work.

It is also desirable to give workers information and guidelines on how best to cope with night and shift work. Counselling and training should be carried out at both an individual and group level and educational programmes should be set up. They should deal with improving self-help strategies for coping, and in particular in relation to sleep hygiene, eating behaviour, stress management, physical fitness, housing conditions, transport facilities, out-of-work activities and proper exposure to bright light. Finally, the occupational health physicians should consider giving scientific and practical support to employers and trade unions in applying preventive and compensatory measures aimed at reducing the problems arising from night and shift work.
Key points

- Work schedules that disrupt the normal sleep–wake cycle and the endogenous body clock are becoming increasingly common.
- As well as disturbing sleep and family and social life, such schedules can result in impaired psychological and physical health and in an increased risk of injuries and accidents.
- The health problems associated with abnormal work schedules include anxiety, depression, gastrointestinal disturbances, cardiovascular diseases, reproductive problems and possibly cancer.
- There are substantial differences between individuals, associated with factors such as age, personality and health status, in their ability to tolerate shift work.
- Designing better work schedules and providing good medical surveillance may minimize the adverse consequences of abnormal work schedules.

light see eye
needle stick and sharps 731–2
repeated 687–712
welding 429, 429–31
see also accidents
trauma (psychological) see post-traumatic distress syndrome; resilience; stress
treatment
altitude sickness 583–4, 585
asthma 951
contact dermatitis 1067
haematological disorders, work-related issues resulting from 1226
hepatotoxic chemicals 1176, 1177
metal exposure/poisoning 44
arsenic 1157
beryllium 1052
cadmium 1133–4
copper 181
iron 186
lead 194–5, 1130
manganese 205, 208–9, 1158
mercury 217, 218, 1135
organic solvents 1139
tularaemia 776–7
tumour biomarkers 1111–12
see also cancer; carcinogens
tungsten ( wolfram) 241–2
tungsten arc (inert gas) welding 422–3
particle emissions 424
thorium-free electrodes 424
tungsten carbide, cobalt metal with 1045
and lung cancer 176, 1043–4
tunnelling see compressed air work
Twin Towers (World Trade Center) attacks, firefighter deaths 261
trigger finger 694
trimellitic anhydride 363, 364
trimethylamine 289
trimethyltin (TMT) 238, 239
trinitrotoluene 1182
trivalent chromium 152, 173, 174
TSI Nanoparticle Surface Area Monitor 916
tuberculosis (M. tuberculosis infection) 90
healthcare workers 739–40
silicosis combined with 1016–17, 1019
slate workers’ pneumoconiosis risk of 1033
tubular damage/dysfunction (renal) cadmium 168, 169, 1132
mercury 217, 218, 1135
organic solvents 1139
tularaemia 776–7
tumour biomarkers 1111–12
see also cancer; carcinogens
tungsten ( wolfram) 241–2
tungsten arc (inert gas) welding 422–3
particle emissions 425
thorium-free electrodes 424
tungsten carbide, cobalt metal with 1045
and lung cancer 176, 1043–4
tunnelling see compressed air work
Twin Towers (World Trade Center) attacks, firefighter deaths 261
twister’s cramp 699
tympanic membrane (eardrum) perforation at high altitude 574
temperature measurement 536
typhoidal salmonellae 760
typhus 9
ulcers (cutaneous) 1071
chrome 173, 1071
as frostbite sequelae, recurrent 531
ultrafine particles see nanoparticles and ultrafine particles
ultrasound
auditory effects 480
imaging with liver (after abnormal liver function tests) 1172
lung 878
in microgravity 611–12
reproductive effects 1207
ultraviolet radiation
ocular absorption 649
ocular damage acute 650, 651
pathophysiology 645
protective filter materials 657–8, 658
welding 423, 430
psoralens and UV-A 656
skin damage (incl. malignancy), welding 423, 429
see also sunlight
Union Carbide pesticide plant in Bhopal 253, 297, 364, 1237
United States and North America biotechnology (incl. genetic modification) regulations 784
cancer deaths 1098, 1099
compensation schemes 107–8

zeolites 1011
mesothelioma 1005, 1011
zinc 249–50
iron interfering with intestinal absorption 186
zinc chloride inhalation 437, 1041
zinc oxide fumes 250, 437, 1040
zinc protoporphyrin (ZPP) lead and 63–4, 192, 196, 197, 1128
vanadium and 247
zoonoses 750–70
The ebook edition of Hunter’s Diseases of Occupations, Tenth Edition, is in VitalBook™ format. You can download the ebook to your computer or access it anywhere with an internet browser. The ebook uses VitalSource® Bookshelf – a digital book reader which allows you to make and share notes and highlights on your ebooks, and search across all of the ebooks that you hold on your VitalSource Bookshelf.

DOWNLOAD AND READ OFFLINE

Downloading the ebook to your computer is a three-step process:

1. **Download the VitalSource Bookshelf.** If you don’t already have VitalSource Bookshelf, you will need to download it. Go to http://www.ingramdigital.com/downloads and follow the instructions on screen to download the VitalSource Bookshelf to your PC or Mac.

2. **Create your account.** Once installation is complete, double-click the VitalSource Bookshelf icon that appears on your Desktop and click the Register button to create your account. Fill out the form completely, including the redemption code shown on the scratch-off panel below. Then click the Register button.

3. **Download your ebook.** Once the redemption code has been redeemed your book will download automatically onto your bookshelf.

If you already have the VitalSource Bookshelf on your computer, select Redeem Code from the Help menu, enter the code, and click the OK button. Once the redemption code has been redeemed your ebook will download automatically onto your bookshelf.

ACCESS ONLINE

Alternatively you may prefer to access your ebook online:

1. **Create your account** at https://online.vitalsource.com/user/new – fill out the form and click the Register button.

2. **Enter your code.** Once you are registered and signed in, click the Account link at the top of the screen and select Redeem. Enter the redemption code shown on the scratch-off panel below in the Code To Redeem box and press Enter.

3. **Open your ebook.** Once the redemption code has been redeemed you will be able to view your ebook online, by clicking on its name in Online.

ACCESS ON YOUR IPHONE/IPOD TOUCH

You can find information about accessing your books through your iPhone/iPod Touch at http://support.vitalsource.com/faqs/vbso/gs-1003

ADDING NEW TITLES

Once you have created your account you can access the titles on your bookshelf and redeem new codes both online, by going to http://online.vitalsource.com/, and offline, by launching your Bookshelf application.

You can also buy other ebook titles from the VitalSource Store at http://store.vitalsource.com/

SUPPORT

If you have any questions about downloading Bookshelf, creating your account, or accessing and using your ebook edition, please visit http://support.vitalsource.com/
