Hunter's Diseases of Occupations
Dedication

Donald Hunter CBE MD FRCP
1898–1978

Physician, The London Hospital
Senior Censor, Royal College of Physicians of London
Director, MRC Department of Research in Industrial Medicine
Founder Editor, British Journal of Industrial Medicine
Author, Diseases of Occupations

### Preface

xvii

### List of abbreviations used

xix

### PART ONE – GENERAL CONSIDERATIONS

1. Donald Hunter and the history of occupational health: precedents and perspectives  
   Joseph Melling and Tim Carter  
   5

2. The changing face of occupational diseases  
   Peter J Baxter, Tar-Ching Aw, Anne Cockcroft, Paul Durrington and J Malcolm Harrington  
   24

### PART TWO – DISEASES ASSOCIATED WITH CHEMICAL AGENTS

10. Occupational toxicology: general principles  
    Peter G Blain and Robert D Jefferson  
    127

11. Risks and hazards in occupational and environmental exposures  
    Robert L Maynard  
    141
### Section Two: Metals

Preface

The publication of the previous (ninth) edition of Hunter’s coincided with the millennium, when in celebratory mood the preface referred to how in the previous 40 years a revolution in biomedical knowledge had led to a transformation of workplace health and safety, accelerating a decline of occupational diseases in advanced economy countries that ranked as one of the greatest triumphs of preventive health of the twentieth century. This success would not have been possible without governments legislating and providing resources to enforce controls in the workplace, with the most radical changes occurring in the 1970s.

The tenth edition goes to press at a very different time, however, with the world reeling in financial crisis and with voices calling for the regulatory ‘burden’ of health and safety on industry in the richest countries to be lifted. On the world scale, the concern is that the existing huge disparities in life expectancy between high and low income countries will get worse. These health inequalities stem from the circumstances in which people are born, grow, live, work and age. Despite the impressive improvements in advanced industrialized countries at the end of the twentieth century, the millennium predictions were for an increase in the global burden of occupational diseases, especially in those economies with large populations and undergoing rapid industrialization, such as Brazil, Russia, India and China, where the basic protections are still mostly lacking.

The need for an updated and comprehensive reference text on occupational diseases is therefore as great as ever. The early detection and diagnosis of occupational diseases depends upon knowledge of the workplace and the likely risks of exposure to workplace hazards, while the elimination of occupational diseases depends upon an effective regulatory framework, adequate risk assessments, and putting in place effective measures to control hazardous exposures. The tenth edition has new chapters on exposure and risk, and on the attribution of disease. The predominant types of work-related ill health have indeed changed over recent years in high income countries. Not all conditions encountered in the modern workforce fit the traditional pattern of defined exposures leading to specific diseases, and the sections on mental health and musculoskeletal disorders have been expanded to take into account their huge rise in prevalence and the sparse evidence base for their successful management. At the same time, it is shocking that classic ‘industrial’ diseases due to asbestos and silica that dominated occupational medicine in the twentieth century, including cancers, still remain as worldwide scourges, and new chapters have been included on their clinical epidemiology to highlight the continuing and serious problems they present.

Donald Hunter’s original work was not only a source of reference: it stood as a bulwark against the tide of global occupational disease. We thank the many authors who have contributed to this tenth edition and whose skill, we believe, will continue to make the volume an invaluable and constant force in the goal of disease prevention. As in previous editions, the book is intended to be an accessible, up-to-date and comprehensive text on occupational and related environmental conditions written for a wide range of clinical practitioners, for consultants writing legal reports, for lawyers, and for others seeking medical guidance on the risks to health of work activities and industrial processes.

With this edition, readers will have the additional bonus of on-line access to Hunter’s original chapters on the history of occupational medicine and a selection from his personal archive of photographs of patients and work processes, many of which illustrated his own editions. We anticipate that the publication of this unique material will be useful to students and many other readers interested in the history of disease.

We are grateful to Dr Paul Grime for providing us with access to the Hunter collection located at the Royal Free Hospital, London. Finally, we acknowledge the outstanding commitment and indefatigable efforts of Jo Koster, Head of Health Science Textbooks at Hodder Arnold, and Susie Bond, Project Editor, in so ably nurturing the book and bringing it to press.

Donald Hunter and the history of occupational health: precedents and perspectives

JOSEPH MELLING AND TIM CARTER

DONALD HUNTER: CLINICIAN, INVESTIGATOR, TEACHER, AUTHOR AND HISTORIAN

Donald Hunter, the son of a Post Office engineer, was born in 1898 in East London. He trained in medicine and qualified in 1922. After a year spent researching lead poisoning at Harvard in 1926, he worked at the London Hospital from 1927 until retiring in 1963. By the 1930s, Hunter had firmly established his lifelong interest in occupational health and a growing reputation as a commentator and teacher. In 1943, he became director of the Department of Industrial Medicine at the London, funded by the Medical Research Council. The following year, he became the first editor of the *British Journal of Industrial Medicine* and in 1955 he published *The Diseases of Occupations*. Hunter's encyclopaedic narrative has been compared with the pioneering works of Bernardino Ramazzini and Charles Thackrah, physicians who completed monumental studies of workpeople's diseases in the eighteenth and nineteenth centuries. Hunter remained deeply interested in the historical origins of occupational medicine, as well as the trends of disease and injury in the workplace.

Hunter's predecessors in Britain as authoritative writers in the field of occupational health were Thomas Arlidge (1822–99), Thomas Oliver (1852–1942) and Thomas Legge (1863–1932). They received their medical training in the Victorian period when industrial disease emerged as a serious subject for investigation. Their work is discussed below. Each had some sense of historical perspective and frequently drew on a range of classical and modern sources to exemplify their studies. However, it was Hunter's own contemporaries who undertook detailed historical research on the identification and treatment of occupational diseases, particularly in the mining industries. Notable publications in the United States, often undertaken by European émigrés sympathetic to the cause of organized labour, were George Rosen's *The history of miners' diseases* (1943) and Ludwig Teleky's *History of factory and mine hygiene* (1948).

In the United Kingdom, renewed interest in occupational health during the 1930s was fired by a group of researchers, such as Archie Cochrane, Philip D'Arcy Hart and Ronald Lane, whose sympathies clearly lay with the social and political cause of the industrial working class.

We can locate Hunter's own investigations and literary concerns, therefore, within a genre of contemporary toxicology research, historical writing and social compassion. His extensive reading was combined with the vigorous pursuit of a wide variety of cases of industrial poisoning in the east end of London and beyond. He assiduously sought out details of cases, questioning his patients on the incidence of illness among fellow employees, corresponding with other physicians on their industrial background and case history.

Notably, Hunter investigated the effects of methyl mercury poisoning from seed dressings on the visual cortex (later of world importance when methyl mercury effluent entered...
the food chain and poisoned people in Minamata, Japan). In these years, Hunter sought out intriguing cases of deformity and occupational stigma, particularly for photographic records (presumably to show his students). He was also sensitive to the geographical origins of illness. Not only were occupations, such as billiard table makers, closely examined for distinguishing signs of pneumoconiosis (lung disease) caused by silica dust from slate rather than tuberculosis, but the diverse case histories of international mining engineers with similar complaints were carefully reconstructed.

In pursuing his research, Hunter had kept in touch with notable members of the Home Office’s factory inspectorate, such as Edward Merewether, requesting items for the collection that Hunter was assembling. In 1943, Hunter was asked if he would be willing to take charge of a research department funded by the Medical Research Council at the London Hospital. London was to be one of a proposed network of university departments in industrial medicine that did not come into being. Hunter believed that Clydeside, Merseyside and Tyneside were the most obvious candidates for such centres. From his department in the London Hospital, he also followed Legge’s example of studies in the Great War (1914–18) by investigating industrial hazards associated with aircraft production and other essential munitions supplies during the Second World War (1939–45).

Hunter fought to raise the status of occupational health and medicine during the late 1940s. In a report on industrial medicine written in 1949, Hunter argued that England (sic) was the leading country in protecting workers against accidents and disease, though the scanty resources allocated by the Treasury to the Factory Department of the Ministry of Labour, deprived it of the capacity to undertake original research and limited its powers of inspection and regulation. He strongly argued that the industrial physician should be closely linked to general medicine and that the university centres should forgo ties within experimental pathology, pharmacology, physiology and with scientists more generally. He considered that the basic practice of industrial medicine should remain within the grasp of the general practitioner.

In the 1950s, Hunter continued his research into occupational health, visiting Charles Fletcher’s Pneumoconiosis Unit in Llandough Hospital (also funded by the Medical Research Council), noting privately the animosity between contemporaries and re-reading recognized materials to trace the circumstances in which scientific knowledge itself (and its authors) became the authoritative account of the natural world and the aetiology of illness. While there is considerable force in recent challenges to the older, more heroic, genre of medical history represented by Hunter, it can be argued that many of his judgements confronted by industrial specimens presented at oral examinations and questions posed on subjects relating to them. He continued to be an inspired teacher into the 1970s, entertaining students long after the scheduled finish of his lecture with historical exhibits produced from a large cardboard box.

**HUNTER’S HISTORICAL PERSPECTIVE**

Hunter brought to the study of industrial illness the distinct scientific and historical perspective of British medicine in the mid-twentieth century. His survey of workplace maladies begins with a broad panorama of human history before he engages in a long narrative of progress in the industrial world. Hunter relies not only on classical texts to illuminate different periods of industrial development, but follows Rosen and others in attempting a serious economic and social history of production since the earliest years of industrialization. His historical writing bears the impress of his own time and his own text has become a significant historical document which should be read in the light of subsequent research by both economic and medical historians. Hunter acknowledges the progress made in the prevention of occupational diseases and notes the role of politics and social concern in this, but the approach he adopts has been seen by more recent historical commentators as focusing on the ‘grand narrative’ and the role of medical investigators in it, rather than acknowledging the views of non-specialists concerned with the harmful effects of work.

Together with Rosen, Siegerist, Teleky and others, we may reasonably identify Hunter as one of the founding figures in occupational health history. In the half-century since his work was published, the discipline of historical writing has been transformed. Medical historians have been influenced by arguments in social and cultural history which have identified how different insights may be gained into familiar historical processes by examining the experiences of individuals and groups not usually included in the story. By retrieving the documents and oral testimonies left by less prominent and powerful individuals, including many of the patients treated by medical personnel, we can derive a deeper understanding of the perceptions and motives of those involved in medical treatment. Many of those who received medical attention, such as the workers suffering occupational diseases, have left few testimonies and even their employers rarely spent time and resources expressing their own views of injuries or ‘malingering’ outside official enquiries and legal documents. It is not merely a matter of discovering new sources which might enable us to hear those who were left without a voice in earlier historical studies: there is also the challenge of re-reading recognized materials to trace the circumstances in which scientific knowledge itself (and its authors) became the authoritative account of the natural world and the aetiology of illness.
have withstood the test of time and scholarly criticism. Hunter’s portrayal of his historical subjects may have encouraged a view of workers mainly as victims of economic change, but the empathy his writing shows with the labour force is in many ways comparable to those social historians who set out to tell a story of events ‘from below’. His discussion of mining reveals interplay between society, work and health in a stark perspective as the growing scale and depth of coal mining led to the employment of women and children alongside an expanding army of adult male colliers (Figure 1.1). He discusses how public concern in the 1840s about the morality of partially clothed women and children working underground in these conditions provoked moral alarm rather than merely regard for physical welfare of those labouring in primitive conditions.

Technological change and the introduction of rock drills are similarly presented in their social context, as Hunter notes, a lethal new threat to the lungs of workers arose as unprecedented amounts of dust were generated by these ‘widow makers’ powered by compressed air.

More recent historical research suggests that the opening themes of the historical section of his book, in which he outlines the human condition and man’s relationship to work before he provides a broad narrative of industrialization, would, if written now, be recast to include the attitudes of a wider range of people and note their distinctive contribution to the workplace, the identification of occupational hazards and the alleviation of illness. Hunter’s work is, however, far more than just a record of power and attitudes of the (mainly male) medical profession of the mid-twentieth century. It is worth recalling the turbulent political struggles which marked his professional life and the intellectual battles of the years before the rise of fascism and during the cold war era in which his own major work was published. Hunter’s long historical introduction to Diseases of occupations does present a portrait of progress in which clinical investigators played a significant and often heroic part in achieving positive change, but it is also a testimony to the social conscience of a minority of distinguished medical investigators in an age of hardship, tension and war, whose legacy remains strong.

**INDUSTRIALIZATION AND RISK**

Early accounts of industrial hazards include the pioneering studies by Agricola (1494–1555) and Paracelsus (1493–1541). Both investigated hazardous working conditions and the toxic hazards associated with mining labour (Figures 1.2–1.4). Their concern to ameliorate the harshness of mine labour and the vulnerability of workers to human as well as environmental abuse remained a strong feature of industrial and medical commentaries into the nineteenth century. Bernadino Ramazzini (1633–1714) also paid close attention to miners’ diseases, but extended his pioneering investigations across the
crafts and trades which populated the urban centres of northern Italy at the end of the seventeenth century, emphasizing the importance of personal examination of workmen and a close attention to their own accounts and experiences (Figure 1.5). Ramazzini’s seminal work *Morbis artificum diatriba* offered prescient comments on the illnesses of people employed in trades such as pottery.
Industrialization and risk

in his day and also miscarriages among women living near obnoxious workshops (Figure 1.6). The search for new sources of power to fuel industrial production during the eighteenth century led to the growth of new industrial settlements and the concentration of larger groups of workers in bigger workshops and factories where economies of scale and a finer division of labour could be realized. Whereas Ramazzini composed his classical text at a time when industrial production was still dominated by relatively shallow mines and the artisan workshops of mercantile communities, Charles Turner Thackrah (1795–1833) made the first detailed study of the toxic effects of working with minerals, chemicals and organic materials in the different trades which were carried out around the mechanized industrial centre of Leeds during the 1830s (Figure 1.7). Earlier investigators had addressed problems of flint dust in the pottery and ceramics workshops of Staffordshire, while lead and mercury poisoning were studied in the eighteenth century, and the exposure of boy chimney sweeps to soot led to Percival Potts’ (1714–88) early recognition of cancerous warts. However, it was Thackrah’s celebrated study which broke new ground in seeking systematically to link the incidence of industrial disease with statistical evidence of life expectancy in different districts. Although he was one of the many commentators on the adverse effects of industrialization he most clearly quantified and detailed the health effects. Thackrah shared with other later investigators not only a deep interest in the statistical evidence gathered by census enumerators and civil registrars, but a passionate commitment to the cause of industrial and sanitation reform.

In reviewing Hunter’s descriptions of these historical changes we can sketch their links with more recent studies on the industrialization of Europe and other parts of the global economy since the late eighteenth century. Concern about risks from work in pre-industrial society does seem to be limited to the writings of medical authors, with the exception of the army and navy where military campaigns were often ineffective because of illness among troops or seamen. The toll from typhus and scurvy in the eighteenth century British navy led to investigations of diet, ventilation and hygiene, notably James Lind’s *Treatise on scurvy* of 1753. Social, scientific and economic factors, as well as reluctance by seamen to change their diet delayed the introduction of his recommendations for the provision of lemon juice as both prevention and cure for several decades – an early example of the interplay of many interest groups in setting the pace of prevention.

The industrial revolution is now viewed differently than it was in Hunter’s day. There are continuities of industrial development between the mechanical improvements of the decades after 1770 and an earlier period of ‘proto’ industrialization based on household and family production. The pattern of commercial, transport and trading change seen during the eighteenth and early nineteenth century did precipitate the mass movement of peoples from country to town and to longer-distance migration which we can see repeated in the industrial transformation of Asia in the past half-century. The social conditions which attended the urbanization of the British and other European populations were vividly depicted in contemporary novels as well as the parliamentary and scientific enquiries, frequently undertaken by medical men such as Thackrah, Gaskell, Kay and Greenhow. Recent studies have tempered many of the bleak depictions of human misery and degradation, demographers noting the rising living standards seen particularly from the 1840s and the improvements in mortality and morbidity statistics seen after the 1870s. Work processes and the relationships at work did undergo major changes with the assembly of large numbers of workers in factories and mills and the dependence on mechanical aids to increase production. Employers were driven by profits and productivity, but responded in different ways to this, with many making expedient use of low cost urban labour while a few, such as Robert Owen, established mills in rural areas and provided model working conditions with the aim of engendering both productivity and loyalty (Figure 1.8). The legal position of the employer as ‘master’ was strong, while that of the employee as ‘servant’ was weak, at least until organizations of workers, initially of craftsmen but later of all groups of workers, in trade unions developed, mainly in the teeth of concerted opposition from employers.
Effective factory legislation began in 1833 with the passing of an Act that could be enforced by dedicated inspectors appointed by the Home Office. This was not the first attempt to regulate but followed earlier measures that failed because of weak and corruptible local enforcement arrangements. Factory regulation at this time was a highly contested area of parliamentary business, not only between capital and labour because it was many years before workers would have the vote, but also between those who upheld the traditional agrarian structures of society and those grown newly powerful from the growth of industry. The law was initially concerned with hours and conditions of work for children and females in textile factories, although provision was also made for the appointment of surgeons to check the ages of children (Figure 1.9). The power to appoint these ‘certifying surgeons’ was formalized in the 1844 Factory Act when inspectors were given the power to recommend such doctors to the Home Office. This was at a time when there was no unified medical profession and the inspectors had to assess suitability from first principles. In the middle part of the nineteenth century, the Factory Inspectorate with support from Robert Baker, the one medically qualified inspector, paid little attention to industrial disease, as the national priority was seen as being the prevention of disease associated with urbanization rather than that arising from work, which was sometimes seen as simply one of the consequences of employment in return for which a wage was paid. In the course of the nineteenth century, similar factory inspection regimes were set up in France, Germany, Belgium and other European countries and their empires. Inspection arrangements in the United States were created in the early twentieth century, some at state and some at federal level.

Statistics were themselves an important part of the story of occupational health and attempts to regulate working conditions after 1800. From 1851, decennial censuses of population included valuable information on occupations and households, while the registration of births and deaths started in 1837. These returns provided medical statisticians with materials from which to calculate mortality rates in different districts and across various occupational groups. The results based on the 1851 census were the first that could be used to measure increased mortality in towns and registration districts where dusty trades, such as ceramic manufacture and metal grinding, were based. Following Edwin Chadwick’s famous Report on the sanitary condition of the population of 1842, the most notable and sustained investigations of the effects of work on sanitary and health statistics were carried out by Edward Greenhow (1814–88) at the instigation of John Simon at the Medical Department of the Privy Council. Greenhow examined pulmonary and other diseases among different occupational groups in meticulous studies in 1854–62 and persuasively demonstrated the link between dusty occupations and increased respiratory disease rates, though his investigations were complicated by co-morbidity from tuberculosis (although the bacillus which caused ‘phthisis’ had not yet been identified).

Research, such as that undertaken by Greenhow, contributed to the debates on workplace health that surrounded the passage of the 1864 Factory Act, which first provided for ventilation of industrial premises outside mines. Recognition of the severe hazard presented by the
metal grinding trades gradually led to the introduction of exhaust ventilation on the sandstone grindstones which caused serious lung damage or ‘grinders’ rot’ in areas such as Sheffield and the Midlands. While factory and mine workers were subject to some state regulation, small workshops and those who were self-employed or contracted to small masters and intermediaries were notoriously unprotected throughout the nineteenth century.26

It was the legislation which dealt with lead poisoning in the years leading up to the Factory Act of 1891 which can reasonably be described as the foundation of both modern occupational health regulation and the use of specialist expertise in the public management of hazardous workplaces. The Act of 1891 empowered the Home Secretary (in practice his Inspectors at the Factory Department of the Home Office) to compel any trade designated as ‘dangerous’ to adopt special rules for the control of hazardous agents to protect workers. The last decade of the nineteenth century and the first decade of the new century deserve particular attention in the history of state attempts to regulate occupational dangers, for they saw the regulation of toxic substances and dusts, as well as establishing the reputation of several leading figures who studied these materials and advised government on their control.

DANGEROUS TRADES AND INDUSTRIAL DISEASES

The growth in government regulation of hazards at work arose in part from greater scientific understanding of the nature of the risks posed by particular substances and their widespread use as chemistry was revolutionized in the late nineteenth century. The new chemistry furnished techniques for the measurement of contaminants in the workplace and a more precise assessment of the relationship between exposure and harm to health. The effects of changes in levels of oxygen, nitrogen and carbon dioxide, as well as methane (in mines) and carbon monoxide (from fires) were investigated by innovative physiologists such as John Scott Haldane, whose field observations and experiments, often on himself in an exposure chamber, led to improvements in a range of industries, as well as in tunnels and wells.27 Investigators in Germany, such as Lehmann, contributed to accurate measurements of toxic vapours in the atmosphere and their effects on the human body.28 The birth of modern bacteriology and immunology with the work of Koch in Germany and Pasteur in France led to the specific identification of infectious organisms and methods of treating them from the 1880s, supplanting earlier disease theories of miasma, but also provoking wide-ranging and sustained controversies on the nature of infection.29

As the technologies for assessing risks and the methods for understanding diseases and their control steadily improved in the later nineteenth century, cases of poisoning affecting specific trades were more clearly identified. Three agents attracted particular attention and established the reputation of the early investigators of occupational illness in the United Kingdom and other countries: lead, phosphorus and anthrax. Lead poisoning had long been a serious problem in a range of industries including the manufacture of white lead pigment for use in paints, ceramic and pottery manufacture (lead glazes), and exposure to the element in mining and smelting operations. The employment of women in a number of these occupations led to the recognition that, as well as the abdominal, neurological and haematological effects of poisoning, they also suffered from repeated miscarriages. The Home Office established a committee to investigate white lead which recommended basic controls which were refined by later Dangerous Trades Committees and leading factory inspectors, including Thomas Legge on his appointment as first Medical Inspector of Factories in 1898. Ceramic and pottery manufacturers resisted any changes to the lead glazes, blaming their workers for poor hygiene and they maintained stubborn opposition to state interference in the early twentieth century. While significant reductions were recorded in notified cases from lead poisoning in the decade before 1914, probably as a result of more precise diagnosis, as well as the diligence of the Factory Inspectorate and increased publicity given to the problem by women’s campaigners as well as health reformers, the mortality rates were little improved in the early twentieth century.30 One indication of the persistence of problems can be found in the continuing research during the interwar years, including Hunter’s period as a researcher at Harvard under Aub.

Phosphorus poisoning leading to necrosis of the jaw affected those working in the match-making industry, yellow phosphorus being used for strike-anywhere ‘Lucifer’ matches in the nineteenth century. ‘Phossy jaw’, the painful, frequently foul-smelling decay of the lower jaw led to disfigurement and death in both women and men who were involved in the making of inflammable paste and dipping of matches. Bryant and May presented themselves as model employers at their east London works until a famous industrial dispute brought the ‘match girls’ out on strike in 1889. Soon afterwards the press exposed the company’s policy of concealing phosphorus poisoning cases by pensioning off afflicted workers. Similar problems in other countries led to proposals in 1900 for an international convention prohibiting yellow phosphorus in favour of safety matches, but the British government refused to support an international convention, seeing it as an unwarranted interference with free trade.

In contrast with the risks to the mostly unskilled females and males involved in lead and phosphorus trades, anthrax rose to prominence in Britain because of the rapid deaths from lung infection and septicaemia among the skilled men who were employed as wool sorters in the Bradford area of West Yorkshire. Suspicions had also been growing that labourers who worked with imported animal hides and hairs in places as distant as Glasgow, London and Liverpool were also suffering from a sometimes fatal skin infection associated with these materials. Dr JH Bell of
Bradford, an ophthalmic specialist, who also contributed to the identification of miners’ nystagmus, achieved a national reputation in 1879–80 after linking pulmonary fatalities among wool workers with the *Bacillus anthracis* recently described in detail by Pasteur. The remarkable success of Pasteur and Koch’s work helped to establish the germ theory of disease among the British medical community, although heated debates continued long after about the proper role of laboratory research in tackling disease.

More practically, the association of anthrax with raw materials used in one of Britain’s staple industries provoked fresh activism in the local labour force and a strong campaign resulted in the adoption in the early 1880s of a voluntary code of preventive measures, including the use of tables with downdraught ventilation for sorting fleeces from regions most associated with dangerous wools. There was some improvement in recorded fatalities from anthrax and the earlier voluntary rules were extended to cover more groups of workers, tightened and made statutory (following a review by the Home Office’s Committee on Dangerous Trades after 1896). The incidence of the more common skin form of ‘malignant pustule’ remained relatively constant, with death in about 15 per cent of cases. While Thomas Legge appears to have been convinced of the case for further legislation well before 1914, the response from the Factory Department of the Home Office can at best be described as lethargic. A contested legal decision taken on appeal to the Law Lords in 1905 that an employee infected by the bacillus should, for the purposes of compensation, be considered to have suffered an accident, helped to prompt the decision to schedule six occupational diseases as qualifying for compensation under the Workmen’s Compensation Act of 1906. Anthrax remained a feature of the industrial scene in the early decades of the century. Hunter himself collected details from patients such as Elsie Mitchell, a horse hair worker aged 19 infected in 1913 and a male agricultural worker whose eye was infected after working with manure in 1921. Ever the indefatigable researcher, in 1935 Hunter interviewed the widow of a horse hair worker who had been infected in 1922 with ‘filthy hair from Russia’ and died. As late as 1938, Hunter examined a Harpenden man admitted to hospital with anthrax symptoms contracted at the artificial manure factory where he worked with wool processing waste or shoddy.

**THE MEDICAL PERSPECTIVE**

In the years when the health of workers was becoming a subject of serious medical interest, three figures arose who largely defined the boundaries of occupational medicine before the Second World War. Two seminal texts were published in the decade 1892–1902. Thomas Arlidge’s *Hygiene, diseases and mortality of occupations* (1892) was based on his Milroy lectures to the Royal College of Physicians delivered in 1889. Originally a psychiatrist who served in an early Victorian lunatic asylum, Arlidge moved to North Staffordshire Infirmary and drew on his own encounters with cases of lead poisoning and lung disease. Arlidge also developed the methods of Thackrah and Greenhow by using census and mortality data to map the distribution of illness. Thomas Oliver was a Newcastle physician who advised the Factory Inspectorate on lead poisoning in the 1890s. His book *Dangerous trades* (1902) brought together leading authorities to describe not only industrial illnesses, but also the changing industrial technologies of the period. Oliver contributed several chapters and again made use of a mass of statistical information on mortality and morbidity. Oliver resisted currently fashionable inclinations to explain the origins of industrial lung disease in bacteriological terms and emphasized the primary importance of mineral dusts (such as silica) in causing lung disease among workers. Both Arlidge and Oliver recognized the central role of the state in disease prevention, but saw workers as passive victims rather than recognizing the role of organized labour in debates on disease prevention.

Thomas Legge’s *Industrial maladies* never achieved the reputation secured by his predecessors and was completed by his successor as senior medical inspector, John Bridge, after his sudden death in 1932. Yet Legge (Figure 1.10) rose to early distinction and influence in a public career which his predecessors hardly contemplated. Legge was the son of a distinguished missionary in China and sinologist. He travelled widely in Europe before his appointment in 1898 to the new post of Medical Inspector of Factories, at the early age of 34 years. The growth of government expertise in industrial toxicology and particularly the analysis of dust problems in the workplace which dominated the agenda for regulation until the 1960s can be dated from...
his appointment. Legge’s writings were influenced by the socialist and egalitarian leanings of the late nineteenth century arts and crafts movements and he frequently acknowledged the contribution of workers and their representatives to the cause of disease prevention. During the 27 years Legge served in the Home Office he investigated a wide range of diseases, undertaking systematic surveys such as that comparing the health of workers in Birmingham and at Woolwich Arsenal to isolate the effects of brassworking on health. 38 Legge continued his early interests in lead poisoning and anthrax infection, developing criteria to be used in diagnosis and supporting laboratory arrangements for anthrax investigation. His Milroy lectures of 1904 were a wide ranging review of industrial anthrax, its bacteriology, presentation, treatment and prevention. From his European visits, he became familiar with Sclavo’s anthrax antiserum and subsequently served on the committee which sat during the First World War and recommended reforms which were embodied in the 1919 Anthrax Act and led to the building of the Liverpool disinfection station. 39

In researching the effects of lead poisoning on workers, Legge struggled against the opposition of employers who sought to blame the dirty habits of their workers for poisoning to establish the primary importance of inhalation of lead particles rather than their ingestion by unclean eating habits. In collaboration with Kenneth Goadby, he refined the measurement of toxicity within the body and worked with other colleagues to restrict the hazards of lead in such booming sectors as the manufacture of lead-acid automobile batteries. 40 The contribution of government controls to the reduction in fatal lead poisoning is doubtful. The fruits of prevention and treatment were rather more apparent in anthrax where modest improvements were recorded in cases and fatality rates just before the First World War (Table 1.1). There was then a deterioration due to the use of poor quality wool to make good shortages of raw materials and to supply the enormous demand for military supplies. Long-term improvements followed legislation in 1919, but government measures probably had less impact than falling imports of more dangerous fleeces and gradual improvements in animal husbandry across the world. Legge’s efforts to secure international cooperation in the control of anthrax and lead met insurmountable obstacles as outlined below.

Hunter’s account of the progress of occupational medicine provides a heroic view of the pioneering efforts of enlightened individuals such as Arlidge, Oliver and Legge. Such an approach was common in many mid-twentieth century studies of medical history, where the concentration on eminent medical men tended to obscure the now current views on the impact of labour activists and interest groups and the complex political and legal context in which they were active. These physicians worked within a legislative framework which defined the terms of their involvement with industrial disease, as well as their legal responsibilities to patients and government. The passage of Workmen’s Compensation legislation, in 1897 and 1906, established employers’ liability for specific illnesses contracted at work, as well as accidents in industry. This placed medical knowledge in the witness box when claims were verified – at times pitting a doctor representing the employer and their insurers against another who represented the worker and their trade union, and increased the requirement for valid evidence on the causes and extent of disease affecting employees. It also narrowed the definition of occupational diseases to those conditions that were either notifiable to the Inspectorate or prescribed for compensation.

Historians have long been aware of the importance of social insurance in the building of state medical services across Europe and in other continents. In the United Kingdom, National Health Insurance was introduced in 1911, providing for the creation of ‘approved societies’ to administer the sickness benefits of workers and to engage panels of doctors who would attend to those insured under a state scheme funded by contributions from employers and workers as well as the Treasury. One of the concerns of nation states which created new social and health services during the late nineteenth and early twentieth centuries was the growing economic and military competition that required human, as well as industrial and territorial, resources. In this race for efficiency and supremacy, the health, and hence military potential, of ‘human stock’ was emphasized while eugenicists, in addition to their concerns about breeding, stressed the vital importance of maternal and infant welfare in an age when unfitness for military service could undermine the foundations of national success. Feminist historians have subsequently argued that

governments developed policies for occupational as well as public health which reflected their concerns about managing the (male) human resources of civil society. Such initiatives also reflected the gender bias and distinctive expectations of males and females in contemporary society, where adult men were expected to serve as breadwinners for the family household and to accept physical risks and working conditions from which females and children, living in a ‘separate sphere’, were protected. The reproductive and maternal health of fertile females was particularly emphasized by physicians, such as Arlidge and Oliver, who examined the dangers posed by lead during pregnancy and attributed poor infant mortality to working after childbirth. Women and girls were also considered to be vulnerable to mental, social and personal hazards which men were assumed to tolerate along with physical dangers or abuse at work. Lady Factory Inspectors appointed from the 1890s were particularly responsible for investigating and reporting on the hazards faced by females in the workplace. This topic remains controversial as other scholars have cast doubt on the claims that pre-1914 governments were particularly concerned with females in the measures passed to promote industrial health.43

Similar debates have surrounded the attitudes of trade unions towards compensation and safety. A common criticism of the labour unions is that they have historically shown more interest in pursuing monetary settlements for injured members than in promoting health and accident prevention in the workplace.44 Such arguments appear to be based on an assumption that unions and their members can effectively choose whether to give priority to receiving monetary returns for injury rather than to securing safe working conditions. In practice, as writers since Ramazzini have noted, workers commonly believe they have few alternatives to tolerating hazardous working conditions and their representatives often pursue compensation payments as a necessary means of support for injured workers and their dependants. Labour leaders repeatedly expressed the largely unrealised belief that significant compensation payments would deter the employers (and their insurers) from persisting with dangerous work practices.45 However, the lethargy of employers, the cover provided by their insurers and the apparent collusion of their medical advisers, as well as governments with poor safety standards has remained a constant feature of trade union concern since the late nineteenth century, hardly indicating widespread union tolerance of hazards in the workplace.

THE INTERNATIONAL DIMENSION IN PEACE AND WAR

In the years when nation states were introducing centralized health insurance, actuarial experts employed by insurance companies and friendly societies were assembling statistics which provided risk profiles of the working population. Statistical returns assumed a fresh importance for governments, as well as private organizations and legal experts.46 The maintenance of the male breadwinner as the foundation for stable household income among the working population remained a theme in welfare reform and concerns about the occupational health of the workforce. International awareness of common health problems and the scope for similar approaches to resolving them certainly increased after Germany embarked on Bismarck’s pioneering social insurance arrangements in the 1880s, although important differences can be seen in the way nation states addressed the question of compensation for injured workpeople and the liability of employers for different kinds of diseases. Crossnational projects, such as the building of the Alpine railway tunnels at the end of the nineteenth century, revealed the appalling hazards to which labourers were exposed, as diseases such as hookworm (ankylostomiasis) spread from the tunnels to many of the mining areas of Europe and its colonies.

Tunnelling and mining projects around the world provided a working laboratory for health researchers and contributed to the establishment in 1906 of the Permanent Commission for Occupational Health, an international grouping of occupational health experts. The huge growth in gold mining using dry drilling in siliceous rocks on the Rand of South Africa produced many cases of silicosis and these were seen in other countries, especially the United Kingdom, when miners returned home to die. Contributions to international understanding of serious respiratory illness in dusty trades were also made by the published investigations of medical experts such as Oliver and Legge. The promising moves being made towards greater international cooperation in regard to workers’ injuries were interrupted by the outbreak of mass warfare in Europe in 1914, spreading to many parts of the world by 1916. Embattled states created a huge, unprecedented demand for essential war supplies, thereby introducing new risks to employees, exemplified by outbreaks of toxic jaundice among workers applying tetra-chloroethane to aircraft wings and filling shells in plants handling TNT.47 Governments responsible for munitions production were drawn into investigating and regulating conditions of work to reduce the toxic effects of chemicals used for armaments manufacture, to provide canteens and welfare services for workers away from home and to control the adverse effects of long hours on productivity and safety.48 At the same time, government ministers in the United Kingdom and other countries were acutely aware of the risks of labour unrest and disruption of production in the extraordinary market conditions of ‘total’ warfare. Concessions to organized workers included guarantees to reserve jobs for returning servicemen on the cessation of hostilities. The legacy of the war for research into and regulation of occupational hazards was a disappointing one for contemporary enthusiasts, such as the Industrial Welfare Society. The wartime research on fatigue led to the creation of the Industrial Health Research Board and was eventually incorporated into the Medical Research Council’s efforts on workplace health in the interwar period, though it
was not until the late 1930s and the outbreak of another international war in 1939 that fresh impetus was given to specific war-related industrial problems, where Hunter played a significant role as an investigator.59

Another legacy of the 1914–18 war was the creation of the League of Nations based in Geneva and its International Labour Office (ILO), which developed transnational conventions to improve labour conditions and reduce the incidence of illness at work. The ILO’s conventions gave a formal status to agreements on the control of dangerous working conditions and enabled trade unions to contribute to such instruments. Dr Carozzi played a notable bridging role as both a staff member at the ILO and as secretary of the Permanent Commission for Occupational Health. Legge contributed to these innovative gatherings and sat on specialist commissions of enquiry, including one on anthrax, where other nations were unwilling to adopt the use of centralized disinfection stations, although they acknowledged the work of the United Kingdom in this area. Legge also played a key role in negotiating the convention to ban lead from interior paints.

One topic on which the British Government was keen to contribute was silicosis. An international conference was convened at Johannesburg in 1930 at which national experts on silicosis exchanged views and agreed standards for classification of disease and methods of diagnosis based on South African and other international developments in radiography and pathology. As a major maritime nation, Britain also helped to draft several new ILO conventions which were important for the eradication of the worst abuses of seafarers by the global shipping industry.

President Woodrow Wilson had played a leading role in setting up the League of Nations, but the United States electorate turned their back on international commitments and Washington maintained only loose connections with the ILO through conventions and correspondence in the interwar years. Historically weaker than central governments in Europe, federal authorities played only a limited role in health and safety before the New Deal of the 1930s, although pioneering investigators such as Alice Hamilton publicized poor working conditions, especially where weakly protected immigrant and female workers were involved (Figure 1.11).

The international dissemination of technological and scientific information between the wars should be understood, therefore, within the strained political and industrial relations that overshadowed many societies during these years. These were also years of economic depression, industrial restructuring and rapid technological change in the global economy. The innovative use of chemicals had accelerated since the late nineteenth century, for instance using carbon disulphide in the manufacture of materials such as rayon (artificial silk), resulting in reappearance of its well-established neurological and behavioural harm in new workforces. The uses of lead featured in a variety of trades including the development of ethyl lead to slow the ignition of motor gasoline and this caused widespread poisoning where it was manufactured or blended. At the same time, traditional industries, such as coal, textiles, ceramics,
Donald Hunter and the history of occupational health

steel and shipbuilding, faced harsher competition and were often slow to improve the poor conditions in their workplaces. It was a time when trade union membership had increased and spread from the craft unions to include the mass of unskilled workers, especially in the more traditional industries. By contrast, the newer sectors such as light engineering, electrical goods and parts of the consumer goods and chemical industries had supplemented their ‘scientific’ approaches to management with welfare provisions and were aiming to avoid a unionized workforce. In well-unionized sectors, such as coal, there was continuing pressure for compensation of industrial disease, especially of the lungs, and for preventative measures. This was at a time when some of the well-established risks, such as lead, phosphorus and anthrax, were diminishing in frequency, while others were being actively investigated. An example of this is the toxicological and chemical research in Manchester that led to improvements in the lubricating oils used for textile machinery (spinning mules) when carcinogenic polycyclic aromatic hydrocarbons were identified as the cause of skin and scrotal cancers in cotton workers.

ASBESTOS AND OTHER TOXINS: DISASTERS WAITING TO HAPPEN?

The lung diseases linked to textiles and coal dust were gradually overshadowed by a controversy around ‘the magic mineral’ that became a hugely important building and transport material where serious fire risks faced manufacturers and consumers. The greatest occupational health risk of the middle and later decades of the twentieth century, and the mineral which has dominated recent debates on the national and international regulation of workplace hazards, is unquestionably asbestos. Soon after asbestos became widely used in the late nineteenth century, an early female factory inspector noted possible links to lung disease in workers. These concerns resurfaced in the 1920s leading to an investigation by the Home Office’s Factory Department in 1928–29. The report of this investigation by Price and Merewether set fresh standards in epidemiological analysis, demonstrating the presence of lung fibrosis or asbestosis among workers who inhaled the mineral fibres, but there was no indication of any link to cancer in workers, nor was the study designed to find one as this risk was not suspected. In 1931, the report did prompt new government regulations for the control of asbestos dust and at the same time for silica.

The attitudes of the employers to these regulations and to subsequent risks have been the subject of fierce academic and courtroom controversy since the 1980s. Much of the heat in these exchanges has been fuelled by the delayed rise in the incidence of cancer among people with little or no connection to the asbestos-manufacturing industry itself, but who were relatives of workers or individuals engaged in using or stripping out asbestos in buildings, transport vehicles, ships and other areas of employment where there was no perception of a risk, even at the time when cases were first appearing in heavily exposed workers. Even those living near asbestos works or consumers of their products developed disease from inhalation of the fibres.

It remains important to distinguish between known, suspected and unrecognized risks in the history of this and other industries, as well as to have a valid view on the state of knowledge at any point in time, untainted by hindsight, before making judgements about past practices. There is little doubt that the considerable risk of lung and pleural cancer was only demonstrated during the 1950s and 60s. It was during this period (rather than earlier) that we can identify efforts by the asbestos companies to suppress scientific research by Richard Doll (1912–2005) into the evidence of cancers caused by asbestos dust. (Doll’s pioneering studies of diseases due to asbestos and smoking were an important stimulus in the development of cancer epidemiology, in which he became a leading exponent (Figure 1.12).) Soon after this, the research of Wagner and others into the geographical pattern of mesothelioma and pleural tumours among South African crocidolite (blue asbestos) miners suggested links with the dust which blew around the streets of the mining communities, as well as with exposure in the mines. The global reach of asbestos and its attendant diseases became apparent as pleural tumours were subsequently found among shipbuilding workers in the United Kingdom and the United States, where Irving Selikoff was both a leading investigator and a campaigner on behalf of those affected.

The asbestos problem became critical for governments as well as for workers, industrialists and insurers when
it became apparent that the boundaries of risk within industry, and more importantly between occupational and public health hazards, were extremely difficult to draw. International scientific collaboration was needed as the different interest groups demanded new techniques and more rigorous epidemiological investigations to understand the dose–effect relationship between levels of asbestos dust and the incidence of illness. Competition as well as cooperation between leading scientists characterized the convening of medical conferences in Europe and the United States which sought to determine the hazards associated with blue and other forms of asbestos. In the 1960s and 1970s, the industry (and their medical advisers) campaigned to present chrysotile (non-blue) asbestos-containing products as essential to society and relatively safe. In particular, they emphasized the need for long-term research before enforcing any prohibition. As public regulators came under increasing pressure, bodies such as the British Occupational Hygiene Society provided standards that addressed, in a flawed analysis, the risk of asbestosis from chrysotile rather than that of cancer. The resultant controversy was sharpened by investigative journalism and media coverage (including the television documentary ‘Alice: a fight for life’), forcing the British Government to introduce a battery of controls, including a licensing regime for asbestos insulation and a register of mesothelioma cases. It was the demonstration of a link between specific industrial products and public, as well as occupational, health which forced politicians to venture beyond the limited controls which had been proposed by civil servants and expert advisers.

A further and decisive blow against the continued use of asbestos and the interests of the producers came with the escalation of litigation, most particularly in the United States from the 1970s, by aggrieved plaintiffs who sought massive damages for the legacy of human and material losses which they faced from exposure to the material or from its incorporation into buildings. The scale of these claims forced the largest asbestos producer (Turner and Newall, Manchester, UK) to sell its assets and cease operations while damages also threatened the international insurance market at Lloyds with collapse at the end of the twentieth century. As a complete ban on all future use of asbestos became politically necessary in the United States and Europe, global mining and manufacture of the mineral went into steep decline, although mining continues and asbestos use persists in some lower-income regions of the world.

While the risks from asbestos overshadowed international concerns for workplace health in the later twentieth century, other occupational hazards were identified in the ‘new’ consumer materials of the period. Some of these toxic risks were known to earlier generations in different forms and the lesson of industrial poisoning was painfully relearned. The serious risk of liver cancer presented by vinyl chloride, the raw material for PVC plastic, was identified in 1973–74 in workers who had been heavily exposed for over 20 years. Cleaners of polymerization vessels developed acro-osteolysis in their fingers and subsequent animal studies revealed disproportionate cancer rates, including the rare liver cancer angiosarcoma which was identified in exposed workers soon after the study results became available to the industry. Delays in the release of results occurred largely because of American concerns about regulatory implications, as the criticisms of historians Rosner and Markowitz make clear. A familiar dilemma faced regulators in confronting the health risks from PVC production: its supporters pointed to the safety benefits of electrical insulation and other uses, as well as disruption to supplies of other essential chemical products (such as caustic soda), if PVC production was halted. Critics demanded immediate action. A compromise was adopted where producers agreed to reduce exposure levels over three years and new monitoring techniques were developed. In the longer term, the confirmation of cancer risks led to more comprehensive testing of other large volume industrial chemicals, resulting in only equivocal evidence of cancer risks in a few cases, though the principle of prior testing of substances and the need for valid risk assessments was established and later came to be incorporated into law. International bodies such as the International Agency for Cancer Research (IARC) and the International Programme on Chemical Safety also assumed a more significant role in such discussions.

Asbestos and especially its effects at low concentrations, as well as a wholly unexpected risk with vinyl chloride both focused attention on the large toll of disease that could arise from any substance with fatal effects that only become apparent after many years. This dented earlier confidence in the idea that the classic industrial poisonings were yesterday’s diseases and that the major challenge of dust diseases of the lungs was now coming under control. It also led to a questioning approach to the pathology of diseases, such as the byssinosis of cotton workers delineated by Richard Schilling, where the effects of the agent in cotton and the less specific effects of pollution and smoking on the lungs had to be disentangled. Successful examples of prevention could be identified but there was now an expectation of diseases becoming apparent from new and even not so new technology, as well as uncertainty about the role of occupational sources of contamination in exacerbating or contributing to conditions that also occurred in the general population. Low level exposures also became prominent, especially as causes of cancer and mutation. The logic of a risk at any dose had been the basis on which protection against ionizing radiation had been founded for a number of years, but now there was evidence of similar patterns with asbestos and this fed into concerns about many other widely used products, such as pesticides, cosmetics and food additives. Indeed, the results of occupational epidemiology provided much of the evidence for the environmental contribution to cancers in general – a topic that remains contested.

The use of epidemiology to help frame regulations has depended on the examination of large groups of workers...
with comparable levels of exposure to risk whose pattern of illness could be compared either with the unexposed or with those who had a different level of exposure. A series of major studies of relatively specific risks was undertaken in the 1970s and 1980s by the Health and Safety Executive, by the Medical Research Council and by academic departments, with governmental or industry support.

The controversy surrounding asbestos and vinyl chloride coincided with a major review of state regulation of occupational safety and health in the United Kingdom by the Robens Committee. The United States had already undertaken a not dissimilar review leading to the creation of the Occupational Safety and Health Administration and the National Institute of Safety and Health in 1970. The aim of Robens was to rationalize and reduce the dense mass of regulations and inspection regimes which had developed since the nineteenth century. The 1974 Health and Safety at Work etc. Act fulfilled Robens’ vision of a governance framework which separated the executive and enforcement functions of safety from the tripartite commission that decided on policy matters. The new regime incorporated the recently formed Employment Medical Advisory Service (EMAS), as well as several inspectorates, into a Health and Safety Executive (HSE). EMAS’s original purpose was to freely provide accurate information on occupational health to industry, trade unions and individuals, although while its connection to HSE’s enforcers probably made it less palatable to employers it became better placed to function as a source of medical expertise within the new executive. Another feature of the new system was the inevitable difficulties which arose from Robens’ definition of health and safety in fairly narrow occupational terms, leaving unresolved the familiar problem of drawing the boundaries of causation between workplace and the wider physical and social environment.

Since the 1974 Act, a number of new health regulations have been adopted including controls on chemicals, lead, asbestos and ionizing radiation, as well as for noise exposure, manual handling, working with pathogens and at display screens. The framework of international directives has been strengthened by European Union agreements that place penalties for non-compliance on nation states, as well as on offending employers. The agenda of occupational health and the expertise of government regulators has also changed in recent years as the historic concern with hazardous substances had to be refocused towards a range of conditions which extended from musculoskeletal pain and dermatitis to asthma, mental distress and the non-specific symptom syndromes which have been attributed to ‘sick buildings’, solvent exposure, pesticide use and other complicated environmental factors. As in the late nineteenth and early twentieth centuries, however, a key driver in the changing priorities and concerns of employers and governments has been the award of compensation settlements in cases of workplace stress and upper limb disorders. This has prompted defensive and preventative action by industries and their insurers.

**A FUTURE HISTORY FOR OCCUPATIONAL HEALTH?**

Hunter first published his major work at a point when the most lethal consequences of asbestos were still to be revealed and it was still possible to see the history of medicine as an almost unbroken trajectory of scientific improvement and heroic discovery. Within 20 years of his first edition, the bitter and escalating controversy around asbestos had blown away the notion of benign technology and consensual regulation. A few years after Hunter’s work Rachel Carson’s *Silent spring* was published, graphically depicting the impact of chemical production and toxic pollution on the American landscape and confirming a dawning consciousness of environmental damage which reoriented public health politics in the United States during the following three decades. The growing challenge to assumptions about the beneficial consequences of new technology and medical research was strengthened by pharmaceutical tragedies, such as the marketing of thalidomide to pregnant women and the initial reluctance of the Distillers Company to reach a compensation settlement with those families affected. We still do not know at the end of the first decade of the twenty-first century what the final toll of deaths and disability will be from the asbestos disaster.

As the promise of scientific progress and new technologies has been subjected to more critical scrutiny in the half-century since Hunter’s text was published, philosophers, social scientists and historians have attempted to offer a more searching analysis of the way science itself is conducted and the terms in which knowledge about the world (and the human body) is authenticated and accepted. Social scientists have also contributed to explanations about human behaviour in the face of risks and hazards as well as to broader questions of social interaction at the workplace and individual assessment of competing responsibilities. The expanding disciplines of psychology, sociology and organizational studies have also exerted greater influence over the ways in which workplace health and risks are understood and analysed. Although the diagnosis and treatment of occupational diseases had traditionally depended on a clinical examination and frequently on the sufferer’s own history of their working life, industrial toxicologists had been largely concerned with the pathology of illness and establishing the nature of the link between environment and illness. In determining the provisions made for both treatment and financial maintenance of the individual worker, a range of social and political considerations has almost inevitably come into play. Governments, as well as scientists, often appeared anxious in the earlier twentieth century to preserve the distinction, however artificial in practice, between the research problem of industrial hazard and the legal and administrative procedures by which financial compensation might be decided.

Preserving these distinctions was particularly difficult when a new range of work-related ailments emerged, including asthma, dermatitis, musculoskeletal pain and
ment is the link between illness and specific occupational conditions was less robust than in circumstances where toxins or dust might be measured with the prospect of defining clear dose–effect relationships. While an increase in prevalence might be established, the nature of individual exposure and susceptibility was much less clear. Greater reliance had to be placed on epidemiological studies of large groups of workers rather than on individual case notification.

The limitations of epidemiological studies provoked further debates about the appropriate methodologies which could be utilized in the discovery of health and illness at work. In many industries, such as oil, chemicals and pharmaceuticals, only a small number of workers were exposed to a particular hazard. Statistical testing of unusual patterns and isolated clusters of disease yielded unsatisfactory results. Researchers also found it difficult to establish valid methods to study the apparent increase in musculoskeletal and psychosocial symptoms reported in British and overseas workplaces as reports depended so heavily on subjective evaluation and self-reporting. Psychologists became contributors to HSE research projects from about 1980. Within the expanding research field of work-related psychology, divisions were also apparent between laboratory-trained personnel who followed the experimental model of study laid down during and after the 1939–45 war, and those who embraced a qualitative and more flexible social approach to the investigation of workplace attitudes and the consequences of monotony, overload and conflict in different occupations.

Most historians of work would place these trends in occupational health and the debates among experts on the nature and causes of workplace illness within the larger social and institutional context of economic and political change during the later twentieth century. Discussions about workers’ welfare had moved from assessments of basic physical and mental capacity to considerations of satisfaction and fulfilment as conceptions of human well-being expanded during the long boom and rising affluence of the post-war period. European countries that developed comprehensive welfare systems funded by near-full employment and corporate bargaining between employers, unions and government embraced at least some principles of improved job fulfillment, as well as rigorous safety standards. Scandinavian research was particularly influential in a burgeoning concern with improving or ‘enriching’ occupational satisfaction, as well as in an escalating literature on sources of ‘stress’ at work and in wider society. The context of these debates was radically changed in the last two decades of the twentieth century as the post-war consensus on national fiscal management and collective bargaining was disrupted in Europe and other continents by the reorganization of global production and the election of free-market conservative governments in the United Kingdom, the United States and other countries. The transformation of the global economy was confirmed by the collapse of planned economies and Soviet power, as well as the commitment of China to industrialization and world trade, in the past two decades.

These changes were reflected in renewed concern with the productivity of the workforce and with devising effective models for managing human, as well as material, resources of production. The last three decades have followed the free market ethos that has dominated in politics and business and have been marked by a cultural, as well as a political, acceptance that the idea that personal fulfilment and self-realization depends on individual responsibility for self-care and personal well-being, as well as on the conditions created by others both in the workplace and elsewhere. Public institutions, as well as private corporations came to set policy goals of transparency and accountability – reflecting increasing customer and consumer rights – as well as agreed performance targets, self-monitoring or peer assessment of performance, open-plan office spaces and technological screening of inappropriate behaviour. The collective protection offered by trade unions has been weakened by the decline of older, often male-centred sectors of production, alongside the growth of ‘flexible’ working, temporary and short-term contracts and self-employment. In parallel to the expansion of the practice and language of management, a significant feature of the renewed drive for productivity and controlled flexibility in global labour markets has been the erosion of the authority and autonomy of the elite professions. The titles and status of professionalism have been stretched to include less skilled and lower status groups, while the capacity of professional bodies to govern their members has been subjected to intense scrutiny by government, media and private litigants.

This changing landscape of global production and unrestricted labour markets has powerfully influenced the terms in which occupational health and safety have developed in recent decades. During the middle decades of the twentieth century, tensions between occupational medical goals and production management were apparent in large companies and organizations where much of the key research was conducted and policies were implemented. Employers promoted safety selectively and most enthusiastically where productivity gains and corporate risk reduction were most evident. This is illustrated by the unintended consequences of initiatives, such as audiometry programmes established to reduce damage to hearing from noise. While firms often ignored the representations from occupational health departments showing the need for better controls, the data recorded subsequently provided strong evidence for compensation claimants. As employment was rationalized and reorganized in the harsher competitive conditions of the late twentieth century, the problem of risk was more closely aligned to problems of output and poor performance rather than a duty of care to employees. A countervailing force appeared in the greater readiness of employees to resort to litigation on the grounds of discrimination, as well as unreasonable exposure to risk, blurring further some of the boundaries between their obligations as employees and their expectations of social responsibility from their
employer. Concurrently, the ‘balance’ of occupational and non-work life became a familiar theme in discussions of personal and organizational stress. Faced with the conflicting pressures and repeated demands for public engagement in questions which had previously been a domain of specific expertise, researchers into workplace health increasingly adopted broader and less technical approaches to the problem of occupational risk. This ‘ecological’ view of ill health rephrased many earlier concerns about the origins and causation of problems by posing questions about the nature of the health issue raised and the circumstances in which concerns began to be expressed about it. Practitioners, as well as investigators, who adopted an ecological approach now had to consider novel links between possible causes and effects in terms of the psychosocial context of the problem and the belief systems of those involved with it, as well as nature of the cause or harm that is being investigated. Rather than seek to exclude and control any stated or implicit values and subjective meanings attached to problems and policies, such studies of workplace health now often share the perspective of historians and social scientists when they study the effects of the power of different interested parties, the reasons for disputes about the significance of subjective complaints and scientific studies and the ethical and expedient basis for taking decisions about action on health concerns and risks at work.

CONCLUSIONS

An early reviewer of Donald Hunter’s massive work noted his regular visits to industrial factories to fire a stream of questions at all and sundry, before departing usually with trophies to illustrate his lively lectures. These voyages of discovery into the occupational life extended to an abiding interest into the afflictions of musicians, as well as metalworkers. Hunter’s remarkable enterprise bears comparison with the famous surveys of Ramazzini and Oliver, for its encyclopaedic scope and detail. The work also bears the imprint of its time and the assumptions which informed occupational medicine in the first half of the twentieth century. His text offers us an authorised version of the heroic role of brilliant individual scientists and medical specialists in a progressive struggle against illness at work, confirming the fundamental importance of toxicology and studies of dust in the rise of the modern specialist and the framework of regulations introduced by government and industry. Such an approach may appear dated now that historical scholarship has challenged many of the assumptions which underlay such a grand narrative of scientific enlightenment, celebrating the role of brilliant medical men who battled selflessly against the dark forces of ignorance and vested interests. Social and political histories of occupational health have, since Hunter, uncovered the contribution of a much larger range of people and a more complex pattern of struggles, including battles along lines of labour rights, gender, ethnic immigration and rival advocates of scientific and legal expertise.

Perhaps most fundamentally, historians now seek to recover the voices of the patients and workplace witnesses who were most directly affected by disease and diagnoses. The identity of those who can be considered as the clients for expertise on occupational health risks has changed in the half-century or more since Hunter’s classic text was first published. Nineteenth century commentators were acutely aware that workplace hazards and effluents were likely to affect not only the workforce but the surrounding community and to result in damage to public health. From the mid-Victorian years, responsibility for workplace and environmental health was allocated to different agencies and government departments and this overview was lost. Hunter was writing at the dawn of a new environmental politics, emanating principally from the United States, but evident also in Europe by the 1960s, that was returning to the nineteenth century model with raised awareness of the dangers presented to wider society by pollution from toxic products and discharges. Consumers, as well as producers, began to articulate their concerns in ways that compelled medical scientists, as well as policymakers, to reappraise the connections between production and public health.

The example of asbestos illustrates the fault lines in the scientific community and the employers’ lethargic response to key research and government controls in the post-war years both in relation to worker and public risk. The different ways in which this story has been interpreted by historians also reveals the deep philosophical divisions which prevail among historians, as well as contemporaries in regard to the management of information and risk by some of the key players concerned with the hazards presented by such materials. Debates over the practical limits of technology for securing workers’ safety provoke bitter exchanges over the legal and moral responsibility for adequate disclosure of historic risk levels. There is much less readiness than in Hunter’s day to accept the veracity of pure science, although it is arguable that historical research often replicates Hunter’s tendency to present history as a polarity between the forces of truth and selfish ignorance. In uncovering a multitude of new historical contributors and fresh complexities in the process of scientific enquiry, historians of workplace illness face the challenge of providing an explanation of human intervention which captures the diversity of occupational injury and political capacity described so vividly in Hunter’s text. It must still be recognized, as Hunter did, that investigators using the techniques of medical science have played a leading part in the identification of health risks at work. They have worked effectively with other technical colleagues and with industry, regulators and trade unions to remove many of the more serious risks to workers. Both the agendas set for investigators and the actions that follow from the results of their investigations are, clearly, part of a social and political process involving a wide range of interest groups. Clinical vigilance and a readiness to challenge remain essential both
for recognizing new risks and for ensuring that those that are known remain under control.

**Key points**

- Donald Hunter was a major contributor to occupational disease prevention as an investigator, writer and as the teacher of a generation of physicians.
- The historical sections of Hunter's text book provide important insights into the development of occupational disease identification and prevention, as well as reflecting the historical approaches among 'practitioner historians' at the time when it was written.
- Occupational disease recognition and prevention are now seen by historians as processes to which medical investigators make a fundamental contribution, but these processes and the guiding assumptions of investigators are decisively influenced by the social, political and economic climate of the period.
- Successful prevention has reduced many risks to the health of workers markedly, although high levels of risk are still found, particularly in developing countries. Current concerns in developed countries now focus on conditions less specific to work and which may be seen as part of a wider environment for workers and communities.
- Hunter's precept that constant vigilance and a readiness to try and secure remedial action remains relevant today if we are to identify and pre-empt new risks or retain control over known hazards.

The changing face of occupational diseases

PETER J BAXTER, TAR-CHING AW, ANNE COCKCROFT, PAUL DURRINGTON AND J MALCOLM HARRINGTON

INTRODUCTION

Occupational diseases are all preventable, but they have exacted and continue to exact a huge human burden on a global scale. Early interventions by public health reformers around the time of the Industrial Revolution in the United Kingdom were hampered by their confusion over whether the diseases that were rife in the population were the result of the degraded and impoverished living conditions in the overcrowded industrial town slums or due to the rank factory environment, where many spent most of their waking lives.

Greater understanding of where the focus for prevention lay and the need for intervention to improve the conditions of workers grew in the late nineteenth century and the government took action to reduce acute and chronic metal poisoning arising mainly from the indiscriminate use of mercury and lead. Exposure to lead in food and drink was also widespread in the UK population and the metal was probably a common cause of undiagnosed illness. Medical science had also developed to the point of being able to diagnose, and provide a limited understanding of, the toxic manifestations of metals, including Mad Hatter’s disease (mercury) and peripheral neuropathy (lead), as well as the action of lead as an abortifacient. The first medical inspector of factories, Sir Thomas Legge, was appointed in 1898 with the principal duty of stemming the lead poisoning epidemic.

The use of machinery to take over manual tasks and the introduction of drilling equipment had by the beginning of the twentieth century unwittingly precipitated increases in exposure to dust in mines and quarries, leading to increased rates of pneumoconioses, such as silicosis and coal miner’s black lung. Whole mining communities fell into the grip of occupational lung diseases from mineral dusts. By the middle of the twentieth century, the chemical industry was expanding rapidly and bringing a new era of synthesized substances to revolutionize lives, but in its wake there was an unwelcome tide of novel toxic hazards, including carcinogens.

Physical hazards and extreme working environments present different risks from those of substances that can be inhaled, ingested or absorbed in the workplace. We know more about the adverse chronic effects of ionizing radiation than any other occupational hazard, in the sense that the dose–response relation for cancer is well delineated and the risk relatively precisely quantified. Deep sea fishing possibly remains the riskiest job in the UK, as was first recognized 40 years ago. In contrast, flying, deep sea diving, working at altitude or at extremes of temperature have been shorn of most of their dangers. Regulations and better work practices have also transformed the risk of back injury from mundane manual handling operations in ordinary jobs. However, the question remains for all types of occupational hazards: as human inventiveness and discovery take us into ever new worlds of work will the changes so produced inevitably present new health challenges, some of which cannot be always foreseen? If so, will the main societal role of occupational medicine in the future be, as it has been since Hunter’s day, to maintain vigilant monitoring over workforces for the unexpected health consequences of ever-changing technology?

THE HISTORICAL LEGACY

Occupational health, as we know it today, is largely the product of the late twentieth century. The last edition of
Hunter’s Diseases of Occupations published in 2001 marked the culmination of a generation of sociopolitical pressures and technological changes in occupational health and safety that began with the governments of most industrialized countries adopting radical legislation in the 1960s and 1970s which, by the end of the century, had led to a dramatic fall in the incidence of work-related ill health and injury. The whole of the twentieth century saw a revolution in public health and preventive medicine which accelerated with scientific and medical advances during a time of unprecedented material growth as the century ended. Fundamental to progress in occupational medicine over this period were developments in the medical sciences and, in particular, toxicology, but it was in the application of the new field of chronic disease epidemiology, spearheaded by epidemiologists in the United States and the United Kingdom after the Second World War, where many of the most important advances in understanding and tackling occupational diseases took place. This was the era when occupational cancer rose to prominence as epidemiologists and toxicologists identified increasing numbers of suspect human carcinogens, and public anxiety was being spurred by revelations over the toxicity of asbestos and the disastrous global legacy of the asbestos industry. The inertia of some industries to adopt costly controls to protect workers was not new, and has always been behind the need for government regulation in health and safety at work, but the uncertainties inherent in epidemiological and toxicological studies were too often cited as a justification to delay or obfuscate, rather than incorporate the lessons of research, as the asbestos saga has shown.

This edition’s opening chapter is a historical panorama of occupational diseases with an interpretation that deliberately owes more to Herodotus, the father of history, than to Donald Hunter. Many Hunter readers have lamented our exclusion in recent editions of Donald Hunter’s own history from the Bronze Age to the twentieth century, a tour de force occupying nearly a fifth of his book which he had already packed with fascinating historical vignettes. (This edition is accompanied by a reproduction of his chapter on the website.) Hunter marked advances in prevention with a pageant of heroic reformers and medical figures, who often ran up against stout resistance from vested interests. Colourful personalities included Sir Humphrey Davy (1778–1829), as the brilliant researcher, who achieved world fame by inventing his famous safety lamp after a brief trial of inspired experimentation, and thereby saved thousands of miners from death in gas explosions, and John Scott Haldane (1860–1936), the physician–physiologist and ‘medical detective’, who uncovered the toxic hazards of gases in mines by performing dangerous experiments on himself and investigating well-publicized, fatal incidents. However, Hunter’s narrative neglected a whole uncharted terrain of social, political and economic history, an omission that Herodotus would have regretted.

When Donald Hunter was practising, physicians in England seeking specialist status had to pass the London Membership of the Royal College of Physicians, which at that time was a hurdle of terrifying difficulty. Hunter’s book became required reading for a whole generation of candidates in case they were confronted in the pathology vivia by Hunter himself as one of a number of regular and distinguished college examiners. As Seaton writes, ‘If you had not done this and had the misfortune to meet him, you were sunk’, as he passed you a hunk of rock or a steel bit across the table. However, Donald Hunter’s retirement coincided with the beginning of a long decline in occupational medicine in Britain: occupational diseases no longer feature as strongly in medical examinations, while medical undergraduates may receive hardly any teaching in the subject at all. Many occupational physicians in high income countries feel a sense of loss to their professionalism through this rapid decline in incidence of the traditional occupational diseases, which has been due only in part to effective prevention in the workplace. Globalization has brought a rise in service industries and a shift of the traditional manufacturing industries to newly industrializing countries. Yet the UK, for example, remains the sixth largest manufacturing economy in the world, with a particularly strong presence in industries such as aerospace, health and construction. This concentration of added-value manufacturing is still a one and a half times larger contributor to the economy than the financial sector. In some UK regions, however, the largest employers are the main universities or district hospitals, not foundries, steel mills or vehicle manufacturing plants. Before the Health and Safety at Work Act in 1973, the health and education sectors did not even fall under the old Factories Acts, and had never been formally inspected, let alone employed occupational health professionals. Yet no occupational health professional working in these sectors today can doubt that new challenges in work-related ill health have emerged as the old industries have moved elsewhere.

THE CONTINUING BURDEN OF OCCUPATIONAL DISEASES

Just as the worst global recession since the Second World War has shattered illusions that the global banking system had eliminated financial risk, it is premature to assume that the health risks of occupational diseases have been assigned to history in high income countries, or to forget that they are much more prevalent in the developing world, especially in the rapidly growing BRIC (Brazil, Russia, India, China) economies, where statistics are unavailable for making meaningful comparisons. Meanwhile, the Health and Safety Executive estimates that in the United Kingdom every year still more than 10,000 people die from past exposure to chemicals, fumes and dusts, a figure that far exceeds the death toll from accidents at work (200–240 annually). Respiratory and skin sensitizers have become common causes of significant morbidity, and dusts may act synergistically with smoking and other causal factors in the aetiology
of chronic obstructive pulmonary disease (COPD) (see Chapter 69, Work and chronic air flow limitation and Chapter 72, Occupational asthma).

Industrial carcinogens remain a special problem due to their number and the lack of adequate exposure controls in many of the smaller workplaces where they may be found. In a key study by Rushton et al., on the burden of cancer at work in the United Kingdom, occupation contributed to around 8 per cent of cancer deaths in men and almost 2 per cent in women, for six selected sites: lung, nasal sinus, bladder, non-melanoma of skin, leukaemia and mesothelioma. Asbestos contributed over half of the occupational cancer deaths, and more than half of these were due to exposures in the construction industry. Respirable crystalline silica (RCS) is judged to cause about 800 lung cancers each year in the United Kingdom, mostly in construction workers who are exposed to silica present in many common building materials.

Annually, at least 4000 people die in the United Kingdom from all diseases linked to asbestos, about twice the figure of deaths in road traffic accidents. Around half of these deaths are due to mesothelioma, which is still on the increase and set to peak in incidence over the next decade. The mesothelioma epidemic is also occurring across other countries in Western Europe and throughout the world. Despite the use of asbestos in factories being banned in the UK since 1998, its legacy continues to give rise to exposures leading to cancer; these exposures were not envisaged early on by scientists or government agencies and have only recently featured in legislation and awareness campaigns. Asbestos production declined in the 1970s and with exposure in buildings containing asbestos supposed to be negligible, it was widely assumed that mesothelioma deaths would soon peak and then fall. However, this reckoning was based on cohorts of factory workers and ignored the exposures of tradesmen engaged in building and maintenance work – plumbers, electricians, joiners, carpenters, painters – who were mostly unaware of the hazard the asbestos in buildings presented if it became disturbed in the course of their work. An epidemiological study published in 1995 provided new projections of mesothelioma deaths and for the first time included the substantial contribution from these building and maintenance occupations, which to date amounts to a quarter of the total number of mesothelioma deaths. These findings raised new concerns about asbestos in buildings, such as schools, hospitals and homes, and the risk from inadvertent low but cumulative exposures, as well as brief exposures to the dust in bystanders. It was not until 2002 that the Health and Safety Executive (HSE) in the UK updated its workplace regulations to compel workplace property owners to hold registers of asbestos in their buildings, and embarked on media campaigns to raise awareness in these small groups of workers, who together numbered 1.9 million in 2009. Asbestos may be present in any building constructed or refurbished before the year 2000, amounting to at least 500,000 workplace premises in the UK.

By 2009, the death rate from mesothelioma in the United Kingdom had become the highest in the world. The occupation with the highest risk was carpenters and this has been attributed to the cutting of board made from amosite (brown asbestos), which was widespread in the UK construction industry through the 1970s into the 1980s. Large amounts of amosite were imported into the UK after crocidolite (blue asbestos) had been banned in 1968, at a time when the carcinogenic potency of amosite had not been established. The mesothelioma risk of amosite is now known to be two orders of magnitude greater than that for chrysotile (white asbestos).

Globally, there are an estimated 90,000 asbestos-related deaths every year and in high income countries the compensation for asbestos-related diseases is likely to reach US$300 billion over the coming years. All forms of asbestos are now recognized to be carcinogenic and to date, more than 40 countries, including all member states of the European Union, have banned the use of asbestos. However, chrysotile asbestos continues to be mined and exported to developing countries by Canada and Russia, with Brazil having its own mines. The largest importer is India. Its use continues to be promoted by the industry as a safer form of asbestos for such purposes as the manufacture of asbestos cement pipes for long distance water distribution and in construction, even though substitute materials are available for all uses of asbestos. Unless international action for a worldwide ban is taken, as called for by the World Health Organization (WHO) and the International Labour Office (ILO), another asbestos disaster is looming, indeed probably already underway, this time in the developing world.

NEW TECHNOLOGIES, NEW HAZARDS

Even though the health hazards of old scourges, such as asbestos and silica dusts, are now well understood, they remain important causes of occupational disease. By the 1970s, the traditional industries were already in decline in western countries, while the chemical industry had expanded rapidly since the Second World War. One chemical, vinyl chloride monomer (VCM), used in many countries in the manufacture of the highly profitable plastic PVC, had been widely assumed to be safe due to its deceptively simple chemical formula (CH₂Cl), and its derivation from ethylene in the cracking of oil, but evidence from laboratory animals in 1973 showed that it could cause angiosarcoma of the liver in humans, a rare tumour and one which could therefore be easily spotted in chemical workers as a cause of death. Within months, cases of angiosarcoma had been reported in VCM workers in several countries, including the United States and the United Kingdom, and rapid action was taken to drastically reduce exposure levels in the chemical plants. This finding of an incontrovertible cancer risk in a chemical previously thought to be safe led to widespread changes in the attitude of the chemical industry and legislators to the health hazards of the large
numbers of chemicals that by then had been introduced into commercial usage, the vast majority of which had not been as adequately tested for carcinogenicity as VCM.

VCM also represented the hazard of new technologies as it was one of a range of new and very useful compounds synthesized by halogenating hydrocarbons, an industrial process which started in the 1930s and grew rapidly. A whole range of chlorinated compounds were synthesized in large quantities which only later came under suspicion of being potentially toxic to humans and wildlife, with some having added dangers because of their biopersistence and their inability to be easily degraded in the environment (e.g. DDT, PCBs). Some became classified as recognized or suspect human carcinogens. The concerns of long-term health hazards arising from exposure also apply to many other chemical groups: by 2009, about 75 000 compounds were in regular commercial usage, but the vast majority of these have not been fully tested for their long-term toxicity or carcinogenicity.\(^{10}\) Following the shock to the chemical industry provided by vinyl chloride, a general consensus arose that all chemicals need to be treated with caution and none should be assumed to be of low toxicity without good evidence.

During the latter part of the twentieth century, it became clear that carcinogenesis was a multistep process. Biomarkers now play a significant role in identifying key events in the process, including occupational carcinogenesis. For many carcinogenic chemicals, there has been much research interest in measuring haemoglobin adducts. In the last decade, one of the most studied genes in epidemiology has been the TP53 tumour suppressor gene (see Chapter 85, Occupational cancer: epidemiology, biological mechanisms and biomarkers). Its role in causing liver and skin tumours is a focus for much research activity. Intermediate biomarkers, such as chromosomal damage and altered DNA repair also point towards evidence of early, non-clonal and potentially non-persistent effects, which if halted or reversed, could decrease the risk of full-blown malignancy. In the past, evidence of family history susceptibility has been a crude marker for inherited susceptibility to cancer. Occupational cancer studies have not shown much evidence of family history as being an important factor, but the possible interaction between NAT2 acetylation status, benzidine exposure and the development of bladder cancer is one positive example. The role of so-called ‘molecular epidemiology’ in the study of cancer aetiology, so far of little practical value in occupational cancer, is likely to expand in this century.

Newer concerns over cancer have arisen with the rapid introduction of technologies such as mobile phones whose use became widespread before studies of their potential health hazard were embarked upon (Chapter 55, Extremely low frequency electric and magnetic fields). The precedent and lessons of asbestos loom large in attitudes towards synthetic fibres, in particular engineered nanomaterials, such as carbon nanotubes and nanoparticles, which have a growing number of commercial uses (see Chapter 70, Health effects of ultrafine particles).

There are now many international and national initiatives addressing occupational, environmental and consumer issues in relation to the control of toxic substances. Much better control technologies and the adoption of risk assessments under legislation, such as the Control of Substances Hazardous to Health (COSHH) in the UK have radically altered attitudes and led to far better control of exposure to chemicals, and mixtures of chemicals, in all employment sectors in recent years. In Europe, future regulations for controlling toxic substances in the workplace, including carcinogens, will flow from EU Directives and technical guidance, with the latest initiative being REACH – a new EU regulation concerning the Registration, Evaluation, Authorization and restriction of Chemicals.\(^{11}\)

### THE NEW WAVE OF WORK-RELATED ILLNESS

In the last two editions we included for the first time syndromes (stress, upper limb pain and lower back pain) that were beginning to change our conceptual framework of occupational disease. The dominant risk paradigm of the twentieth century which has been so successful in controlling diseases from chemical, physical and biological hazards, is based on being able to define the relationship between the degree of exposure to an agent at work and the development of a disease outcome, and then controlling the risk by eliminating or reducing exposure. Founded in toxicology, this framework became enshrined in epidemiological studies of workers in the form of exposure–response relationships and is implicit in the drawing up of risk assessments in the workplace and for a clinician to establish when a patient is suffering from an occupational disease. Diseases with high morbidity and fatality, such as chemical-induced cancers and pneumoconioses, had identifiable causes and so proved readily preventable. However, the paradigm was no longer so apt when dealing with the new wave of health problems that became the most common single cause of referral to occupational health clinics and a new burden of illness, disability and sickness absence across all employment sectors. Features of these disorders include a relationship with work that cannot be wholly explained by their assumed occupational causes and they are rarely associated with evidence of underlying pathology.\(^{12}\) In one group of conditions, the symptoms can be remarkably similar, or non-specific, despite their causal exposures being very different, examples being Gulf War syndrome, exposure to organophosphates and sick building syndrome. It has become necessary to clearly distinguish between illness and disease in occupational disorders: illness is by definition a subjective state and disease is a pathological process that at least in theory is amenable to objective, external verification.\(^{12}\)

We are still far from understanding the implications of these latest disorders not being a simple function of excessive exposure to noxious agents or activities, and we need more research on the role of psychological risk factors or psychologically mediated responses in these conditions, and
embracing this change in thinking (see Box 2.1). The term ‘work-related illness’ has become accepted as social and behavioural factors within the workplace itself: a shift from reductionist biological models to one which incorporates the role in the future to anticipate and identify the new and unforeseen health consequences arising from innovative technologies, changes in work patterns and the ageing workforce. and consequent increased levels of stress. We will have to look beyond the old paradigm which lends itself to reductionist biological models to one which incorporates social and behavioural factors within the workplace itself: the term ‘work-related illness’ has become accepted as embracing this change in thinking (see Box 2.1).

THE FUTURE OUTLOOK

The challenges facing the modern world cannot be met without the creation of new technologies with the potential to improve lives enormously. Some of these will have adverse health consequences, and in a small proportion these may be unforeseen under current regulatory approaches. The present global picture and outlook for control of occupational diseases is bleak, with many rapidly industrializing countries having inadequate legislative controls and infrastructure to protect workers from even well-known and preventable occupational health hazards. Despite the huge advances in disease prevention in industrialized countries in the last decades, or perhaps because of them, the provision of specialist advice and expertise is not keeping pace with the rapid changes in the work environment. Occupational diseases and disorders will continue to exact a significant and unnecessary burden on the societies of developed countries unless this shortfall is adequately met.

Box 2.1 Definition of terms.12

- **Illness.** An absence of well-being as perceived:
  - by the affected individual (in the form of one or more symptoms); or
  - by others (from an abnormality of function or from an abnormality of behaviour for which the affected individual cannot be held responsible).
- **Pathology.** Abnormality of tissue structure or of biochemical or physiological function that has the potential to cause illness or death.
- **Disease.** A combination of pathological abnormalities that are thought to be inter-related.
- **Disorder.** A broader term encompassing both illness and disease.

Key points

- Occupational diseases still present significant burdens in advanced industrialized countries, despite legislative and technological changes based on epidemiological and toxicological evidence during the late twentieth century.
- For countries undergoing rapid industrialization, the outlook is bleak, with the prospect that occupational diseases will escalate worldwide.
- Occupational carcinogens remain an important cause of mortality in industrialized countries. Asbestos has left a deadly legacy: tradesmen and construction workers now contribute to a significant proportion of asbestos cancer deaths. The UK now has the highest incidence of mesothelioma in the world.
- Illnesses, such as stress, musculoskeletal disorders and non-specific fatigue syndromes, have become prominent types of work-related ill health in industrialized countries. These have substantial subjective components and their management and prevention requires strategies that incorporate social and behavioural factors.
- Occupational medicine has an important societal role in the future to anticipate and identify the new and unforeseen health consequences arising from innovative technologies, changes in work patterns and the ageing workforce.

On visiting a poor home, a doctor should be satisfied to sit on a three-legged stool, in the absence of a gilt chair, and he should take time for his examination; and to the questions recommended by Hippocrates he should add one more – What is your occupation?1

Bernadino Ramazzini, 1713

WHAT IS THE OCCUPATIONAL HISTORY?

The occupational history refers to obtaining details from an individual about his job. It has two main components:

1. **The present job.** This includes not just the job title, but also the work tasks, chemicals used, the work environment, and availability and use of personal protective equipment. It is also important to enquire about the duration of the job, whether there is shift work, overtime work and whether the person has a second job.

2. **Previous jobs.** Similar details are required about the different jobs (paid or unpaid) that the person has done before. It is best to be systematic when obtaining the past work history; either starting from the present job and working back to the first job, or beginning from the first job and working forward to the present employment. Periods of unemployment, voluntary work locally and overseas, part-time work, casual or temporary work, and hobbies should be included, especially if these involve exposure to chemicals or contact with biological materials that might pose a risk of sensitization or infection.

A suggested template for recording the occupational history is shown in Figure 3.1.2

Taking the occupational history is an important part of the general medical history obtained when a patient is seen by an examining physician. Unfortunately, this is often overlooked or not taken in sufficient detail. Clinical management of a patient without information on what a person does at work can be incomplete or inadequate. This is because of a possibility of missing a condition caused by work or not recognizing the work-related nature of a common condition, such as asthma. The necessary clinical advice regarding fitness to return to work or dealing with possible occupational factors contributing to the disease will then be lacking.

In taking the occupational history, the physician should be a good listener. Much information can be obtained from a patient’s description of what job activities are done at work, and how work tasks are performed. This can give an indication of workplace exposures and possible risks. In addition, the patient’s occupational history may provide additional insight about a workplace, which might not be apparent even after a worksite visit. Listening to the patient may provide information on issues such as the morale of the workforce, commitment to health and safety measures by both employer and employees, and whether other workers have similar health problems.

Sometimes, evidence of significant occupational exposure or disease is discovered by chance in the course of investigations for other diseases. For example, the incidental detection of calcified pleural plaques from asbestos exposure may be detected on a chest or upper abdominal radiograph performed for other clinical reasons. In these
circumstances, all clinicians should make further enquiry about relevant occupational and environmental exposure.

**ASKING ABOUT SYMPTOMS IN RELATION TO WORK ACTIVITIES**

When a substance produces an acute effect, direct questions should show the relation between symptoms and work; a useful pointer is evidence of remissions at weekends and holiday periods. Some clinical effects may not appear until a few hours after exposure. Examples are delayed pulmonary oedema from exposure to phosgene gas, ozone or oxides of nitrogen, and occupational asthma where both an ‘immediate’ and ‘delayed’ reaction to exposure may occur and the delayed response is often more prominent (see Chapter 72, Occupational asthma). Patients may wake up breathless at night as a result of workplace exposure during the day. Caution is needed in interpreting a temporal relationship with work, because some patients with non-occupational disorders may also feel better when they are away from work or on holiday.

**DELAY BETWEEN EXPOSURE AND SYMPTOMS**

For chronic effects, it is not uncommon for there to be a considerable delay between first exposure to materials encountered at work and development of clinical symptoms or signs. This can be for several reasons. Sensitization of the skin or respiratory tract may not occur until an individual has worked with the sensitizing agent for some time (months or years). It may be even longer before it manifests as a clinical condition, e.g. as in occupational asthma. Once the allergic condition has developed, the effects following re-exposure to the causative agent may be immediate or occur within hours. Sometimes disease only develops after considerable cumulative exposure. For example, it usually takes at least ten years for underground coalworkers to develop evidence of coalworkers’ pneumoconiosis. Once begun, the disease process may progress even after exposure ceases. In the case of occupational cancers, there is a latency period between exposure to the carcinogen and development of the cancer.

Mesotheliomas from asbestos exposure typically have a latency of 20–40 years, and the exposure at that time could have been brief. The link with previous occupational exposure may be harder to investigate when the patient has left the suspected job some years before the illness is diagnosed.

### Relevant factors regarding an occupational history

#### THE JOB TITLE

Even when the question ‘What is your job?’ is asked (Ramazzini’s exhortation), it is recorded in medical records as a word or phrase often with very little or no information about what the job entails.

A person who states that he is a ‘dentist’ may convey to the physician a reasonable idea of what the job involves. However, a job title such as ‘general labourer’ or ‘maintenance man’ does not give much insight into the job activities or the possible occupational exposures. A general labourer may perform primarily manual work or may rotate between several tasks, including some with chemical exposures. A maintenance man’s work may involve a variety of hazardous exposures, depending on what equipment or work process needs to be maintained.

A well-designed and properly functioning plant will operate without much danger to process workers, but when things go wrong and repairs have to be carried out, maintenance workers can be at risk. Hazardous exposures may also be encountered in ‘routine maintenance’. The recognition of possible risks have led to the development of various formal procedures, such as the ‘permits to work’ that are required in some chemical plants or on work involving high voltage switchgear, or before doing so-called ‘hot work’. The exposures of maintenance men are sometimes heavy and may be ‘mixed’ (i.e. to a variety of substances) and variable.

Another occupational group who often have problems with protection against occupational hazards are contract workers. These workers often have little training or experience in the job they are asked to perform. They may be
migrant or even illegal workers who can be subject to exploitation by unscrupulous employers. Contract workers are often asked to perform a variety of different tasks from day to day, usually with little information, instruction and training regarding those tasks, known risks and preventive measures.

A job title may give some indication about the work tasks, but some job titles can be vague and encompass a variety of activities, while the same job title in different industries or in different countries may on occasions refer to completely different jobs. Thus, a ‘general labourer’ may dig holes in roads or carry bricks up ladders; they can also work in such diverse places as a chemical factory, a foundry or a cotton mill. The job title ‘dresser’ may indicate someone who treats seeds with pesticides, or assists a stage actor with costumes and cosmetics, or removes excess sand from metal castings, or deals with cuts and wounds in a village hospital in a developing country. A ‘linesman’ assists a referee in a game of soccer. A ‘linesman’ (or ‘lineman’) is also a technician who deals with electric powerlines, telephone lines or installs wiring for cable television. A process worker on an assembly line for plastic toys may not be exposed to many chemical hazards, whereas a process worker in the electronics industry can be exposed to a wide range of hazardous materials (see Chapter 45, The semiconductor industry).

History is full of interesting and often cryptic job titles. The Dictionary of Occupational Titles, published by the US Department of Labor, Employment and Training Administration has a compilation and description of several hundred job titles, including puzzling jobs such as ‘barrel scraper’, ‘dope-house operator’ (may not be quite what you think it is), ‘egg smeller’, ‘frickertron checker’, ‘head beater’ and many more.

A good way of finding out precisely what an individual does at work, what materials he works with, and what hazards are encountered, is to ask the patient directly. The immediate supervisor at work would be another good source for such information. Even if a patient is not aware of the exact chemical that he handles daily, the availability of a trade name or a label from the container, or a copy of the material safety data sheet (MSDS) might be a starting point for finding out the hazards of the material.

‘HAZARD’ AND ‘RISK’

‘Hazard’ is the potential for causing harm and ‘risk’ is the likelihood (or the probability) that such harm will result. The term ‘risk’ is now extended to include consideration of the severity of effect. If handling sheets of paper at work is just as likely to cause cuts (paper cuts) to the skin, as sharpening knives, the probability of injury from both processes is the same, but cuts from knives are more severe than ‘paper cuts’. Therefore, of the two processes with equal likelihood of skin injury, sharpening knives is viewed as more risky because of the severity of the effect. The distinction between hazard and risk is important in regards to choice of suitable measures to reduce the likelihood of occupational injury or disease. Minimizing risk may be more cost-effective than eliminating hazards.

**EXTENT OF EXPOSURE**

A careful occupational history will indicate not only the materials a person has been exposed to, but also the extent of exposure. Recent overtime work, or weekend working can indicate acute exposure. The number of weeks or years spent on the job will give some idea of chronic exposure.

Hobbies, such as home maintenance and do-it-yourself (DIY) home improvement, may involve hazardous exposures away from the workplace. A worker in a shoe factory with contact dermatitis may suspect the adhesives at work as being responsible for his skin problems. However, this can also be the result of his hobby using glues at home for building model aeroplanes. Employers and employees can have differing views on the relative contribution of work duties versus hobbies and social activities to the development of ill health.

**DETERMINING SPECIFIC EXPOSURE**

When taking the occupational history, there can be uncertainty regarding the nature of the materials to which workers are exposed. This may arise in a number of ways:

**Caution on chemical names**

It is essential when investigating a case of possible exposure to a workplace chemical that the exact identity and nature of the chemical involved is obtained.

Benzene (C₆H₆), used in industry as a solvent and known to cause aplastic anaemia and leukaemia, is frequently confused with benzine, which is also used as a solvent, but is a mixture of liquid hydrocarbons (generally straight chain) and without the same serious haematologic effects. Another common confusion is between dioxin and dioxan (see Figure 3.2).

---

![Figure 3.2](image-url)
Dioxan (dioxane) has been used for many years as a solvent for fats and other materials. It has narcotic properties similar to other organic solvents and has been reported to be toxic to the liver and kidneys. Dioxin has a different chemical formula. It was the chemical released in the Seveso incident in Italy when an uncontrolled exothermic reaction resulted in workers and the surrounding population being exposed to dioxin causing chloracne, peripheral neuropathy and an increased risk of lympho-haemopoietic system malignancy.4

Chlordecone (Kepone™), a pesticide known to cause spermatogenic effects in occupationally exposed male workers5,6 is sometimes confused with the similar-sounding 'dodecane'7 – an aliphatic hydrocarbon used as a solvent. Chlordecone is no longer produced commercially, although dodecane is available and used widely.

‘Methanal’ is the systematic name for formaldehyde and can be confused with ‘methanol’, which is an alcohol.7 The former is an irritant, allergen and carcinogen, while the latter is best known for causing optic nerve damage leading to blindness in people ingesting illicit alcohol containing more methanol than ethanol.

Patients may know only the commonly used name of a chemical that they are exposed to at work, e.g. 'trike' for trichloroethylene, or 'perk' for perchloroethylene. It can therefore be difficult for a clinician not familiar with these short names to recognize the specific chemical. Trade names are generally not helpful.

**Impure chemicals**

Even when the correct chemical name is obtained from the occupational history, the physician must always bear in mind that books or journals sometimes refer to the toxicity of the pure or relatively pure substance whereas, when sold commercially, chemicals will often not be pure and may well carry contaminants. For example, toluene (methyl benzene), apart from narcotic properties, does not have the same haematotoxic effects as benzene, because it is metabolized along the side chain (the methyl group), whereas benzene is metabolized on the ring, initially by the formation of an epoxide which may react with the macromolecules of the cell. Toluene is therefore recommended and used as a ‘safe’ substitute, but commercial toluene has been known to contain up to 15 per cent of benzene.

Formalin solution used as a tissue preservative contains formaldehyde, but methanol is also present (about 10 per cent) as a stabilizer, in addition to paraformaldehyde and formic acid. Hence, formalin solution is not pure formaldehyde.

**Decomposition**

When industrial processes go wrong, the chemical composition or physical properties of the materials can alter and increase the risk from exposure. Trichloroethylene, a widely used degreasing agent, if overheated, may produce phosgene gas which causes delayed pulmonary oedema. Methyl isocyanate heated above 400°C under pressure may decompose to hydrogen cyanide:8 CH₃NCO = H₂ + HCN + CO. Cadmium-plated bolts do not pose a risk unless cut with an oxyacetylene, oxypropane or oxybutane torch giving rise to cadmium oxide fumes, capable of causing chemical pneumonitis (see Chapter 17, Cadmium).9

**PHYSICAL NATURE OF MATERIALS**

Metallic lead in solid form presents a physical not a toxicological hazard, but once heated to above its melting point, it is converted into fume which if inhaled will cause lead poisoning. Metallic mercury, on the other hand, is liquid at room temperature, and can vapourize easily to cause dangerous air concentrations to develop, especially in poorly ventilated rooms (see Chapter 26, Mercury).

Both toluene diisocyanate (TDI, or 2,4-tolylene diisocyanate) and methylene diphenyl diisocyanate (MDI, or diphenyl methane 4,4 diisocyanate) (see Figure 3.3) are well known as potent causes of occupational asthma (see Chapter 72, Occupational asthma). However, because TDI has a much higher vapour pressure, at room temperature, than the viscous MDI, it might be expected that MDI is safer to handle. So it is, unless the process is exothermic or involves spraying. In either of those circumstances, the advantage of the low vapour pressure of MDI in regards to safety is negated, and it has been found on a number of occasions to be a potent respiratory sensitizer.

**OBTAINING FURTHER INFORMATION ON CHEMICALS**

In the United Kingdom, the Control of Substances Hazardous to Health (COSHH) regulations10 require employers to provide adequate information, instruction and training in such matters, with the result that patients may arrive at the surgery or the outpatient clinic carrying...
specially prepared leaflets (material safety data sheets) on chemicals, if they suspect that these may be responsible for their ill health. Material safety data sheets are prepared by suppliers for users and also for importers. A standard format for the preparation of such sheets is suggested by the Occupational Safety and Health Administration (OSHA) for suppliers in the United States and by European Community legislation in Europe. Most MSDS contain some data on the properties of the chemical, the possible health effects, first aid treatment and safe handling and use of the chemical. There is unfortunately often some confusing variation between MSDS produced by different organizations in different countries.

A clinician can pursue enquiries on properties and toxicity of chemicals directly with an employer, preferably through the firm’s occupational physician if there is one, or from the firm’s health and safety officer. In the UK, information on chemicals can also be sought from the Health and Safety Executive or from the National Poisons Information Service. Section 6 of the UK’s Health and Safety at Work Act requires manufacturers, suppliers and others to provide adequate information about measures that are necessary to protect the user. An employer should therefore know about any possible harmful effects (or the absence of harmful effects) of a substance used or produced on his or her premises. Furthermore, where such information is not available, the manufacturer or supplier may be obliged to undertake research to eliminate or minimize any risks to health and safety. A patient is often able to obtain from his workplace the name and address of the supplier of a chemical or provide a copy of the MSDS.

Databases, such as Haz-Map and CCINFO, also provide information on hazardous chemicals and toxic effects, and websites, such as www.ilpi.com/msds, allow access to thousands of MSDS.

USE OF PERSONAL PROTECTIVE EQUIPMENT

A patient may have been provided with, and may claim to have used for all or part of the time, some form of personal protective equipment (PPE). A careful occupational history should explore the adequacy or suitability of PPE, and the availability and use by the individual. This will give some indication as to the extent of protection provided. A ‘mask’ can be anything from a simple gauze pad, a filter device, to a full face respirator with an external fresh air supply, or self-contained breathing apparatus (SCBA). Similar considerations will apply to enquiries about protective measures for skin and eyes, e.g. whether gloves, an eye shield or safety spectacles, have been used and the length of time that they are used for that work cycle. Inappropriate use of, or care for, gloves can increase the risk of dermatitis instead of protecting the skin. For example, the use of powdered latex gloves in healthcare workers has been linked to allergic reactions in sensitized individuals and therefore is detrimental to health instead of preventing ill health. Use of the same pair of gloves for prolonged periods may lead to permeation of the gloves by solvents, and spillage of liquids into gloves can prolong contact between the skin of the hands and irritant or allergic substances.

SMOKING STATUS

Smoking affects the development of some occupational diseases. For example, both smoking and asbestos exposure independently increase the risk of lung cancer, and concomitant exposure to both factors multiplies the risk. This is also the case with smoking and exposure to radon gas, as shown in studies of underground uranium miners who are exposed to radon in their work environment. While smoking increases the likelihood of byssinosis developing in cotton workers (see Chapter 73, Byssinosis and other cotton-related diseases), the evidence for smoking causing an increased risk of occupational asthma is controversial (see Chapter 72, Occupational asthma). However, smoking apparently decreases the risk of extrinsic allergic alveolitis, possibly because of impaired function of alveolar macrophages (see Chapter 74, Extrinsic allergic alveolitis).

Sometimes patients claiming compensation (or disability benefit) for occupational respiratory diseases may be reluctant to admit to smoking, or to their true level of smoking (or prepared to admit to smoking but only at home and not at work, because of restrictions in smoking at the workplace). This may be due to a concern that it may prejudice their chances of being diagnosed with an occupational condition or reduce any financial settlement or pension.

The ascertainment of current smoking status and smoking history, in addition to the occupational history, is especially important for assessing patients with respiratory disorders.

COMPENSATION

A physician may be asked by a patient about entitlement to compensation if there is an indication that his condition is work-related. The occupational history will have been instrumental in coming to a decision about any likely occupational aetiology. However, a diagnosis of an ‘occupational disease’ does not necessarily lead to compensation. State compensation schemes are governed by their rules regarding eligibility for benefits. For example, State benefits in the UK are only payable for specific prescribed occupational diseases. Claims for benefits must also be made within a specified time frame, e.g. within five years of leaving an employment where exposure to noise resulted in occupational deafness, and within ten years of leaving a job with exposure to a sensitizer causing occupational asthma. For many prescribed conditions, no benefits are paid if the extent of disablement is assessed as <14 per cent (often referred to as the ‘14 per cent rule’). In Australia, Commonwealth government employees need to be assessed as having >20 per cent impairment to be eligible for hearing loss compensation. How a decision is reached...
regarding percentage disablement is a separate issue. A patient with an occupational disease may therefore not receive state benefits despite a doctor’s diagnosis of the condition and a clear occupational history of a relevant exposure, if eligibility criteria are not met.

An occupational history is also important in civil cases where a worker sues his employer or ex-employer for exposures in the workplace that have caused or contributed to ill health or injury. Again, a firm diagnosis of an occupational disease supported by an occupational history, does not necessarily guarantee that there will be financial recompense. In many countries, there is also a requirement to demonstrate negligence of the employer. In New Zealand, a ‘no-fault’ system is in place that ensures compensation for all occupational injuries and some occupational disorders, e.g. occupational noise-induced hearing loss, without the need to prove negligence. Good doctor–patient communication is essential in making clear the distinction between obtaining an occupational history to make a clinical diagnosis versus using an occupational history as evidence to obtain compensation.

ETHICS AND CONFIDENTIALITY

Clinicians may face ethical dilemmas, including issues of confidentiality, in handling information obtained from an occupational history. For example, a worker may provide information on workplace exposure to chemicals that are deemed confidential trade secrets (such as exact ingredients and amounts of materials used for a specific process – a trade secret for the employer, but an essential piece of information for the doctor in order to assess the extent of exposure and likely contribution to ill health). A patient may describe a novel work process that is the subject of a patent application. A patient may indicate that other co-workers have ill health possibly from contact with a workplace chemical. If the outcome of identifying affected colleagues is their transfer to other jobs or ill-health retirement or redundancy, this may not be their wish nor will it necessarily be in their best interest. How should the clinician handle the information provided?

Published guidance is available on the ethical responsibilities of a doctor when there appears to be a conflict between responsibility to an individual patient and any responsibility to the employer. UK occupational physicians have access to advice from the ethics committee of the Faculty of Occupational Medicine. A helpful chapter is one on ‘Relationships with others’ in the Faculty of Occupational Medicine’s guidance on ethics for occupational physicians. Guidance on ethical issues for all physicians is also available from the British Medical Association, covering areas such as confidentiality, consent and disclosure of health information.

A patient may be reluctant to reveal the identity of his/her employer. This may be because of the perceived consequences for continued employment if the employer should become aware that one of their workers has developed ill health from workplace activities or exposures. The affected worker may be torn between concerns for his health, and the need to keep his job despite the risk. From the information provided in the occupational history, the clinician can advise on individual preventive measures, but the implementation of any measures at work inevitably requires the involvement of the employer. The employer may want to know what the specific health issue is, and this may intrude into areas of confidential clinical information. The guidance resources mentioned above cover issues of patient confidentiality.

How reliable are occupational histories?

Occupational histories can be obtained during a face-to-face encounter with a patient as during a clinical consultation; or by use of an interviewer-administered or self-administered structured questionnaire. Occupational history questionnaires have been shown to provide information that is reliable and valid. They are relatively free from bias, and are acceptable to both patients and doctors. However, the accuracy of self-reported work history appears lower in those with frequent job changes and accuracy of information is affected by number and duration of jobs.

WHY TAKE AN OCCUPATIONAL HISTORY?

The two main reasons why an occupational history is important are: (1) because of the effects of work on health and (2) because of the effects of health on the safe and efficient performance of work. The value of the occupational history lies in the use of the information gathered in assessing the nature and extent of exposure to hazards in the workplace. This assessment is necessary for a physician to advise on possible occupational aetiology of a disease, and on fitness for work.

Effects of work on health

The occupational history is used when a physician has to decide if an occupational factor might have caused or contributed to a patient’s illness. If there is an occupational aetiology, failure to take an adequate occupational history will lead to inappropriate management of the patient. The patient may be treated and then sent back to work in the same environment that has caused the disease, and therefore full recovery will not occur. An example is a patient with a rash that is treated with a steroid cream, and then sent back to work in an environment where exposure to the causative chemical continues. The rash may improve temporarily with treatment, but will invariably worsen with continuing contact with the causal agent.
Work can affect health in several ways:

- Occupational exposures may be a direct cause of ill health, for example exposure to hydrogen cyanide gas encountered by firefighters during their work can cause cyanide poisoning, or exposure to metallic mercury in gold miners or in dentists causes mercury poisoning.
- Workplace exposures, while not necessarily being the sole factor causing a disease can be one of a number of contributory causes. Cigarette smoking, as mentioned earlier, multiplies the risk for lung cancer if there is exposure to asbestos fibres or radon gas. Each of these can cause lung cancer independently, but a worker who smokes, lives in a high environment radon area, and is exposed to asbestos from work activities has a much increased risk of lung cancer. Another example is that of exposure to carbon monoxide which can result from smoking, following exposure to methylene chloride (used as a paint stripper), and working in an enclosed space such as a garage which is heated by a gas-fired heater, and has a car engine running. All these factors can act independently to increase blood carboxyhaemoglobin, but when several of these sources of carbon monoxide are present, there is an elevated risk of carbon monoxide poisoning.
- The nature of the job may worsen pre-existing non-occupational disease, e.g. hairdressing procedures or working in a kitchen can result in a worsening of endogenous eczema.
- The work environment may give easy access to potentially harmful materials, increasing the risk of their abuse. Examples of adverse health effects resulting from availability of toxic agents are effects of anaesthetic gases in anaesthetists or other health-care staff, suicide in farm workers using pesticides, and alcoholism in publicans.

The effects of disease on occupation

Following a period of sickness absence, it is in a patient’s and society’s interest to encourage a return to work. Most patients are able to return directly to their own job after an illness or injury but some, because of residual disability, are unable to return to their former work. Many people with some impairment of function either seek work or seek to remain at work and may ask for medical advice.

The main areas where this advice is needed are:

1. The patient’s condition may limit, reduce or prevent him performing the job effectively (e.g. musculoskeletal conditions that reduce mobility or diminish manipulative ability).
2. The patient’s condition might be made worse by the job (e.g. excessive physical exertion in some cardiorespiratory conditions; exposure to certain allergens in individuals with asthma, for example exposure to cat fur or animal dander in a vet or a technician in an animal laboratory).
3. The patient’s condition is likely to make it unsafe to do the job (e.g. liability to sudden loss of consciousness while working alone and at heights).
4. The patient’s condition is likely to make it unsafe for third parties, such as co-workers, visitors or members of the public. For example, a bus or train driver who is prone to episodes of unconsciousness with no warning symptoms may cause an accident affecting other crew members, passengers and the public.
5. The patient’s condition might make it unsafe for the community (e.g. for consumers of the product, if a food-handler transmits infection).  

Some of the above areas are concerned with direct risk to the patient and some relate to risks to others, either risks to the health and safety of third parties or substantial financial risks to employers.

The occupational history will help a doctor in encouraging a timely return to appropriate work, and to retain people at work that will not harm their health. The emphasis in the UK today is on changing perceptions of fitness for work by discouraging stigmata around health and disability. In the UK, proposals to reduce sickness absence include replacing the ‘sick note’ signed by the family physician with a ‘fit note’ involving discussion as necessary between the patient, the doctor, occupational health professionals and the employer. This was implemented in April 2010.

For occupations such as drivers, divers, airline pilots and seafarers, specific guidance is published by different agencies. In the UK, the Driver and Vehicle Licensing Agency (DVLA) has produced a guide to medical standards for fitness to drive. The guidance covers drivers of motor cars and motor cycles (group 1 licence holders), as well as professional drivers of large lorries (group 2, category C) and buses (group 2, category D). There are special provisions for drivers in the police force, ambulance drivers and taxi drivers. The information is updated online periodically. The latest guidance is accessible via the DVLA website (www.dvla.gov.uk). Telephone advice is also available from the DVLA for medical professionals in regards to the health status of drivers and fitness to drive. The Department of Transport has also produced a manual with advice on fitness to drive for patients with medical conditions, and this includes the basis behind the standards recommended. In the United States, similar standards for commercial drivers are produced by the US Department of Transportation.

For other occupations, Fitness for Work: The Medical Aspects gives authoritative guidance using as its starting points the diseases (impairments) and disabilities from which a patient might suffer. It also has appendices on the medical standards for civil aviation, divers, offshore workers and seafarers. Advice regarding fitness for work of
seafarers was updated in 1999 by Merchant Shipping Notice No. MSN 1746 issued by the Department of Environment, Transport and the Regions. The International Labour Organisation (ILO) has also produced guidelines for the medical fitness of seafarers. In the UK, NHS Plus and the Royal College of Physicians have produced national guidelines on occupational aspects of managing infected food handlers, shift work in pregnancy and other clinical conditions related to occupations or work activity.

DIAGNOSING AN OCCUPATIONAL DISEASE

The occupational history is an important component for diagnosing an occupational disease. It can provide critical information on relevant occupational exposures, and on the link between the onset of symptoms and work. In general, several criteria should be met before concluding that a patient has an occupational disease. The main criteria which should be satisfied are:

1. The effect, i.e. symptoms and signs, must fit with what is known about the clinical features of the suspected occupational disease. The less the features match what is expected, the less likely the diagnosis.

2. The exposure must be sufficient to cause the disease. Information on exposure may be obtained from the patient’s occupational history and a description of what hazards are encountered at work. It is not sufficient just to know that there is exposure. It is essential to estimate the extent of exposure. I.e. number of substances to which the patient was exposed, intensity, frequency and duration of exposure. Sometimes, occupational hygiene data or biological monitoring records may be available and these can provide further evidence of the extent of exposure. Interpretation of exposure information for the most widely used substances can be assisted by reference to published occupational exposure standards. In the UK, the Health and Safety Executive publishes updated standards annually for about 500 substances in a document referred to as ‘EH40’. This contains workplace exposure limits and biological monitoring guidance values, and is available free via the internet. In the United States, there are several sets of similar standards, e.g. threshold limit values and biological exposure indices produced by the American Conference of Governmental Industrial Hygienists (ACGIH), permissible exposure limits produced by the Occupational Safety and Health Administration (OSHA), and recommended exposure limits from the National Institute for Occupational Safety and Health (NIOSH). In Germany, the equivalent standards are known as MAK values. In 1995, the European Commission established a Scientific Committee on Occupational Exposure Limits (SCOEL) to obtain independent scientific expert opinion on chemicals in the workplace. SCOEL’s efforts could contribute to harmonizing occupational hygiene standards in all European Union member countries. There are differences between the standards from the various organizations, and the basis of how they are set should be understood as a prerequisite for use. Caution must be exercised in the use of occupational hygiene monitoring results for diagnosing occupational disease. Even if exposure levels are above current workplace exposure limits (in the United Kingdom) or threshold limit values (in the United States), it does not necessarily point to the agent concerned as the cause. There are safety factors introduced in the development of exposure standards. The standards are also not purely health-based levels, but can be influenced by cost–benefit considerations. Susceptibility of exposed individuals is a factor that can cause health effects at levels of exposure even below current standards. Readings showing excursions above current standards on a single occasion may be less important than frequent measured excessive levels. The frequency and intensity of the exposures exceeding current standards demonstrate poor workplace control of exposures, and give an indication of the likelihood of the exposures causing disease. Some of the limitations in the use of exposure information as an aid for diagnosing occupational disease apply to both occupational hygiene readings, as well as biological monitoring data (see Chapter 5, Biological monitoring). Workplace exposure standards proposed by different agencies in different countries for some chemicals vary. In part, this reflects the imprecision of estimating the limit of exposure needed to protect against ill health. There is continuing debate for some substances, such as silica, about whether disease (silicosis) may develop despite exposures below the current standards (see Chapter 79, Silica and silica-related diseases).

3. The time sequence must be correct. This includes the consideration of the latent period between exposure and effect. For occupational cancers, generally a very short time interval (less than five years) between first exposure and the diagnosis of cancer suggests that the exposure may not be the relevant causative agent. For occupational asthma and allergic contact dermatitis, there may be several weeks, months or even years between first exposure and clinical manifestations. Some acute exposures produce clinical effects immediately or within minutes of exposure, e.g. hydrogen cyanide gas, or upper respiratory irritants, such as sulphur dioxide, ammonia or chlorine gas (see Chapter 39, Gases), while the time interval between exposure and effect may be several hours or one or two days for agents that cause delayed pulmonary oedema. It may appear obvious that for a diagnosis of occupational disease due to a specific agent, the exposure to that agent must precede the occurrence of clinical effects. However, there are situations where even though a disease has developed earlier in life, subsequent occupational exposures may trigger an episode or worsen the condition,
e.g. occupational asthma or contact dermatitis. In this case, a previous history of the disease does not necessarily rule out an occupational aetiology if the disease manifests again later, during working life.

4. Consideration must be given to the differential diagnosis. The examining physician should consider possible non-occupational diagnoses, as well as occupational conditions. Missing an occupational disease with its possibilities for prevention is as inappropriate as labelling a condition occupational and missing an opportunity to provide early treatment for a non-occupational disease. An example of the former is failure to recognize contact dermatitis due to a workplace agent, and an example of the latter is assuming that a peripheral neuropathy is due to $n$-hexane when the patient has diabetic neuropathy. The decision on whether an illness is occupational or non-occupational in an individual patient can often rest on the balance of probability in the absence of supportive or confirmatory clinical and pathological evidence. This requires good clinical diagnostic skills and an understanding of workplace activities and exposures and their effects.

CONCLUSION

The occupational history is the most effective instrument for the proper diagnosis of occupational disease.\(^48\)

Landrigan and Baker, 1991

Key points

- The occupational history is key to determining the occupational aetiology of a disease, and is essential for advising patients on return to work.
- Taking the occupational history should be systematic and the history must be sufficiently detailed to indicate the nature and extent of workplace exposures.
- A general medical history taken during a doctor–patient consultation is incomplete without asking for information about the patient’s occupation.

ACKNOWLEDGEMENTS

REFERENCES

Determined the cause of an individual’s ill health or disease is one of the most important roles that a physician performs. Understanding the cause and linking exposure to disease can often be essential to the treatment and improvement of the patient’s life quality. At a wider level, it can enable identification of unacceptable exposures to a workforce population and, with appropriate intervention, lead to prevention of further ill health in others. There are also sentinel cases where new hazards and new relationships between exposure and disease are discovered, leading to changes in work practices and perhaps even legislation.

Occupational hygiene offers a simple paradigm for investigating the link between exposure and disease by the processes of recognizing hazards, evaluating the degree of risk from exposure and then controlling risk to health to an acceptable level. The first element of this involves hazard identification and this can be achieved by careful review of the safety data sheets (SDS) relating to the chemicals being used in the workplace. Where there is access to the worksite then the SDSs should be available and, if not, then there are specific legal requirements on suppliers that require them to provide these. When access is not available or the patient’s exposure is more historical, then a detailed occupational history is required and contact with the employer and/or investigation of a similar worksite may be fruitful in identifying the substances used in or released by the work process. A literature review of the industry or job title using websites ranging from the International Labour Organisation through to more specific searches of published scientific papers held on PubMed, or another online bibliographic database, may also provide useful insights to the substances to which the worker may have been exposed. In cases where the physician works closely with the employer and has direct access to the site then a simple ‘walk-through’ investigation is often the first step. Creating a list of the chemicals used and making a simple qualitative assessment of the amounts handled or processed, the degree of contact and the level of hazard as depicted by any container labels or SDS data is a useful output from such a walk-through survey.

A comprehensive understanding of how workers interact with hazardous substances in their place of work is necessary and knowledge of exposure and exposure routes is essential in making judgements about the likely causation of ill health. Exposure monitoring records may exist and, in the United Kingdom where collected, they should have been kept for a minimum of 40 years under the Control of Substances Hazardous to Health (COSHH) regulations. Where data on exposure are not available, the physician has two choices: collection of current measurements of exposure, or reconstruction and/or modelling of the past concentrations based on descriptions of the worksite, use of analogous data or mathematical models that predict how much chemical exposure would take place in a given space under the described work conditions.

Ideally, measurements of inhalation exposure in the workplace should be carried out by personal sampling, that is the attachment of the sampling device to the breathing zone of the worker – an area within a 10-cm radius of the nose and mouth. In some cases, this is not possible and...
static or area sampling, where the sampler is located at a fixed point, is performed. It is generally considered that, in most circumstances, static sampling will underestimate exposure of individual workers due to periodic close contact or handling of the exposure source.

Quantification of the exposure allows the process of evaluation of risk to begin. The concentration of a dust or vapour in the air can be compared to occupational exposure limits (OELs). In the United Kingdom, these are called workplace exposure limits (WELs) and are provided by the Health and Safety Executive (HSE) through the COSHH regulations for many chemicals. These limits are produced by considering toxicological and epidemiological data on health effects observed where possible after human exposure, but more often as a result of controlled exposure of animals or cellular models. The basic premise is that exposures below the WEL will limit the risk to the worker to ‘acceptable levels’, but it is important to be aware that not all limits are set at levels that will achieve no adverse effects and for some carcinogenic or sensitizing substances any exposure will carry some degree of risk. Other countries have their own OELs.

Treatment of the patient may be modified with knowledge of what workplace exposure has or has not caused their condition. Reduction or elimination of the exposure experienced by the worker may form one part of the medical intervention and this can have an effect on both the worker’s health and also the current and future health status of other workers within the facility.

Exposure control is the final part of the role of the occupational health professional. Control of exposure to hazardous substances in the workplace is enshrined in the legislative framework of most nations. In the United Kingdom, the COSHH regulations, the Control of Lead at Work regulations and the Control of Asbestos regulations are the three principal pieces of law aimed at encouraging control of workers’ exposure. All are based on a hierarchical approach to control beginning with elimination of the hazard, substitution with less hazardous materials, control by containment, ventilation and process changes and moving to the control method of last resort, namely personal protective equipment worn by the employee. There is now a wealth of guidance available to those using hazardous substances on best practice and methods of control that will lead to exposures that are less than the OELs. COSHH Essentials is a web-based tool that provides the user with targeted guidance based on easily obtainable information from the safety data sheets, the quantity and frequency of use, and how the material is being used in the workplace. The system uses simple hazard banding and exposure model estimates to recommend the type of control options that should be considered as best practice for the generic type of task being performed.

This chapter will explore in more detail how we can understand workers’ exposures, both within and beyond the workplace, how to interpret measurement data and compare these to limit values and, by using illustrative examples, we will look at the process of attributing a disease to an exposure.

EXPOSURE AND EXPOSURE ROUTES

Exposure is defined as contact between an individual and a hazardous substance. Workers may be exposed to hazardous substances by inhalation, inadvertent ingestion of chemical contamination, skin or eye contact and direct injection where a sharp object punctures the skin and the chemical enters directly.

Exposure occurs at the interface between the environment and the person and is measured on the outside of the body. For inhalation, exposure is conventionally defined as the concentration close to the nose or mouth multiplied by the duration of the exposure – sometimes referred to as ‘cumulative’ exposure. Therefore, someone exposed to a concentration of 0.1 mg/m³ of benzene for four hours would have an exposure of 0.4 mg/m³ × hour. However, to simplify the measurement and assessment of risk, it is conventional to express workplace exposure over a fixed time interval, e.g. eight hours. In the example above, the benzene exposure would be 0.05 mg/m³, as an eight-hour average, i.e. 0.4 (mg/m³ × hour) divided by 8 (hours).

Other factors may influence the amount of hazardous substance taken up into the body by inhalation, most notably the breathing rate of the worker, with a greater mass of contaminant being inhaled when a person is undertaking physical work than when they are sedentary. Although this factor will affect the risk for an individual, it is seldom taken into consideration when evaluating risk.

There is much less consensus about the definition of dermal exposure, although Schneider et al. described a conceptual model of the processes involved. Chemicals that come into contact with the skin may permeate through the stratum corneum and diffuse towards the peripheral blood supply. The ideal measure of dermal exposure would be related to the potential uptake, which is mainly driven by the concentration of the chemical in the surface layers on the skin (the skin contamination layer (SCL)), the area of skin exposed and the duration of exposure. Other factors, such as the composition of the mixture of substances present in the SCL and the integrity of the stratum corneum, will also affect dermal uptake.

It is difficult to measure the concentration of chemicals in the SCL and so the mass of chemical in the SCL or the mass that impinges onto the SCL during a period of time are often used as surrogate measures of exposure. In these cases, exposure may be expressed as mass per unit area over a defined part of the body, e.g. mg/cm² on the torso, or as the mass on a specific body part, e.g. mg on both hands. There are no OELs for dermal exposure.

There is no consensus about how exposure by inadvertent ingestion should be assessed, although this is generally associated with hand-to-mouth contacts. Key factors
involved with this type of exposure are the extent of hand contamination, the type of work, whether protective gloves are worn and personal traits of individual workers, e.g. nail biting.

For injection exposure, crude measures, such as the number of injuries per day involving contaminated objects, are often used, e.g. in the case of needle stick injuries.

The term ‘aggregate’ exposure refers to the risks over time from multiple sources, pathways and routes for a single chemical, and so for example, someone exposed to pesticides in their job as a farmer and then in their own garden when they spray their flowers would get aggregate exposure from these two sources. The term ‘cumulative’ exposure is then often used for assessments where there is exposure to a mixture of different chemicals that all have the same potential to cause an adverse health effect and some attempt is made to combine the overall exposure to produce some estimate of the overall risk. As noted earlier, the term ‘cumulative’ may also be used in the context of exposure in units of concentration multiplied by duration of exposure, e.g. mg/m$^2$ × hour, as for example might be the case in an epidemiological study investigating the relationship between the lifetime exposure to a hazardous substance, where the duration would be the working life of the individual.

In some circumstances, biomarkers may be used as an index of aggregate exposure, for example the concentration of lead in blood among workers exposed to inorganic lead compounds. These are not measures of exposure, although they are related to exposure and may offer some advantages in providing an estimate of aggregate exposure arising from more than one route. For example, blood lead will reflect exposure by inhalation and inadvertent ingestion. Considerable care has to be taken in interpreting biomonitoring data in relation to exposure because of the complex relationship between the pattern of exposure and the biological half-life of the biomarker.

**WHAT IS THE LEVEL OF EXPOSURE?**

Developing methods to assess the amount of contact between a worker and a chemical over a given time period has been the core of much occupational hygiene work in the past 50 years. Methods of exposure assessment can range from detailed, objective quantification using real-time direct-reading instruments through to subjective qualitative categorization into broad bands such as ‘low’, ‘medium’ and ‘high’.

The first place to start is to examine what exposure monitoring information exists in the workplace. Larger worksites, in particular, may have records of regular monitoring taken as part of programmes to demonstrate compliance with legislation. Others may have sporadic records collected at the time of inspection by regulators or before/after the introduction of new processes or control equipment.

Where existing information is not available then it may be possible to measure current exposure of the worker. Depending on the chemical hazard to be assessed there are a wide range of methods available for measurement. The HSE Methods for Determination of Hazardous Substances (MDHS) series of guidance notes are freely available via the internet (www.hse.gov.uk/pubns/mdhs/index.htm). MDHS 14/3 covers sampling and analysis of total inhalable and respirable dusts, while MDHS 39/4 provides guidance on sampling asbestos fibres in air and MDHS 70 details general methods for sampling airborne gases and vapours. Similar descriptions of methods for measurement of particular chemicals is provided by the US National Institute for Occupational Safety and Health (NIOSH) through their online Pocket Guide to Chemical Hazards (www.cdc.gov/niosh/npg/).

For most measurements of airborne exposures, the basic premise is in the gravimetric sampling of workplace air. This involves drawing air at a defined rate through a sampling medium which allows collection of a mass of the chemical being assessed. Simple division of the mass collected by the volume of air sampled during the collection period produces a concentration typically milligrams per cubic metre of air (mg/m$^3$), although units of parts per million (ppm) are more commonly given for gases and vapours by conversion using the molar constant.

For dust and particulate matter, air sampling is achieved by using a small battery-operated pump to draw air through a filter (glass fibre, PVC or PTFE are the most common types) held in a holder that selectively samples the aerosol by its size. When measuring total inhalable dust, that is the fraction of airborne dust that is inhaled through the nose and mouth, an IOM (Institute of Occupational Medicine) head (see Figure 4.1) set at a flow rate of 2.0 L/min can be used. For respirable dust (the finer fraction of dust that will reach the gaseous-exchange areas of the lung), samplers such as the cyclone (Figure 4.2) are used at flow rates of 2.2 L/min. After sampling, the filters are then reweighed and the mass increase is divided by the volume sampled, which is the product of flow-rate and duration expressed as m$^3$.

The approach for sampling for gases and vapours is generally similar to that for particulates with a pump pulling air at typically 50–200 mL/min through a small sampling tube with a collecting substrate, often charcoal, on which the gas or vapour is absorbed. The analysing laboratory then desorbs the chemical from the charcoal and quantifies the mass before dividing this by the volume of air sampled during the measurement period to produce a resulting concentration (e.g. mg/m$^3$).

Fibres, such as asbestos, are measured in a slightly different way with the concentration expressed not by mass, but as a count of the number of fibres on the filter per unit volume of air sampled (fibres/mL).

All of the above examples are suited for collection of personal sampling data and are typically employed when determining if workers are exposed at levels above or
below statutory limits. They all have the disadvantage that they take some time to collect and analyse, and generally involve expensive chemical analysis and involvement of a laboratory. In addition, these methods only provide information on the average concentration over the duration of the sampling and do not indicate anything to do with temporal changes and peaks of exposure while performing specific tasks. Direct reading instruments can assist when there is a need to have either immediate results or data about changes in exposure over a workshift.

Direct-reading instruments, which provide an instantaneous reading, range from simple tubes through to expensive electrochemical or photo-electric devices that can provide a log of changing concentrations in real-time. Colorimetric tubes undergo a reaction with the chemical under study to produce a colour change, with the length or intensity of this colour stain providing an instantaneous indication of the airborne concentration. There are many different types of these tubes with the media generally specific to a small number of chemicals, so proper selection is important. More accurate and sensitive portable direct reading instruments for gases and vapours using flame ionization with gas chromatography or infrared or ultraviolet photometry exist, although these instruments tend to involve large capital investment and need frequent calibration. For particulate matter measurement, small logging personal aerosol monitors can now be purchased. These operate by using light scattering methods coupled to size-selective air inlets that mechanically remove dust above a particular size.

Figure 4.3 shows the type of concentration-time output that can be generated from direct reading instruments and
how these can be used to identify peaks in exposure generated from particular tasks or methods of working.

While some simple exposure assessments can be carried out using direct reading instruments by those with no special training, collection of more complex sampling data is best undertaken with the help of an experienced occupational hygienist. Input from a hygienist will help maximize the amount and quality of exposure information that can be collected with the resources available and will cover issues such as the timing and duration of sampling, how many samples should be collected to give a representative indication of exposures, the type of instruments that can be used and how to transport and analyse the resulting samples. The British Occupational Hygiene Society (BOHS) has a listing of members who carry out hygiene consultancy work in the UK. Similar occupational or industrial hygiene societies and associations exist across the world with details of national organizations available via the International Occupational Hygiene Association website (www.ioha.net).

Measurement is expensive, labour intensive and not always a practical option when the worksite has been closed or access is restricted due to geographical, political or budgetary constraints. In recent years, there has been a growing push to use existing workplace information to model exposures. Modelling can range from complex statistical examination of large datasets of previous measurements to tease out determinants of exposure through to relatively simple logic structures that utilize readily available information on the chemical properties of a material, the quantities being used, the environment within which it is being handled (confined, open, well-ventilated, outside), and the methods of application or use (contained, dispersive, low energy, high energy, etc.). The online software tool Stoffenmanager (www.stoffenmanager.nl) allows the user to enter data on each of these parameters and then produces an estimated distribution of exposure concentrations generated for the scenario provided.

Figure 4.4 shows the distribution provided for exposures to xylene during a spray painting task. The exposure distribution is broadly log-normal and so the median value, or 50th percentile is 203 mg/m³, while the 95th percentile is over 3400 mg/m³. Understanding ‘worst case’ exposures is extremely important in determining disease causation and Figure 4.4 clearly demonstrates how some workers at certain times may perform the task in a rushed manner, without the ventilation system in operation, without their usual protective equipment and perhaps with much greater quantities than they would normally use. In these cases, the exposure will be towards the upper end of the distribution and may be many times higher than the median value. There has been a great deal of recent work in understanding variability in exposure and the factors that influence both the measured level and degree of variability across a population of workers performing similarly described jobs. The British and Dutch Occupational Hygiene Society have recently published draft guidance on how to interpret exposure data in light of exposure variability and how to judge the likelihood of measurements failing to identify exposures that exceed given limits.

EXPOSURE VARIABILITY AND EXPOSURE DETERMINANTS

Exposure for a single worker varies from minute to minute throughout the day as she undertakes different tasks and interacts with work equipment or processes. Two workers performing the same job in a factory will have different exposures because of differences in their work tasks, the way they do their work and their location in the plant. Workers doing a different job may have higher or lower average exposure from the first two workers, depending on how their work brings them into contact with the contaminant, their work and other exposure determinants. In all of these cases, some of the variation can be explained by exposure determinants, such as job, process, equipment, environment or other factors, and some is less clearly defined and is attributed to random influences. It is not unusual for the exposure measurements on a single day from two individuals doing the same job in the same factory to differ by more than one or two orders of magnitude. It is, therefore, very important when measuring exposure to make a careful record of the key exposure determinants, e.g. the materials handled, the way that they are handled, the presence and effectiveness of workplace control measures, the size of the workroom, the amount of general ventilation, the use of personal protection and the amount of time spent doing specific tasks or activities. In addition, the extent of the typical variation in exposure means that one or two measurements of exposure made in a specific workplace may not be particularly informative about average exposure and a more extensive dataset may be needed before clear conclusions can be made as to the
extent of exposure of a group of workers in a particular workplace.

Some workers may be consistently exposed to higher or lower levels than a typical worker doing their job, either because of the way they do the work or because of the work tasks they undertake. It is important to understand these intraintgroup differences in exposure when attempting to understand the role of exposure to hazardous substances in the causation of disease.

INHALATION EXPOSURE METRICS

Adverse health effects can broadly be categorized as either acute or chronic, reflecting the timescale over which the effects of exposure occur. For simplicity and practicability, exposures related to acute effects are generally measured over a 15-minute averaging period and for those related to chronic effects over an eight-hour period. For some substances, there may be both acute and chronic effects and in these cases exposure should be assessed against both time bases.

For chronic hazards, measurements would typically be made over less than eight hours and an assumption would be made about the exposure during the missing time in calculating the eight-hour average exposure. For example, a worker exposed to ethylene oxide was sampled for six hours and the measured concentration was 5 mg/m². If the sample had been collected over the whole of the time when the individual was exposed, i.e. the remaining two hours of his work shift did not involve any exposure, then the eight-hour average exposure would be 3.75 mg/m³, i.e. ((5 × 6) + (0 × 2))/8. If, however, the unmeasured period was judged similar to the measured period, the eight-hour average exposure would be 5 mg/m³, i.e. ((5 × 6) + (5 × 2))/8.

When a worker performs several distinct tasks, then the process of calculating a time-weighted average (TWA) is often employed. This combines the product of the exposure intensity and duration of each task and divides by the total work duration. So, for example, a baker who spends two hours decanting sacks of flour to small tubs may have an exposure to flour dust of 15 mg/m³ for that period, followed by four hours of general baking activity, when the intensity of exposure is 2 mg/m³ and a final two hours of bakery cleaning with an exposure of 5 mg/m³. The time-weighted average is calculated using the equation below:

\[ \text{TWA} = \frac{(15 \times 2) + (2 \times 4) + (5 \times 2)}{8} = 6 \text{ mg/m}^3 \]

where measurements are made over part of a working day to investigate whether peak exposures are associated with the risk of acute ill health. For irritation, it is common to sample for 15 minutes on a number of occasions when it is likely that exposures are likely to be at their highest, e.g. during filling of drums with a volatile liquid or when cleaning a store contaminated with a toxic dust.

EXPOSURE LIMITS

Risk is most often judged by comparing the exposure to an appropriate occupational exposure limit. OELs are derived by a number of scientific and/or policy bodies and typically have legal status in the country where they were derived. Scientific limits are often set to protect the health of those exposed, i.e. exposure below these health-based OELs would not be expected to give rise to any adverse effects. Where it is either not possible to define a health-based limit or where compliance with this type of limit would be impracticable on either technological or economic grounds, a limit may be set to restrict the risks to health to some societal acceptable level.

In the European Union, health-based limits are derived by the Scientific Committee on Occupational Exposure Limits (SCOEL). These limits are then implemented in each country within the EU by national legislation. Outside the EU, most countries have their own regulatory systems, although limits from different countries are often broadly comparable. A key influence on limits worldwide is the list from the American Conference of Governmental Industrial Hygienists (ACGIH). These limits, which are known as Threshold Limit Values (TLVs), were first published in the 1940s and now provide guidance on exposure levels for about 650 substances (www.acgih.org/TLV).

In the United Kingdom, the OELs are known as workplace exposure limits (WELs) and they are given legal force through the COSHH regulations. There are WELs for a few hundred of the most common chemicals used at work, which incorporates the limit values that have been agreed by the European Commission following the recommendations of the SCOEL; details are available from the HSEs website (www.HSE.gov.uk/COSHH).

OELs are straightforward to understand and make for easy management of the risks from chemicals in the workplace. However, they do not explicitly consider exposure by routes other than inhalation and they do not take account of some of the individual factors that may influence risk, e.g. genetic determinants of risk or the person’s work rate and its effect on the quantity of chemical inhaled. However, despite this, they are the internationally accepted way of judging whether occupational chemical exposure is acceptable.

HOLISTIC EXPOSURE ASSESSMENT

Those involved in occupational health commonly make the mistake that the worker’s exposure to chemicals stops at the factory gate or when they leave their place of work. There are several reasons why this is commonly not the case. First, there is the concept of take-home exposure
where contaminated overalls or clothing is transported back to the home, where exposure continues and indeed other family members inhale or ingest the contamination within the apparent safety of their own home. Recent cases involving the spouses and children of shipbuilders and others who worked with asbestos have highlighted the potential for this take-home exposure to produce long-term health effects in those who were never directly occupationally exposed. In addition to asbestos, it is possible that other chemicals and workplace hazards, such as metals, pesticides, flour dust and animal allergens, may be transported from work to home by clothing and tools.

The worker’s skills may also be in demand within the community and so they may receive additional, perhaps less well-controlled exposure to the chemical when they perform their task by doing ‘homers’ or self-employed work during evenings and weekends. Industrial painters are a common example of this, often working their normal workshift for their employer and then doing additional evening work for family and friends to earn extra income. It is important that the physician enquires about second jobs, home working or even hobby exposures. Farm workers exposed to pesticides during their employment may also have gardens and pick up additional exposure spraying plants with pesticides as part of their hobby, while painters exposed to solvents at work may inhale high levels of solvent maintaining an old sports car in their poorly ventilated house garage.

Dietary intake of chemicals also requires consideration and it is at this point that occupational and environmental medicine begin to overlap. For example, biological monitoring to assess off-shore workers’ mercury exposure may be a poor way of identifying work exposure if the same workers have a high dietary consumption of shellfish that are known to contain mercury. Similarly, farm workers who live in rural areas may actually have greater intakes of pesticide chemicals from contaminated drinking water sources than from any direct occupational exposure. Lead piping in old domestic buildings can produce high lead intake during periods at home compared to those experienced in a well-controlled workplace.

Non-work exposure can extend beyond chemicals. Noise exposure within the home life can be important. Listening to loud music with personal head- or earphones or taking part in noisy hobbies, like shooting, can lead to noise-induced hearing loss that is additional to that produced in the workplace. Dermatitis is another ‘occupational’ disease that can become established or exacerbated as a result of home life exposure to chemicals and even exposure to wet tasks, including dish washing, DIY and childcare. The importance of performing a holistic assessment of the worker and their work, home and leisure environments should not be underestimated. One of the challenges for those involved in occupational medicine is to look beyond the workplace, extend the reach of their skills and to consider how the wider environment may be affecting the patient.

CONTROL OF EXPOSURE TO HAZARDOUS SUBSTANCES

Where exposures have been identified as being poorly controlled, then intervention in the workplace is called for. An occupational hygienist may be the first port of call in order to discuss the control hierarchy for the particular industry or task. Elimination of the hazard or substitution with less hazardous material may be an easy step to removing the cause of the disease. Technology moves on and newer materials or working methods may be appropriate, but the changes never implemented because of workplace inertia. Cases of illness or disease may be the prompt the company requires to review purchasing policy or consider investing in new plant that eliminates the need for a particular chemical. Engineering controls, containment and local exhaust ventilation (LEV) are the next possible steps in controlling exposure. Intervention may simply be needed to examine the maintenance and performance of existing control measures, perhaps a fan in an extraction system has stopped working or a splashguard is no longer in place causing high dermal exposure to a fluid. LEV systems are extensively used to control exposure by extracting contaminated air from close to the source before it can mix into the workroom where workers may be exposed.

Raising worker awareness through the provision of information, instruction and training is another important intervention. Making sure that workers have knowledge of the risks to their health and what steps they can take to minimize their exposure and risk can be very powerful. Other ‘software’ intervention methods include introducing job rotation to limit the duration of exposure to the hazard, and biofeedback-type strategies where the worker is given much more detail about the determinants of their own exposure. Visualization and real-time exposure monitoring is one such example where workers receive instant feedback about their individual dermal or inhalation exposure during particular tasks and methods of working. It can be a particularly useful educational tool in modifying workers’ behaviours when handling highly toxic or hazardous materials.

Personal protective equipment (PPE) should be the intervention of last resort and should generally only be used when other control options are not possible or have failed to reduce exposures to acceptable levels. Respiratory protection is widely used to reduce the risk from inhaling hazardous substances. These devices are of two basic types: breathing apparatus where the wearer is provided with clean fresh air from a cylinder worn by the individual or through a pipe connected to a source of fresh air, and respirators, where the contaminant is removed from the air by means of a filter. Both types of respiratory protection rely on a facepiece to connect the device to the wearer, either a half-facepiece covering the nose and mouth or a full-facepiece covering the whole of the front of the face. Figure 4.5 shows a selection of respirators.

PPE carries particular problems as a means of controlling exposure. For a start, PPE only protects the wearer and
not those other workers in the vicinity who do not have access to, or have decided not to wear, the same level of protection. Second, it only protects the worker while it is being worn and worn correctly. Workers will remove masks during breaks or to hold conversations and during these times no protection is afforded. Then there is the problem of proper fitting – respiratory protective equipment is typically of one size and takes little account of different face shapes and sizes to ensure a good seal between the mask and skin. Proper fit-testing of respiratory protection is extremely important if PPE is part of the workplace intervention programme. Finally, there is evidence that wearing PPE can encourage less careful working practices that actually increase exposures.

A final approach may be to remove the worker from the exposure by changing their work tasks or even recommending that they change job. The worker themselves may initiate this change once they identify the cause of their ill health. This option should be considered carefully and only when other appropriate measures in the control hierarchy have been reviewed. Simply removing the worker from the causative agent without first attempting to intervene will leave conditions unchanged and the other remaining workers exposed to the same conditions that produced the illness in the sentinel patient. In the same way that this would be deemed an unacceptable strategy for handling an outbreak of infectious disease, it should not be the primary mechanism for dealing with worker ill health.

**ATRIBUTION OF A DISEASE TO AN EXPOSURE**

As discussed, there are a number of reasons why it may be necessary to attempt to attribute a causal exposure to a disease suffered by a particular individual. A high degree of confidence is needed where, for example, the person may be seeking compensation for disablement from an industrial disease or a view on causation may be needed as part of civil or criminal court proceedings. However, at a simpler level it may be important to understand whether occupational exposures could have caused a disease to assist in the clinical management of the individual.

In all cases, the attribution should be based on the person being exposed to a hazard that is accepted to cause the specific disease and that the magnitude of the risk is sufficient to make it unlikely that the disease would have arisen in the absence of the exposure. For some diseases, it is almost certain that a single agent causes the disease, e.g. mesothelioma and asbestos, although it may be less clear whether exposure during a single period of employment was solely responsible. In other cases, there may be numerous risk factors linked to the disease, none of which are necessary or sufficient causes, e.g. lung cancer where cigarette smoking and several occupational and non-occupational exposures increase risk. Despite these uncertainties, it is certain that exposure must precede onset of the disease for it to be potentially causal.

Causation in individual cases where there are multiple risk factors is generally accepted if the relative risk associated with the exposure is greater than two, which corresponds to more than half of the cases of the disease occurring in a population exposed similarly to the case being due to the exposure. This is a stringent test of causation, which relies on good information about the hazard and risks in the particular circumstances being considered.

The following list sets out a general strategy that can be followed to attempt to identify whether exposure of the case in one or more jobs is likely to have caused their disease. It is followed by three short case studies illustrating the approach.

1. Conduct a literature review to identify exposures that are known to be associated with the disease, including the likely time frame, i.e. whether exposures would be expected to be close to onset of symptoms or diagnosis (acute = days, months) or more distant (chronic = years, decades).

2. Obtain a careful occupational history from the case, taking particular care to identify relevant jobs and exposures held by the individual. As part of the work history, obtain good descriptions of the source of the hazardous substance, how the worker interacts with the source, the local controls in use, the work environment (i.e., size of the room and general ventilation), the time spent in the area by the worker, the use of personal protective equipment, such as respirators or protective gloves, and any accidental conditions that have arisen in the past. Enquire about other cases of similar disease among co-workers.

3. If possible, visit the workplace to collect more detailed information about the exposures and the circumstances where they arise.

4. Estimate exposures using any available monitoring data from the worksite, any data published in the scientific literature relating to that industry, the output from a suitable software tool such as Stoffenmanager, or from an actual simulation of the work activity in a controlled environment.

5. Identify relevant epidemiological literature that might shed light on typical relative risks for the disease and exposures in question, particularly studies where the magnitude of the exposures were similar to the case.

6. Decide whether it is possible/likely that exposure was implicated in causation, based on the exposure and the likely risk.

The following examples are intended to illustrate how this approach could be applied in practice.

**Case 1: Asbestos**

Mr A, a life-long non-smoker, was diagnosed with lung cancer in 2001. He had worked as a miner constructing tunnels for metro systems and roads. Between 1960 and 1978, he worked alongside a team of men who were using a caulking rope containing amosite (brown) and/or chrysotile (white) asbestos along with a cement binder. The caulking was placed between the concrete tunnel lining sections and compressed into place using a pneumatic tool. Mr A always worked at least 2–3 metres from those performing this task.

Both amosite and chrysotile are known to cause lung cancer. Mr A’s diagnosis was 40 years after he was first exposed, which is again consistent with this asbestos exposure contributing to his risk. It is generally accepted that a cumulative exposure of more than 25 fibres/mL × years is associated with a more than doubling of risk for lung cancer.

The tunnels where Mr A worked were of a fairly large diameter and there tended to be some forced ventilation to provide fresh air to the workers. The caulking was not continuous, but took place about 10 per cent of the time. Up to 1970, amosite asbestos was used in the caulking rope, but for the last eight years chrysotile asbestos was used in the caulking and when it was used he wore a half-face respirator. Asbestos was no longer used in this type of work after about 1989.

The UK Health and Safety Executive have published guidance on the levels of asbestos fibres in air for a number of different work activities, although not for caulking. The nearest analogous work is machine-cutting asbestos cement boards – producing concentrations of 10 to 20 fibres/mL.
for chrysotile. Data from work on naval shops in the late 1960s showed that men working with amosite asbestos ropes could be exposed to between 5 and 340 fibres/mL (average 100 fibres/mL). There is good evidence from other sources to substantiate that amosite products were dustier than those containing chrysotile.

Mr A’s exposure was likely to have been lower than the men working with the caulking because he generally worked 2–3 metres from the task and it can thus be estimated that his personal exposure would have been about a third of their exposure. Also, the respirator would have reduced his exposure by approximately 90 per cent. Based on these assumptions, his exposure can then be estimated as shown in Table 4.1.

The majority of his exposure occurred before 1970 and there was probably sufficient cumulative exposure (33 fibres/mL × years) to more than double his risk of lung cancer, so it is reasonable to attribute his cancer to his asbestos exposure. It is generally assumed that there must be at least a ten-year gap between first exposure to asbestos and there being a risk of disease, i.e. a ten-year latency period, and this was the case for Mr A. Given that he was a non-smoker and there are no other identifiable risk factors, it seems probable that his disease was caused by his asbestos exposure.

### Case 2: Organophosphates

Mr P was born in 1940 and left school at the age of 14 to work as an under-shepherd at a hill farm in the Scottish borders. In 1960, he became head shepherd and he continued in this job until 1970 when he left farming. Throughout his employment, Mr P was required to treat sheep with pesticides to prevent scab and other conditions. This was done by immersing sheep in a pool of dilute organophosphate pesticide, a process known as ‘dipping’ and took place four times each year during June, August, October and November. Between 2000 and 3000 sheep were dipped every year. Mr P has been diagnosed with Parkinson’s disease and it has been suggested that his exposure to organophosphate compounds while dipping sheep could have caused his disease.

Mr P used a large 2000-litre dip tank. Sheep were pushed into the tank and then submerged using a T-shaped pole. He wore waterproof leggings, an oilskin jacket – which he wore back-to-front for added protection – Wellington boots and rubber gloves. He did not wear a respirator and during the summer dip the jacket was not worn because of problems with the heat. Also, Mr P was provided with one set of protective clothing each year and he reported that after a few weeks of use it was no longer completely water resistant. Occasionally, he fell into the full dip tank while dipping. Mr P also prepared the solution used in dipping by diluting concentrate organophosphate-based products. At the end of the dipping, Mr P had to clean and drain the tank.

The work involved potential dermal exposure to the concentrated and dilute dip (from direct contact and splashes), but there was little opportunity for inhalation exposure (these dips are of low volatility and there is little opportunity for a fine aerosol to form). The main focus of the exposure assessment is therefore on skin exposure. Ingestion exposure during accidental immersions of Mr P may also have contributed significantly to his overall dose, but this is difficult to quantify.

There are a number of epidemiological studies that have supported the hypothesis that pesticide exposure may increase risk of Parkinson’s disease. However, the studies do not present a consistent picture and they do not provide evidence on specific compounds or even classes of compounds, such as organophosphates. In 2008, the UK Industrial Injuries Advisory Council (IIAC) examined the case for prescribing pesticide exposure and Parkinson’s disease for state compensation and concluded that the evidence base was not sufficiently strong, i.e. the existing epidemiological studies do not consistently support a doubling of risk. Despite this, it is important to understand whether this man’s exposure could have been implicated in causing his disease.

There are no universally accepted ways of estimating exposure to chemicals on the skin and very few measurements of dermal exposure from such situations. The most appropriate method of assessing skin exposure combines the concentration of the chemical on the skin, the area of skin exposed and the duration of exposure. This measure should be related to the amount of chemical taken up into the body through the skin. Tahmaz et al. developed an exposure model based on this approach for sheep dipping to assist in a study of farmers with chronic fatigue. They defined the skin exposure ($E_{sk}$) as the product of the concentration of the active compound (organophosphate) on the skin ($C_{sk}$), the duration that the skin is contaminated ($t_{sk}$) and the area of skin contaminated ($S_{sk}$). In mathematical form, this is:

$$E_{sk} = C_{sk} \times t_{sk} \times S_{sk}$$
Table 4.2  Mr P’s estimated exposure to organophosphates.

The measurement units for this assessment are m² × days, i.e. area multiplied by the duration (concentration being dimensionless, i.e. without measurement units). For example, 100 m² × days skin exposure could be the result of 1000 days of exposure where 0.1 m² of skin was exposed to concentrated pesticide (Csk = 1).

To ensure that the estimate of exposure is representative of different areas of skin that may become contaminated and the pattern of exposure, the exposure estimate was further subdivided by Tahmaz et al. into skin exposure to dilute pesticide during dipping sheep (Ek,dip), exposure to concentrate while preparing the dilute dip (Ek,conc), exposure while handling sheep (Ek,handling), inhalation exposure during dipping (Einhalation) and skin exposure on occasions where the person accidentally fell into the dipping bath (Ek,falls). Mathematically, this is expressed as:

\[ E_k = E_{k,dip} + E_{k,conc} + E_{k,handling} + E_{inhalation} + E_{k,falls} \]

Each of the above terms is further elaborated in the Tahmaz et al. approach to take account of the use of protective clothing and other factors that influence the exposure. The estimated exposure can then be calculated using a computer spreadsheet.

The results from the calculation of Mr P’s exposure are shown in Table 4.2, along with the range of lifetime exposures from Tahmaz et al. for 95 per cent of the farmers in that study – subdivided by whether or not they scored highly in terms of the questionnaire on chronic fatigue.

Mr P’s estimated lifetime exposure was above the 95th percentile of farmers who had high chronic fatigue scores. Note that the highest estimated exposure from Tahmaz et al. was about 8500 m² × days.

Despite Mr P having very high exposure to organophosphate compounds during sheep dipping, it is not possible, given the current state of scientific evidence, to clearly attribute his exposure to his disease. However, it would seem prudent to advise him to avoid further exposure to organophosphate compounds at work or in other situations, such as home gardening.

**Case 3: Isocyanates**

Mrs I, who works in a factory making various adhesives, sealants and coatings, was diagnosed with asthma. This woman was employed on a process making a photo polymer resin product, in a fully enclosed process. One of the main raw ingredients in the process was toluene diisocyanate (TDI). During the TDI loading task, the operator wore a full-face filtering respirator, fitted with a combination gas and dust filter (note these are not recommended for use with TDI and would not provide reliable protection). She also wore cotton overalls and natural rubber (latex) gauntlets. A rubber apron was available, but was not worn. Self-contained breathing apparatus (BA) was provided for use in emergency situations and one BA set was located in the main process control room and a second set was located outside the building. The majority of Mrs I’s work time was spent in the air-conditioned control room.

The company regularly undertook air monitoring for isocyanate (NCO) using the method recommended by the Health and Safety Executive (MDHS 25/3 Organic isocyanates in air). Samples were obtained using IOM sampling heads loaded with chemically impregnated glass fibre filters, treated with 1-(2-methoxyphenyl) piperazine (1-2MP) solution. The sampling head was attached to the lapel of the operator and connected to a battery-operated personal sampling pump drawing air at 2 L/min through the filter. The samples were analysed for total isocyanate content using high performance liquid chromatography.

None of their measurements showed detectable isocyanate exposure for Mrs I, all the measurements being <0.001 mg/m³ as total NCO (the long-term occupational exposure limit is 0.02 mg/m³). The only detectable isocyanate levels have been obtained for quality assurance technicians who have to extract a sample of resin for testing (maximum reading 0.004 mg/m³).

An interview with Mrs I indicated that in the months before she first started to experience symptoms there had been a series of maintenance issues on the plant and that two pumps in the process had been replaced because they were leaking. No measurements of airborne isocyanate level had been made during this time, but it seems plausible that there was episodic peak exposure to TDI vapour during this time. The exposure of the quality control technician arises from a short period when the containment of the process is breached, typically 20 minutes each day. If it was assumed that the leak was continuous and that the room ventilation was sufficient to provide ten air-changes per hour then a simple calculation suggests that an eight-hour average exposure level of 0.004 mg/m³ could be associated with peak exposure of about 0.1 mg/m³ during the short period of sampling. Using the exposure modelling software package IHEMOD (which is freely available at: www.aiha.org/insideaiha/volunteergroups/Documents/EASCIHMOD.xls), the exposure over a full shift can be calculated. As can be seen from Figure 4.6, the concentration with a continuous leak similar to that during quality control sampling gives rise to a level of 0.2 mg/m³.

There are no good exposure–response epidemiological studies for asthma associated with TDI exposure, but there is evidence that a significant proportion of exposed
individuals may become sensitized to TDI at exposure levels above about 0.1 mg/m$^3$ and so it is possible that Mrs I’s exposure during this time could have caused her asthma. However, confirmation of causation could be obtained from an inhalation challenge test (see Chapter 72, Occupational asthma, p. 941).

**CONCLUSIONS**

Understanding the relationship between disease and occupational exposure is important for the treatment and well-being of the patient. The occupational hygiene framework of identifying hazards and evaluating the risk from those hazards provides a simple method when approaching complex problems concerning attribution. There are often many sources of information available on hazards in the workplace including safety data sheets, COSHH assessments and online guidance on how specific chemicals should be handled. All of these provide the physician with the means of hazard recognition.

Discussion with the patient and the taking of a detailed occupational history are also key to identifying hazards and, often, gathering important data on likely exposure levels that can then be compared to health-based limits. Discussion can also be useful from the perspective of providing reassurance and allaying fears that specific exposures can have had an effect on health.

In some cases, the attribution of disease is not always straightforward. Some exposure–response relationships lack good quality or consistent epidemiological data on risk, indeed only a small number of substances have been classified by the Industrial Injuries Advisory Council.

While identifying the cause of a worker’s disease can be useful in targeting the treatment of symptoms or improving the patient’s quality of life, the real benefits of linking exposure to ill health are reaped from occupational health interventions to reduce the exposure. For most diseases, treatment of symptoms will not provide long-term help if the underlying causative exposure continues and therefore following a framework for intervention is important. For the physician who identifies illness caused by work, intervention in the workplace should also be considered as a vital public health measure. Poor working practices and high exposures will continue to cause ill health in other workers and for this reason it is necessary to remember that treating the workplace is as important as treating the worker.

---

**Key points**

- Inhalation exposure to hazardous substances is measured as the concentration in the air close to the worker’s head (i.e. within 30 cm).
- Dermal exposure is often measured as the mass of chemical on the skin or the mass that impinges on to the skin during a given period of time, although the concentration on the skin would be a more appropriate measure.
- Mathematical models to estimate worker exposure are becoming more widely accepted.
- Exposure varies considerably from one person to another performing the same job and from day to day for the same worker and, as a consequence, several measurements of exposure are needed to get a reliable assessment.
- Inhalation exposure should always be controlled to an appropriate level using local ventilation or some other intervention, and should be below any relevant occupational exposure limit (OEL).
- Personal protective equipment (PPE), such as a respirator, must be carefully selected to ensure it is appropriate and comfortable for the wearer.

Biological monitoring

JOHN COCKER AND HOWARD J MASON

INTRODUCTION

Biological monitoring (BM) is based on the analysis of hazardous substances or their metabolites in biological fluids, usually urine, blood or breath. BM is a tool to assess systemic exposure and reflects absorption by all routes, inhalation, ingestion and through the skin. Often, the term ‘biological monitoring’ is also used to include biological effect monitoring (BEM), which reflects the early consequences of systemic exposure, although others have also used the term ‘biomonitoring’ to encompass BM and BEM. Both BM and BEM are located on a spectrum ranging from low exposure at one end to disease, frank toxicity or death at the other (Figure 5.1). It is preferable to keep the term ‘biological monitoring’ for assessment of exposure separate from ‘biological effect monitoring’ which is an indicator of early effect and sits within ‘health surveillance’. Health surveillance is the periodic clinical examination of workers designed to protect their health through the early detection of adverse effects and intervention to prevent further harm, and complements biological monitoring.

This chapter will first discuss the role and practical application of biological monitoring in the workplace, followed by an overview of the current status of biological effect monitoring.

Workers may be exposed to hazards in the workplace in the air they breathe or from contaminated surfaces and equipment. In some cases, workplace exposure can be in addition to a non-occupational hazard in the environment. Hazardous substances may enter the body via inhalation, ingestion or through the skin and the consequences largely depend on the amount absorbed and rate of absorption. Control of exposure in the workplace should prevent levels of exposure that lead to harm and monitoring techniques which provide the feedback to ensure the controls are working and being used correctly. Clearly, early detection and control of exposure is more desirable than diagnosing occupational disease after it is fully established. The objective of health professionals is to

---

Figure 5.1 The exposure-disease paradigm.
keep systemic exposure as low as is reasonably practical and to the left of the spectrum in Figure 5.1.

Monitoring techniques can be divided into those that assess exposure and those that assess the consequences of exposure. Thus, BM relates to exposure assessment and BEM is usually part of effects assessment, and can help in the diagnosis of disease. The distinction is important because the motivation for doing the monitoring influences the way results are interpreted. A physician in the workplace may initiate BM as part of health surveillance, but the results can often only be interpreted in terms of exposure and not (directly) health. There are international differences regarding the role of BM, e.g. between Europe and the United States, with BM historically performed as a medical activity in European countries, while in the United States and now in the United Kingdom, BM also belongs within the specialism of occupational hygiene.

Biological monitoring guidance values are produced by various organizations to aid the interpretation of results, but the majority of guidance values relate to exposure assessment with the aim of controlling occupational exposure at levels below those causing noticeable health effects. In contrast, there are comparatively few biological effect guidance values.

A recent development, under the auspices of the European Centre of Ecotoxicology and Toxicology of Chemicals, has been the development of a framework for the interpretation of BM data through evaluation of their analytical integrity, their ability to describe dose (toxicokinetics), their ability to relate to effects, and an overall evaluation and weight of evidence analysis. This framework may provide a rational basis to allow better use of current biomarkers and the development of novel, interpretable BM and BEM markers.

**BIOLOGICAL MONITORING**

**Roles**

Unlike air or surface monitoring which assess potential exposure, biological monitoring can help to assess actual systemic exposure, from all routes. BM is particularly useful where air monitoring alone will not give a complete picture of exposure. These roles include monitoring substances where the dermal route can contribute significantly to systemic toxicity such as those with ‘Sk’ or ‘skin’ notations in tables of exposure limits. Biological monitoring also has a role where the control of an inhalation hazard relies on personal respiratory protective equipment. In such situations, it is not very helpful to measure the ambient air levels of the substance and often difficult to measure the effectiveness of the respirators in use. A third role for biological monitoring is the overall assessment of exposure controls, including worker behaviour. The best exposure controls may not protect the worker if they are not used correctly. The individual nature of biological samples collected from workers can help provide a personal message and influence worker behaviour or give reassurance.

**Legal framework**

In most countries, there is a legal requirement for health surveillance of workers who may be significantly exposed to lead. In the UK, the Control of Lead at Work (CLAW 2002) regulations require the regular monitoring of workers exposed to lead. This involves both clinical examination by an appointed physician and analysis of blood samples for lead with defined action levels based on the results. Some countries have compulsory biological monitoring for a few other substances, but the legal framework for BM usually comes under the regulations to control hazardous substances in the workplace, and biological monitoring is not compulsory.

In the UK, biological monitoring has roles under the Control of Substances Hazardous to Health (COSHH) and in particular regulation 10 (Exposure Assessment), regulation 11 (Health Surveillance) and regulations 6 and 7 (Assessing and Controlling Exposure/Risks). In the case of health surveillance, it is used when it is possible to link the results of biological monitoring to an adverse health effect. Implicit in this requirement is that a ‘no-adverse effect level’ has been established. However, often there is insufficient data available to do this and there are many substances in the workplace where it is not possible (e.g. carcinogens and allergens), and then the prudent approach is to try to minimize exposure to as low as possible.

In the absence of a recognized ‘no-adverse effect’ level for a chemical, an alternative, pragmatic approach is to establish an appropriate level based on the levels (usually the 90th percentile) seen in workplaces with good control of exposure. This approach does not require knowledge of a dose–response relationship or yield a health-based value. Instead, it allows exposure to be monitored, controlled and reduced to minimize risk of ill health, and any reduction of exposure is then reflected in reduced health risk. This approach is in line with the current approach to controlling exposure based on good occupational hygiene practice and is comparatively easy to establish. Thus, although BM is not compulsory, its simplicity and utility mean that it is increasingly being used and incorporated into codes of practice and in-house guidance for working with and controlling exposure to chemicals.

**Ethics**

Since BM involves the collection and analysis of biological samples from people, it is essential that the rights of the individual are protected. These rights can be protected by obtaining informed consent to collect and analyse the samples, and gaining their permission regarding who will
see the results and understanding what action will be taken on the results. The programme should be discussed and agreed with all concerned, employees, employers and worker representatives. In the UK, with the exception of lead, BM is not compulsory, and workers need reassurance that their participation or non-participation will not affect their conditions of employment. To get their informed consent to participate, the purpose of the BM programme must be explained along with the type of biological samples that will be collected, and any associated risks. Workers need to be made aware of what will be analysed in the samples and reassured that no other tests (e.g. alcohol, drugs, HIV) will be performed. They need to know what action might follow depending on the BM results and what the benefits (if any) are to them as individuals. Workers should be informed that the results will be treated as personal data, treated as confidential and only revealed as grouped data without identifiers, and/or to others with specific consent, e.g. to health professionals or managers. Within the UK, the Information Commissioner has also produced guidance that relate to such issues.

The programme must be supervised by a competent person, often (but not exclusively) an occupational health professional. In our experience, these arrangements do not pose any particular problems and a well-designed and executed biological monitoring programme can be an effective way of protecting workers’ health.

### SETTING UP A BIOLOGICAL MONITORING PROGRAMME

Guidance is available to aid setting up biological monitoring programmes for a wide range of substances and covers the basics of the ethical issues, consultation, choice of analyte, sample collection, analysis and guidance on interpreting results. The main steps include:

- Define the purpose of the programme as exposure assessment or part of health surveillance.
- Appoint a competent person to oversee the programme. If the programme is for health surveillance, a health professional should be appointed.
- Select a biological monitoring strategy (who to monitor, how often, what samples to collect, when to collect them, methods to analyse them, availability of guidance for results). A competent laboratory should be employed and can help with developing the strategy. The laboratory should run appropriate internal quality control schemes and participate, if available for the analyte in question, in external quality assurance schemes.
- Consult on the programme with employees and their representatives.
- Discuss and agree the programme with the individuals concerned.
- Establish procedures for sample collection, storage, transport, analysis and quality assurance.
- Provide feedback and interpretation of the results.
- Take appropriate action on results, if required.

For many of the most common substances in the workplace, there is guidance available on the technical aspects of biological monitoring. The UK Health and Safety Executive (HSE), the American Conference of Governmental Industrial Hygienists (ACGIH) and the German Deutsche Forschungsgemeinschaft (DFG) all produce guidance documents that detail the type of sample, when to collect it, the substance to be analysed and a guidance value to aid in interpreting the results.

### Sample collection

The collection of non-invasive samples (e.g. urine, breath, saliva) is preferred, provided a validated method is available. Non-invasive samples are more acceptable to workers compared to collecting blood samples. Non-invasive sampling also reduces the risks from venepuncture and disposal of blood-contaminated material. Appropriate precautions should be taken when collecting and handling biological samples and particular attention should be taken with regulations for sending pathological samples through the post or by courier. Within the United Kingdom, appropriately packaged and labelled samples may be sent by first class post or special delivery, and the Royal Mail offers a prepaid packaging system for diagnostic biological samples. Where samples need to be sent internationally, courier rather than postal service must be used and International Air Transport Association (IATA) regulations followed, sending BM samples assigned to UN3373 or as ‘exempt human specimen’. In essence, sending BM samples within the UK or internationally as ‘exempt human specimens’, should involve primary and secondary leak-proof packaging, the latter of appropriate strength, with enough absorbent material between the packaging to absorb the entire contents and also appropriately labelled, including a return address. Any laboratory involved in BM will be able to advise on ensuring compliance with postal and transportation regulations.

Most biological monitoring is based on collection of urine samples. If the analyte is the substance to which the workers are exposed, e.g. metals, care should be taken to avoid contamination of the sample during collection. If the analytes are volatile, e.g. most solvents, care needs to be taken to avoid loss of analyte, usually by supplying a urine sample where there is little headspace remaining in the sample bottle. Most BM analytes are stable enough that refrigeration is not necessary during their transport by first class post to the laboratory.

### When to sample

The optimum time for sample collection is determined by the toxicokinetics of the substance and depends mainly on
the half-life of elimination. This toxicokinetic parameter also largely defines the relationship between a BM measurement and the period of exposure that it reflects.\textsuperscript{8} Ideal sampling times are often compromised by the practicalities of sample collection in the workplace that usually dictates samples are to be collected at the 'end-of-exposure', 'end-of-shift' or prior to the start of the next shift. The route of exposure (inhalation or dermal absorption) may also have an impact on sample collection times. The apparent half-life of an inhaled substance will generally differ from the same substance if dermally absorbed, where it is subjected to a lag phase due to transit across the stratum corneum with the skin acting as a reservoir for the substance. Table 5.1 gives a generalized relationship between elimination half-life, sampling time and exposure reflected in the BM sample taken at the sampling time.

### Interfering factors

Biological monitoring results can be influenced by interfering factors. These may include additional exposure through a non-occupational route, by exposure to a chemical that is also metabolized to the BM analyte being monitored, and also by altering the metabolism of the BM analyte of interest.

Sometimes, the collection of additional information by questionnaire or analysis is necessary. For example, consumption of seafood may increase total urinary mercury and total arsenic levels, but more complex analysis of the species contributing to total urinary arsenic can help attribute exposure to occupational and dietary sources.\textsuperscript{9} Where a biomarker is derived from external exposure and also endogenously, it may be advisable to collect pre-exposure or baseline samples. Smoking can contribute to a wide range of biomarkers, including thiocyanate used to monitor exposure to cyanide and naphthols.\textsuperscript{10} Consideration should also be given to the possibility that the chosen biomarker may also be a metabolite of another substance, e.g. mandelic acid is a widely used BM metabolite of styrene, but is also formed from ethyl benzene, while carboxyhaemoglobin is formed from both carbon monoxide and dichloromethane. Alcohol and some drugs can compete for metabolism of many solvents, tending to extend their half-life of excretion. However, chronic intake of alcohol and some drugs can also induce enzymes potentially involved in metabolism of some solvents and chemicals, again altering the normal relationship between BM measurement and exposure.

Physiological factors, such as work rate, can also influence BM results for some substances where increased respiration leads to increased absorption and consequently increase systemic dose, e.g. someone exposed to xylene working moderately hard will have two to three times the respiration rate and urinary metabolite levels compared to a worker at rest with the same airborne xylene levels.

### Choice of analyte

The choice of analyte will depend on the purpose of the monitoring. If the level of exposure is being assessed, then

</tbody>
</table>
for inorganic substances such as metals, the element itself is usually measured. The choice for organic substances depends on the metabolism and kinetics of the substance and the possible interference from other endogenous sources. As an example, biological monitoring for toluene was once based on the analysis of its major metabolite hippuric acid, but as regulatory exposure limits for toluene were reduced the interference from dietary sources of hippuric acid made this approach no longer viable and monitoring switched to using the minor metabolite o-cresol or the measurement of toluene itself in urine.

Biomarkers that reflect flux in the toxic metabolic pathway are preferred over those that reflect detoxification and simple elimination. Examples include haemoglobin adducts after exposure to aromatic amines or alkylating reagents.

A relatively recent and comprehensive review of BM analytes and strategies for monitoring workplace chemical exposures is available.[11]

### Analysis

Confidence in the results of laboratory analysis is essential. The laboratory should have analytical methods with sufficient sensitivity and specificity to accurately and reproducibly measure the analytes of interest. The laboratory should have internal quality assurance procedures and, where possible, take part in external quality assurance schemes.

Quality assurance begins with sample collection and the use of appropriate equipment to prevent contamination or loss of analyte. Samples must be unambiguously labelled and must be transported to the laboratory in a way that ensures the integrity of the sample. A few analytes may require preservatives or refrigeration prior to transport. Some analyses are within the scope of routine clinical laboratories but many may require a specialized laboratory. A good laboratory will provide sample collection equipment, packaging materials and guidance on sample collection, transport and interpretation of results.

A recent review has suggested that the potential availability of both sensitive analytical techniques and quality assurance schemes for BM means that interpretation of results has become the key, important issue.[12]

### Creatinine correction

Urine concentrations of metabolites can vary widely not only due to variations in exposure, but also as a result of variations in fluid intake and insensible losses, such as sweating, which can alter urinary flow rate over a wide physiological range. Most biological monitoring is based on spot samples and it is common to make some adjustment to the analytical results to compensate for short-term concentration or dilution effects. The two most common types of adjustment are based on urine specific gravity or creatinine concentration, both of which largely adjust for the rate of urine production. However, the use of creatinine or other adjustment is not without ongoing debate.[13-15] Some authorities take the stance that no correction is the default position, others use creatinine correction as their default position, and there is ongoing work proving the value of such correction for an analyte on a case-by-case basis.[16,17]

Adjustment of analytical results for certain analytes (e.g. urine methanol) using either creatinine or specific gravity adjustment is not appropriate, where the chemical simply equilibrates between intra- and extracellular fluids, including urine. For other analytes, creatinine correction is not advised if the creatinine concentration is less than 3 mmol/L or more than 30 mmol/L suggesting the extremes of urine flow rate. Interpretation may be subject to considerable error, and a further sample is warranted.

### Interpreting results: Guidance values

To aid the interpretation of BM data, various international organizations produce biological monitoring guidance values (Table 5.2). These are derived from review of data in the peer-reviewed literature and the objective, if possible, is to produce a health-based guidance value. However, for many substances, there is insufficient data to be able to derive a BM value linked to the absence of health effects from the dose–response relationship, and guidance values based on good occupational hygiene practice and ‘achievability’ are used instead.

Examples of health-based guidance values are the biological exposure indices (BEIs) of the ACGIH[2] and the biological tolerance values (BATs) from the DFG.[6] These are derived from dose–response relationships between a biological parameter and either the absence of health effects or, more usually, from a relationship between a biological parameter and an airborne exposure limit that is itself health based. For substances where a health-based dose–response relationship cannot be established, e.g. for many carcinogens and respiratory sensitizers, biological monitoring guidance values can be based on a relationship between a biological parameter and the airborne exposure limit. Examples of this type of guidance value are the DFG biological exposure equivalent values (EKA values).[6] An alternative approach is to base the biological monitoring guidance value on the levels of a biological parameter found in samples from workplaces employing good occupational hygiene practice, and examples are the HSE’s published guidance values for carcinogens and suspect carcinogens like hexavalent chromium, methylene-bis-2-chloroaniline (MBsCA) and methyl-enediylamine.[4] HSE has also adopted this approach for

isocyanates where a dose–response for respiratory sensitization has not yet been established. The guidance value is based on the 90th percentile of data from workplaces with good control and is a practical guide to exposure control. Biological monitoring results that exceed the guidance values are unlikely to be predictive of ill health, but should stimulate an investigation of exposure controls and further monitoring. Regularly exceeding the guidance values indicates that controlling exposure could be improved.

An alternative approach was taken by the ACGIH to develop a guidance value for exposure to polycyclic aromatic hydrocarbons. It has not been possible to derive a health-based guidance value for this complex and variable mixture of carcinogens. Instead, 1-hydroxypyrene (the urinary metabolite of pyrene) is used as a marker substance and the guidance value was derived from the upper end of the distribution from non-occupational exposure. This background level approach clearly defines when biomarker levels result from occupational exposure, but controlling exposure down to these levels may be a challenge in the workplace.

Biological monitoring results reflect systemic exposure by all routes into the body, so if the values found are significantly higher or lower than anticipated for a given airborne concentration the results may indicate the route of exposure. In Figure 5.2, biological monitoring results above the dose–response line (e.g. from a BAT or BEI guidance value) derived from average inhalation exposures may indicate additional exposure due to absorption of the substance through the skin or possibly by increased absorption due to increased respiration when working hard. Conversely, if results are lower than expected, they may reflect reduced absorption due to use of respiratory protective equipment.

Where biological monitoring guidance values are not available from international authoritative or regulatory organizations it may be possible to derive in-house guidance values based on either dose–response relationships or good occupational hygiene practice with the objectives of monitoring and controlling exposure. Such types of in-house guidance values for BM are prevalent in the pharmaceutical industry and often in other sectors with strong trade associations.

**BIOLICAL EFFECT MONITORING**

**Definition, examples and relationship with biological monitoring**

Unlike biological monitoring (BM), biological effect monitoring (BEM) does not attempt to quantify, or act as a surrogate marker of, the absorbed dose of chemical. It reflects the combined effects of dose (current and past) and those factors in an individual which modify dose in moving to the right along a recognized toxicological pathway in the exposure-disease model (see Figure 5.1). A BEM marker should give some idea of an increased risk, or early evidence of a move towards a specific poor health outcome in an individual. Therefore, the practical use of BEM is in:

- confirming, where the potential ill-health outcome may be significant, that the risk to an exposed cohort is negligible with the current control measures in place;
- identifying that appropriate action needs to be taken to reduce the health risk for a worker, whether due to their individual work practices and subsequent exposure or physiological, genetic or other predisposing factors in that individual.

As such, it has remained in the domain of health surveillance and performed by occupational physicians, unlike BM where there has been substantial uptake in use by occupational hygienists. Also, BEM often entails the use of more invasive samples, such as blood, in comparison to BM, this increased invasiveness being permissible on the grounds that the marker is closer to a defined adverse health outcome.

The relationship between BM and BEM for an exposure is illustrated in Figure 5.3. These data are collated from routine blood lead (Pb) monitoring carried out at the UK Health and Safety Laboratory (HSL) under Control of Lead at Work Regulations (CLAW), where blood Pb is the measured BM tool and zinc protoporphyrin (ZPP) is the BEM tool reflecting the effect of absorbed Pb on
haemopoiesis in bone marrow. Pb has a number of effects on both the production of erythrocytes, and on formed red blood cell that can ultimately lead to anaemia. Increased ZPP in blood largely reflects Pb inhibition of the insertion of the ferrous iron into protoporphyrin IX, which is a key step in the formation of the haem molecule involved in oxygen carriage by blood to tissues.

There is a significant statistical relationship between these BM and BEM markers (Figure 5.3), but it would be difficult to predict the likely blood Pb level from a ZPP measurement and vice versa in any single subject. It has sometimes been wrongly thought that BM markers are surrogates for BM measurements reflecting absorbed dose. The variability in the relationship between blood Pb and ZPP is influenced by toxicokinetics and the pattern of exposure of the metal, and the interindividual variations in Pb transport and storage within the body, as well as at specific enzyme pathways within the bone marrow. The influence of analytical imprecision in the two measurements is relatively small compared to these biological factors. In terms of dose, blood Pb can be considered as a measure of absorbed metal, while ZPP indicates the influence in an individual of the Pb concentration at the target site(s) of interference in haemopoiesis. Figure 5.3 also shows a general feature of the relationship between BM and BEM reflecting the same exposure, in that the former is more sensitive in detecting low-level exposure than the respective BEM marker, e.g. comparison of urinary alkyl phosphates (BM) and depressions in blood cholinesterase measurements (BEM) resulting from organophosphate pesticide exposure.18

An ideal BEM marker should be able to measure a change in a biological parameter within an understood toxicological pathway that links exposure to clinical disease or frank toxicity. It should also be able to detect an early change at a preferably reversible stage. However, even some well-established BEM do not necessarily fully meet such a definition. For example, urinary retinol binding protein (RBP) (or other low molecular weight proteins, such as α1-antitrypsin) has long been considered as a useful BEM marker in those exposed to cadmium.19–21 The urinary increase in RBP is a sensitive marker of the metal’s toxic effects on renal proximal tubular reabsorption. RBP can be readily measured in urine, and is sensitive to very small cadmium-induced changes in the proximal renal tubular reabsorptive process. However, the evidence is that any significant measured increase in RBP is not reversible even with complete removal of the subject from further exposure.

**Biological effect monitoring, susceptibility and diagnosis**

While the exposure-disease model in Figure 5.1 suggests that ‘uptake’, ‘effect’ and ‘disease’, and the associated analytical categories of ‘biological monitoring’, ‘biological effect monitoring’ and ‘diagnosis’, are clearly delineated, in practice there are grey areas and debate. There are some areas of uncertainty about where some analyses may be better considered as biological monitoring, biological effect monitoring or better defined as diagnosis of overt occupational disease.

For example, blood carboxyhaemoglobin (HbCO) could be considered a classical BEM marker for situations where there is direct exposure to carbon monoxide, from an industrial process or, often more hazardously, the use of internal combustion engines in confined spaces,22 and through the metabolism of dichloromethane and smoking status. Circulating levels of HbCO are both a direct indicator of the reduced oxygen-carrying capacity of blood and an indirect marker of likely tissue anoxia. The relationship between HbCO and the classical toxic symptoms are well defined, so that health-based occupational limits have been readily set. Breath carbon monoxide is a non-invasive measurement that can be assessed on site using readily available instrumentation and showing a good relationship with HbCO levels.23 Thus, in this case, the distinction between BM and BEM is arbitrary, and in higher exposures HbCO is the diagnostic test confirming possible symptoms of frank toxicity and the possible need for aggressive therapy, such as hyperbaric oxygen.

The influence of susceptibility factors on the move from exposure and frank ill health, are often linked with biological effect markers. Susceptibility factors may be protective in an individual, as well as increase the risk of possible toxicity and disease. While there are a few examples where distinct susceptibility factors can be identified as significantly altering the risk of adverse outcome (e.g. α1-antitrypsin deficiency and exposure to lung irritants24,25), altered risk is often related in a complex manner to a range of factors. In some cases, metabolic polymorphisms have been shown to be a risk factor for one ill-health outcome, but protective for another outcome (e.g. acetylator status for N-acetyltransferase-2 and risk of bladder and colorectal cancer when exposed to carcinogenic aromatic amines26). The use of biomarkers of susceptibility in occupational monitoring has raised considerable and ongoing ethical concerns, and the emphasis remains on keeping chemical exposure as low as possible to protect all workers, rather than identifying a cohort within a possible workforce who are best able to handle exposure.

An ‘ideal’ BEM marker would have both high sensitivity and specificity, low analytical imprecision and physiological variation, low cost and measureable in as non-invasive a sample as possible. These would be the same ideal characteristics for a clinical diagnostic test or test for an occupational disease. Therefore, a blurring between a BEM marker and diagnostic test is possible for the ‘ideal’ test, and this transfers to the real world where often tests are very much less than ideal. The difference between a test used as BEM or diagnosis may be defined by the rationale for their use and the interpretation put on the results. The value of a test used to diagnose an (occupational) disease...
may be expressed in terms of ‘likelihood ratios’ reflecting how much a positive (or negative) test is likely to change a physician’s opinion of the presence (or absence) of specific disease in a patient before the test was performed. The same test used within an occupational monitoring/BEM context can be viewed as similar to ‘screening’ within a population where there is a significant risk of relevant ill-health outcome, where the ‘positive (or negative) predictive value’ of the test is more relevant in terms of the test’s value. In practice, most tests are primarily developed for use in clinical diagnosis and their investigation in terms of value in occupational monitoring is secondary, often the evidence for evaluating the value of a test within occupational monitoring is scant in comparison to its clinical validation. Also, the problems of tests with less than ideal sensitivities and specificities in the context of screening in terms of false positives and negatives are well understood, which may have limited the wider spread of BEM.

In contrast, in the last 10–15 years there has been a very significant increase in the number of candidate BEM markers. This is due to the development of the experimental laboratory ‘-omics’ disciplines (e.g. proteomics, genomics and metabolomics) in identifying changes in large numbers of proteins, enzymes and cellular control mechanisms after a toxic insult in experimental studies. Whether some or any of these potential BEM markers develop into routine occupational monitoring procedures is uncertain.

The following sections deal with BEM with regard to specific potential outcomes or sites of toxicity.

CARCINOGENS

Protein–chemical conjugates involving haemoglobin may be considered as BM markers reflecting cumulative chemical exposure over the lifetime of haemoglobin. However, DNA-chemical adducts could be considered as BEM markers, showing the potential of reactive electrophilic chemical species, or their metabolites, to become both intracellularly located and then covalently adduct to DNA with direct relevance to a potential carcinogenic pathway. Other authorities have coined the term ‘biological effect dose monitors’ for such DNA adducts. Over the last decade or so, a number of assays have been developed to investigate the measurements of DNA adducts in readily available nucleated cells (e.g. lymphocytes in blood) which fits within a genotoxic model of how some chemicals may cause cancer, but their actual relationship to risk of cancer is uncertain. However, both haemoglobin- and DNA-adducts reflect that an absorbed chemical can cross cell membranes to produce intracellular reactive electrophilic species capable of covalently linking to structural or functional cell elements.

On an international basis, the use of haemoglobin conjugates have become an acceptable routine biomarker, highlighted by the development of guidance values for some chemicals by the DFG. In contrast, DNA adducts in circulating nucleated cells remain almost exclusively within the research area. Historically, DNA-adduct analysis has relied on highly sensitive, but non-specific radiological techniques, such as $^{32}$P post-labelling techniques. Recently, sophisticated chromatographic and some immunoassay-based methods have been developed. However these techniques, in particular $^{32}$P post-labelling, suffer from technical difficulties and complexities that would hamper their widespread adoption even if their value as risk biomarkers of cancer was better validated.

Another approach for monitoring DNA adducts takes advantage of the generally efficient DNA repair mechanisms, which leads to the urinary excretion of excised adduct-nucleic acids, e.g. urinary markers of oxidative DNA adduction.

Further measurements in the exposure-disease model (Figure 5.1) in terms of a mutagenicity/carcinogenicity pathway have been the measurements of genotoxic BEM markers, such as DNA strand breaks, chromosomal abnormality, sister chromatid exchange, micronuclei, COMET assay, modified bases, e.g. 8-hydroxy-2'-deoxyguanosine (8-OHdG) within circulating blood lymphocytes. These markers certainly reflect alterations in genetic material, although less specific generally in relation to exposure and influenced by non-occupational lifestyle issues, especially smoking habits. Recent reviews still caution about the lack of dose–response relationships that allow some risk assessment of the relevant health end point from such measurements, and therefore their value in routine monitoring. There is some evidence that DNA repair capacity within an individual may be an important determinant of cancer risk. This may be related to the concept of susceptibility and polymorphism with DNA repair or metabolic enzymes systems. Some studies continue to find clear relationships between metabolic polymorphisms and evidence of DNA damage in peripheral cells and actual risk of cancer in some cases, for example, polymorphism of acetylator status of NAT2 can be associated with a doubled risk of bladder cancer among individuals with high exposures to carcinogenic arylamines, with possible other metabolic polymorphisms in glutathione-S-transferases being additional risk factors.

There is considerable international effort to define the relationship between biomarkers of specific chemical adduction to DNA or exposure-induced changes in DNA, genetic polymorphisms in metabolic enzyme systems and the risk of cancer. Until such progress, Hb adducts as measures of exposure have gained a higher practical use on a worldwide basis than DNA adducts. Other protein–chemical adducts, such as albumin adducts have also been used in monitoring genotoxic chemical exposure. While albumin adducts reflect a shorter time frame of exposure estimation than Hb adducts, and introduce the possibility of non-invasive urine monitoring, they do not reflect that a reactive species that has become intracellularly located before covalent adduction, as albumin is an extracellular protein.
CENTRAL AND PERIPHERAL NERVOUS SYSTEM

The classical BEM markers associated with nervous system toxicity are the inhibition of the blood cholinesterase enzymes, namely plasma butyrylcholinesterase (BChE) and erythrocyte acetylcholinesterase (AChE) for anticholinergic pesticide exposure. Such pesticides inhibit AChE, mainly found at neuromuscular junctions and cholinergic synapses in the central nervous system, where its activity serves to terminate synaptic transmission. Excessive absorption of anticholinergic pesticides, namely organophosphate (OP) and carbamates, block the function of acetylcholinesterase and thus cause excessive acetylcholine to accumulate in the synaptic cleft, causing a number of symptoms in various body functions, but potentially leading to death by asphyxiation through neuromuscular paralysis.

Monitoring is based on identifying an OP-induced depression in the enzyme activity of AChE and BChE. Given the extent of normal, physiological inter- and intraindividual variation, especially in BChE, OP-induced depressions are detected through comparisons with baseline, unexposed measurements or changes in serial measurements within an individual. There have been attempts to produce a BChE monitoring system, based on specific activity measurements, that does not rely on serial monitoring within an individual. While this more complex specific activity measurement does not show a substantial improvement in sensitivity over the simple enzyme measurement to detect OP-induced inhibition, it has value in detecting subclinical OP exposures where baseline measurements are not available.

While AChE in erythrocytes is the same enzyme as that inhibited by OPs in nervous tissue and neuromuscular junctions causing their frank toxicity, it is usually less sensitive than BChE in terms of absorption and inhibition by OPs, so BChE is often also measured, or is the sole BEM measurement. While BChE is sensitive to OP (and carbamate) inhibition, BChE inhibition has no toxicological relevance in itself and the relationship between BChE inhibition and the risk of, or actual severity of OP poisoning is weak, with very significant inhibition of BChE having been noted in the presence of minimal symptoms. The relationship between erythrocyte AChE and symptoms/toxicity is much better. Thus, in this case, two BEM markers may be employed together to monitor workers using OP pesticides, with one marker a closer index of exposure and the other of toxicity. Alternative BM for anticholinergic OP exposure can be based on either a specific metabolite or a generic group of metabolites, such as urinary alkyl phosphates, that can certainly detect OP absorption far more sensitively than using BChE depressions.

RESPIRATORY AND LUNG BIOMARKERS

Respiratory sensitization and occupational asthma remains a significant occupational problem. The ability to predict, or test, whether chemicals may be respiratory sensitizers capable of producing an allergic status in exposed workers remains relatively poor. Specific IgE measurements in sera have a long history in aiding or confirming the diagnosis of allergy or confirming sensitization to a specific chemical or protein. The sensitivity and specificity of specific IgE in reflecting symptoms or clinical diagnosis of respiratory allergy appears much better for proteinaceous allergens than low molecular weight chemicals, where the sensitivity of specific IgE tests appears poorer. The restricted availability of radiolabelled anti-human IgE and the availability of large automated analysers for immunoassays in hospital laboratories has meant that the radioallergosorbent test (RAST) has been superseded by non-isotopic commercial assays for specific IgE measurements. These commercial non-isotopic assays cover both occupational and environmental allergens that can be used to investigate an individual’s sensitization status (Table 5.3), but tend to focus on commonly encountered allergens. Therefore, IgE tests add to symptom questionnaires, longitudinal peak expiratory flow monitoring in the workplace and, in the clinical setting, bronchial challenge testing that can be used to investigate an individual with asthmatic-type respiratory symptoms. Specialized flow cytometry analysis also allows measurement of the T-cell populations, including the T_{H1}/T_{H2} balance, and T-regulatory cells, which have been implicated in the mechanism underlying sensitization and symptoms of asthma.

In contrast to specific IgE, the measurement of specific IgG to proteins and low molecular weight has tended to be seen as only indicating significant, historical exposures which the immune system has recognized and responded to, without necessarily reflecting an altered increased risk of work-related respiratory disease. However, recent evidence in a longitudinal study of paint sprayers exposed to di-isocyanates has suggested that increases in specific IgG and IgG4 appear to have a protective effect on the incidence of work-related lower and upper respiratory symptoms, respectively.

Other toxic effects on the lung have been identified in the occupational context, largely through the use of symptom questionnaires and simple physiological measurements, such as FEV_{1}, out of a much larger armoury of diagnostic procedures used clinically. Biochemical markers were only measured in an aggressively invasive sample, such as bronchial lavage fluid, which has no role in any routine occupational monitoring strategy. However recently, interest has been stimulated in the measurement of specific lung proteins in blood plasma as biomarkers of toxicity in the lung. The change in plasma levels of these ‘pneumoproteins’ generally reflect the relationship between the increased synthesis or depletion of the proteins in the lung and alteration in the integrity of the blood–airspace barrier within the lung.

The proteins most investigated are the lung surfactant proteins (e.g. SP-A, SP-B and SP-D) involved in the innate immune response system of the lung, Clara cell protein...
Biological effect monitoring

Serum levels of the immunoregulatory CC16 protein are derived from secretions of Clara cells, largely found in the bronchio-tracheal tree, with passive transudation of the CC16 through the lung–blood barrier. Decreases in serum CC16 in chronic exposure to gases and dusts reflect the sensitivity of Clara cells to toxic insult. Increases in serum SP-A or SP-D are ascribed to increased lung–blood membrane permeability by toxic insult. Such pneumoproteins continue to be investigated in the clinical context, and a number of research studies relevant to occupational exposure and using serum measurements are now being published.

Whether these invasive biomarkers, using blood measurements, may move from research studies into routine occupational monitoring or health surveillance, is unclear. However, these tests do show a high degree of specificity for reflecting abnormalities in the lung.

Other recent interest has been in the analysis of exhaled breath in inflammatory lung diseases, including asthma, chronic obstructive pulmonary disease (COPD) and interstitial lung diseases. Analysis of various biomarkers, including volatile chemicals and gases such as nitric oxide (NO), carbon monoxide and many non-volatile molecules, such as inflammatory markers/mediators, oxidation and nitration products in exhaled breath allows non-invasive monitoring of inflammation and oxidative stress in the respiratory tract. The measurement of NO in exhaled breath can be increasingly measured using available, relatively low cost equipment, with some devices having Food and Drug Administration (FDA) approval for monitoring asthma status.

While NO in exhaled breath is not specific for asthma, as it is also increased in lower respiratory tract inflammation and chronic bronchitis, an increased level may be useful in differentiating asthma from other causes of chronic cough. Its diagnostic value in distinguishing between healthy subjects with or without respiratory symptoms and patients with confirmed asthma has been identified with a specificity of 90 per cent and positive predictive value of 95 per cent using a NO cut-off of 15 ppb in exhaled breath.

Furthermore, non-volatile biomarkers can be condensed from exhaled breath and analysed. The collection of this exhaled breath condensate (EBC) for analysis of non-volatiles is somewhat more difficult and involved than direct measurement of volatiles in exhaled breath. Standardized physiological conditions for collection, the development of more robust, cheaper collection equipment and high sensitivity methods for measuring the biomarkers in the EBC are necessary. Thus, the technique remains at a research stage, but recent work has shown the potential for the non-invasive measurement of inflammatory markers reflecting pathophysiology in the lung. While biomarkers in EBC are in their infancy, with their relevance and use within an occupational context still to be completely mapped out, publications with direct relevance to occupation are beginning to appear.

RENAL MARKERS

A number of specific chemicals such as mercury, cadmium and more diffuse ill-defined chemical occupational exposures, such as solvents, have been associated with occupational exposure and renal toxicity.
Serum creatinine, more recently cystatin C, and urinary albumin and total protein are accepted biomarkers of altered glomerular filtration rate andglomerular permeability, respectively. They are the classically used general clinical biomarkers reflecting such pathological alterations, but without any relationship to any occupational involvement of chemical exposure.

Over a number of years, there have been investigations into possible early renal biological effect markers reflecting the various renal effects of chemical exposures, and a number of markers have been suggested as of potential value.

These markers are usually urinary protein or enzymes (e.g. N-acetylgalactosaminidase) reflecting direct renal cellular damage, functional changes (e.g. albumin, retinol-binding protein, transferrin), structural components (e.g. collagen/laminin fragments) or induction of protection mechanisms (e.g. metallothionein). However, currently there is no universal agreement on a validated panel of effect biomarkers that may be suitable to detect or monitor chemical-induced nephrotoxicity in the context of occupational and environmental exposure. Neutrophil gelatinase-associated lipocalin (NGAL) appears increasingly useful in clinical nephrology and specifically as a sensitive marker of clinically encountered nephrotoxins, such as contrast media, cisplatin. Increases in urine NGAL have been found to precede changes in urinary NAG and β2-microglobulin, or serum creatinine. Even more recently, kidney injury molecule-1 (KIM-1) has been found to be a sensitive marker of tubule-interstitial damage. Thus, NGAL and KIM-1 appear potential useful candidate damage markers in terms of monitoring occupational or environmental exposure to nephrotoxins to add to the tests historically employed.

Urinary biomarkers, such as the low molecular weight proteins, retinol-binding protein (RBP), β2-microglobulin (with its more pH-dependent stability problems) and alpha-1-microglobulin reflect abnormality in the specific renal tubular process of protein reabsorption and are widely used to monitor the possible effects of cadmium. Cadmium is a cumulative nephrotoxic where its concentration within the nephron finally overcomes defensive mechanisms and leads to measurable changes in reabsorptive processes in the proximal tubule. Significant cadmium-induced effects appear non-reversible; however, the ability to measure very small induced changes in the proximal tubular process of low molecular weight protein reabsorption does allow exposure modification in an individual at an early stage to save the latter, grosser cadmium-induced changes due to the loss of substantial numbers of functioning nephrons.

In contrast, mercury, another acknowledged metal nephrotoxin, does not have suitable specifically associated BEM biomarkers, as with cadmium. Mercury has been associated with an immunologically mediated, rapidly presenting glomerulonephritis or nephrotic syndrome, with little clear understanding of dose–response relationships, except that it is rare in current occupational exposure conditions, and may have a large genetic component. Large increases in urine levels of high molecular weight proteins, which are not usually filtered by the glomeruli, and cellular proteins (such as NAG) are a marker of the glomerulopathic and general inflammatory nature of this mercury-associated condition, but there appears no good evidence that regular monitoring of, for example, urinary albumin can predict or identify early development of the mercury-induced glomerulonephritis. However, mercury as a general nephrotoxicant can cause some increase in the excretion of proteins and enzymes suggesting some subclinical toxicity. There is some evidence that occupational mercury exposure leads to small reversible increases in urinary enzymes, such as urinary N-acetylgalactosaminidase. This probably reflects that NAG is a lysosomal enzyme involved in the normal process of exocytosis of heavy metals from renal tubular cells into forming urine, possibly together with other tubular cell membrane enzymes.

**BLADDER**

The bladder as a site of occupational toxicity has been sustained largely by the actual and suspected additional risk of bladder cancer in those exposed to a number of toxic chemicals, including rubber fumes, dyes and various aromatic amines, including those in cigarette smoke. Urine cytology in normally voided urine has been historically part of health monitoring or health surveillance for current and ex-workers in high-risk industries. However, in order to get meaningful analysis, there is a need for fresh urine samples to be delivered to a centre where there is the appropriate expertise in this microscopical analysis. Centralization of hospital pathology units in the United Kingdom has increased the logistic difficulties in providing such occupational monitoring for workforces or ex-employees. Also urine cytology, while it has high sensitivity in detecting high-grade tumours, has low sensitivity in detecting low-grade tumours.

There has been considerable clinical effort in investigating molecular biomarkers that might reduce the need for periodic, invasive cystoscopies or, ideally, offering a non-invasive test with better sensitivity than urine cytology. Recently, some urinary biomarkers have been suggested as fulfilling a similar role, based on the excretion of altered cellular process and components at the pre-cancerous and cancerous stages. Some commercially available biomarkers, e.g. BTA, ImmunoCyt™, NMP22 and UroVysion™, have already been approved by the US FDA for bladder cancer surveillance, while many other markers are still undergoing development for preclinical and clinical investigation. However, the clinical trial data on the majority of these markers are conflicting in terms of their diagnostic power compared against cystoscopy as the gold standard diagnosis. Individual case–control studies have produced indices of diagnostic power for one or more biomarkers, e.g. NMP22 has been shown to have
sensitivity and specificity of 76 and 87 per cent, respectively, in diagnosing transitional cell carcinomas, although the sensitivity does decrease significantly for the lowest staging.93 However, a review of such studies (Table 5.4),94 while suggesting that the novel markers tend to have better sensitivity than voided urine cytology (although traditional voided urine cytology generally has high specificity) highlighted the variation in reported sensitivity and specificity between studies for individual biomarkers. They suggested that the variation in sensitivity and specificity was due to varying case definitions between studies. The use of cross-sectional studies with cystoscopy as the ‘gold standard’ to validate these new bladder biomarkers has also been criticized.95

In general, the uptake of such tests in clinical diagnosis has been relatively low, although with wide international differences. This probably reflects that none evaluated over the last years showed remarkable improvements in sensitivity or specificity for the identification of any of the diverse types of bladder cancer in clinical practice.92 A combination of tests may be necessary for screening in occupational cohorts at risk, in order to detect real cases of bladder cancers, without causing concern to much larger numbers of normal subjects through false-positive results.

Some of these new commercially available biomarkers (e.g. NMP22) have begun to be used in the United States, Europe and Japan in specifically monitoring occupational cohorts considered at risk. However, the evidence is scant for the value of traditional tests, such as voided urine cytology and detection of microscopic haematuria. Similarly, there is lack of evidence for the effectiveness of newer FDA-approved biomarkers, in screening current and past workers identified with occupational risk factors in order to detect bladder tumours at an early stage. This is essential for improved prognosis and long-term survival. As such, neither urine cytology nor proposed biomarkers can be considered as early markers reflecting a reversible stage.

While there is some evidence that susceptibility markers related to metabolism (NAT-2), slow metabolism and GST null/low activity may indicate some increased risk of bladder cancer in those exposed to carcinogenic arylamines.38 Such tests of susceptibility remain in the research arena, with concerns about their ethical application and interpretation in workforces.

**LIVER**

The panel of liver function routinely used in clinical diagnosis has also been employed in monitoring workers exposed to hepatotoxic chemicals. These tests include alanine transaminase (ALT), aspartate transaminase (AST), gamma glutamyl transferase (GGT), alkaline phosphatase (ALP) and bilirubin.96 Such tests reflect hepatocellular damage (ALT, AST), bile duct obstruction and cholestasis (ALP, bilirubin). GGT is a microsomal enzyme widely distributed in the liver and hepatobiliary tree, as well as other organs. It is sensitive to enzyme-inducing drugs and chemicals, and can also be elevated in chronic alcohol consumption. Other tests in this standard liver function test (LFT) panel may also show some abnormalities due to chronic alcohol abuse. There is a lack of published evidence about the value of such a panel of tests in detecting early occupational hepatotoxic effects, and the frequency of idiopathic low level abnormalities in such tests unrelated to liver disease has been highlighted.96 The prevalence of alcohol abuse in many communities means that any abnormalities in such LFT in workers, and especially the highly inducible GGT, may be unrelated to occupational exposure97 or that effects of occupational exposure may be masked.

If the occupational physician considers that the identification of chronic alcohol abuse is legitimately part of their role in maintaining a healthy workforce, then identification of workers with such problems can be done with better sensitivity and specificity by the measurement of serum carbohydrate-deficient transferrin (CDT). This can also be used in the monitoring of compliance by any workers undergoing an alcohol abstinence regime.98,99

Serum bile acid measurements have had some use as sensitive routine liver function tests. It has also been shown that bile acids can be measured in urine, and reflect serum levels, therefore there is the potential for a non-invasive measurement of liver function,100,101 particularly in detecting chemically induced cholestasis.

Other widely available tests for potential occupational hazards involving liver abnormality include immunmoasays for antibody status in those exposed to hepatitis B or hepatitis C or determination of antibody titre in high-risk occupational groups who undergo protective immunization regimes, e.g. for leptospirosis. DNA-based detection tests offer potential advantage over tests based on antibody detection for early diagnosis of leptospirosis.102 Since

antibodies may only reach detectable levels several days after the onset of the infection. Polymerase chain reaction amplification techniques may well afford the capability of detecting pathogenic leptospira in urine samples, but currently such tests are not widely available.

CONCLUSIONS

Distinctions in the boundaries between the categories of BM, BEM and diagnosis are sometimes not always clear and can lead to debate about which category a biomarker may fit. However, such a debate is largely irrelevant, the focus should be on why the biomarker is being used and where it may aid in understanding and controlling any move to the right in the exposure-disease model (Figure 5.1). Any test that is used to define the extent of uptake of any chemical by any route of exposure is BM, whereas tests that are used to gauge the potential ill-health risk or substantiate the lack of increased risk in individual workers or workforces constitute BEM.

There is an ongoing increase in the routine use of BM in workplaces, allied to the availability of appropriate biomarkers to monitor chemical hazards encountered in the workplace at current levels of exposure. In reality, where the relationship between exposure and risk of ill-health is very uncertain or unknown, the application of BM to help ensure that control of exposure is as low as practical, is a reasonable strategy. Any expansion in the use and range of BEM markers has not been so noticeable. However, a significant number of potential BEM markers for various target organ toxicities are potential candidate markers. Validation data that can substantiate their use in occupational monitoring strategies are required.

The exposure-disease model and the application of biomarkers are not necessarily confined to chemical exposure, but may well have a role in exposure to physical agents and psychosocial issues, such as hand–arm vibration exposure, stress and shift work.

Key points

- Biological monitoring is based on the analysis of hazardous substances or their metabolites in biological fluids.
- Biological effect monitoring reflects the early consequences of exposure.
- BM and BEM can be helpful in programmes of health surveillance.
- BM and BEM can aid the assessment of systemic exposure and consequences through ingestion and dermal absorption, as well as inhalation.
- BM and BEM can provide a valuable feedback loop to aid the control (including behavioural aspects) of exposure.

INTRODUCTION

Epidemiology is the branch of science that is concerned with the distribution and determinants of health outcomes in populations. The health outcomes investigated include not only diseases, but also illness (subjective absence of well-being) and disability. Determinants are predictors of the risk that an outcome will occur. They may directly cause the outcome, or while not being causal themselves, they may serve as markers for causes. For example, employment in manual work predicts a higher risk of cervical cancer, but it is not thought to cause the disease.

Along with toxicology, ergonomics and psychology, epidemiology is one of the main scientific disciplines that underpin the practice of occupational medicine. One major application is in the identification and confirmation of health hazards, in their characterization (understanding how the risk of adverse outcomes varies according to the circumstances and extent of exposure to the hazardous agent or activity), and in monitoring the effectiveness of control measures. It is also used in the prioritization of research and of interventions aimed at the prevention of occupational disorders. In addition, it can inform decisions in the management of individuals who have developed occupational diseases (e.g. whether they should change to a different job) or who have characteristics that would render them more susceptible to an occupational hazard if they undertook certain types of work. Another important use is in determining eligibility for compensation for occupational diseases, both through social security schemes and through litigation.

This chapter introduces the main concepts of occupational epidemiology and describes the methods of investigation that are used most frequently. It also outlines the methods by which epidemiological and other scientific evidence is collated so that that occupational health policy and practice can be optimized.

CONCEPTS AND TERMINOLOGY

Like most scientific disciplines, epidemiology has its own technical vocabulary. Terms are used with precise meanings that do not always correspond exactly with their usage in everyday language. To complicate matters further, not all of the meanings are universally agreed and some terms are used differently by different epidemiologists. The sections that follow describe some of the most important epidemiological concepts, where possible using standardized nomenclature.

Measures of disease and illness

CASE DEFINITION

Epidemiological investigation of a disorder requires quantification of its occurrence. Some diseases, such as cancer, are relatively all-or-none. While it may sometimes be
difficult to decide whether or not a tumour is malignant, most people can be classified with some confidence as being either cases or non-cases of cancer. Many other disorders occur in a continuous spectrum of severity, in which the distinction between normality and abnormality is ill defined. For example, it is debateable at what point mild impairment of hearing on audiometry should be classed as deafness, or how much lower than the expected value forced expiratory volume in one second (FEV₁) should be before a patient is considered to have chronic obstructive pulmonary disease (COPD). However, to simplify their consideration, disorders of this type are also classified dichotomously, so that, for example, a person is deemed either to be a case of COPD or not. Where this dichotomization is performed, the definition of a case should be unambiguous, even if somewhat arbitrary. Otherwise, findings cannot be interpreted satisfactorily.

**Incidence, mortality and prevalence**

Various measures are used to summarize the frequency with which disease or illness occurs in populations. The **incidence** of a disorder is the rate at which new cases occur over a defined period of time. For example, in 2004, the incidence of newly diagnosed mesothelioma among men in England was 6.2 per 100,000 per year. The **mortality** or death rate from a disease is the incidence of deaths for which it is thought to be the underlying cause. The **prevalence** of a disorder is the proportion of a population who are cases at a defined point in time or over a defined period. For example, the prevalence of low birthweight (<2.5 kg) in a sample of babies born over the course of two years might be 5 per cent. In contrast to incidence, which relates to an event (becoming a case), prevalence refers to a state (being a case).

Each of the above measures has its particular applications. Incidence is the index of disease occurrence that is of most immediate relevance to understanding of causation. For reasons of practicality and availability of data, mortality or prevalence may sometimes be used as a proxy for incidence in studies of causation, but care is then needed in interpretation. For example, a factor might be associated with increased mortality from a disease not because it increases people’s risk of developing the disorder, but because it makes them more likely to die from it should they get it. Similarly, a factor could be associated with a higher prevalence of a disease because it delays recovery or promotes survival (i.e. people remain cases for longer) rather than because it increases incidence.

**Proportional mortality**

All of the measures that have been described are rates in which the occurrence of cases is related to a population ‘at risk’. Sometimes, however, the size of the population that gives rise to a group of cases is unknown. For example, we may know from death certificates how many carpenters died from pleural mesothelioma in Scotland over the course of a year, but not the total population of carpenters from which these cases came. In these circumstances, the number of deaths from all causes is sometimes used as a proxy index of the population at risk. Thus, we might compare the proportion of all deaths that were ascribed to pleural mesothelioma in carpenters with that in other occupations. This use of proportional mortality is less satisfactory than analysis based on mortality rates insofar as the total number of deaths in a population depends on its overall (all cause) death rate, as well as its size (see Routine surveillance of occupational mortality, p. 84).

**Crude and specific rates**

Disease rates may be ‘crude’ (i.e. relating to a population in its entirety), or sex- and age-specific (i.e. relating to specific subsets of the population defined by sex and age). Because the occurrence of most disorders varies substantially by sex and age, sex- and age-specific rates usually allow more useful comparison between populations than crude rates. They can, however, be rather unwieldy, especially if there are a large number of sex and age strata in an analysis.

**Standardized rates**

One way of overcoming this difficulty is to summarize the sex- and age-specific rates for each population by a weighted average, the weighting factors being derived from the demographic distribution of a defined ‘standard population’. This technique is known as direct standardization.

Another method of accounting for sex and age when summarizing disease occurrence in a population is indirect standardization. Here, the number of cases that occur in the study population over a defined period is compared with the number that would have been expected had the study population experienced the sex- and age-specific rates of a defined standard population. The ratio of observed to expected cases, expressed either as a decimal or as a percentage, is known as a standardized morbidity ratio, or if the cases are deaths, standardized mortality ratio (SMR).

**Measures of association**

Much of epidemiology involves comparing rates of disease or illness between populations. For example, to assess the risk from a chemical in the workplace, the incidence of adverse outcomes might be compared in people with different levels of exposure to the chemical. Various measures can be used to summarize associations between risk factors (characteristics or exposures that might influence or predict the risk of a health outcome) and health outcomes.

**Attributable risk** is the difference in risk between someone who is exposed to a risk factor and someone who is not. According to the nature of the health outcome, this might correspond to a difference in incidence, mortality or prevalence rates between exposed and unexposed populations. Attributable risk is the measure of association that is most relevant to the management of risk for the individual. For example, when deciding whether or not it is acceptable for a person with a history of asthma to work with a respiratory
sensitizer, it is the attributable risk of illness and disability from undertaking the job that must be considered.

**Relative risk** is the ratio of risk in a person who is exposed to a risk factor to that in someone who is unexposed. This corresponds to a ratio of incidence, mortality or prevalence rates in exposed relative to unexposed populations.

An **odds ratio** compares the odds of a health outcome in people with and without an exposure (odds being defined such that a risk of $I/N$ equates to odds of $1/(N - 1)$). In most circumstances, odds ratios approximate closely to relative risks. Unlike relative risks, however, they can be estimated directly from case–control studies (see Case–control studies, p. 83).

**Population attributable fraction** is the proportion of cases in a population that would be eliminated if risk of the health outcome in exposed people were reduced to that in the unexposed. It is useful in characterizing the impact of a causal factor in a population, and therefore in the management of risk at a population level.

The **attributable fraction in exposed persons** ($\text{AF}_{\text{exp}}$) is the proportion of cases among exposed members of a population that would be eliminated if their risk of the health outcome were reduced to that of the unexposed. It provides an index of the confidence with which a disease can be attributed to a causal factor in a case that has been exposed to that factor. For example, if the $\text{AF}_{\text{exp}}$ for lung cancer from a given exposure is greater than 0.5, this implies a more than 50 per cent chance that lung cancer occurring in an exposed person would not have occurred in the absence of the exposure. $\text{AF}_{\text{exp}}$ is thus relevant to decisions about compensation for occupational diseases.

It is related to relative risk (RR) by the formula:

$$\text{AF}_{\text{exp}} = (\text{RR} - 1)/\text{RR}$$

**Considerations in the design and interpretation of epidemiological studies**

**POPULATIONS AND SAMPLES**

Epidemiological investigations normally collect and analyse data from a sample of individuals or populations with the aim of drawing conclusions that apply more widely. For example, a study might assess the association between occupational lifting and hip osteoarthritis in a sample of people selected from the general population, with the aim of characterizing the association in the population as a whole. A ‘statistic’ for the study sample (the relative risk of hip osteoarthritis from occupational lifting in the sample) is used to estimate a corresponding population ‘parameter’ (the relative risk of hip osteoarthritis from occupational lifting among people in general).

**BIAS**

An important consideration in the design and interpretation of epidemiological studies is the potential for ‘bias’. Bias is a systematic tendency to underestimate or overestimate a parameter of interest because of a deficiency in the design or execution of a study. It may arise, for example, if the study sample is systematically unrepresentative of the wider population because of the way in which it has been recruited, or if the information about risk factors or health outcomes in the study sample is inaccurate. Because of the practical constraints on research in human subjects, complete elimination of bias from epidemiological studies is virtually impossible. However, studies should be designed to minimize bias and their interpretation should take into account the possible impact of any bias that remains. It should be noted that bias is specific to the parameter that is being estimated. A low response rate from people invited to take part in a study might seriously bias estimates of one parameter, while not materially influencing estimates of another.

**CHANCE**

Even where the method of recruitment to a study is unbiased with regard to the parameter of interest, the study sample may still be unrepresentative simply by chance. Thus, another study sample selected in a similar fashion, but perhaps a different time period, would not be expected to give exactly the same estimate for the parameter. The scope for chance variation of this type depends partly on the size of the study sample. Other things being equal, larger samples are less likely to be unrepresentative by chance than smaller samples. Therefore, studies should be designed to ensure that they have adequate size and ‘statistical power’. Furthermore, the uncertainties relating to chance variation between samples must be taken into account when interpreting studies. This will be assisted by calculations of **statistical significance** or (more informatively) of **confidence intervals** around parameter estimates.

**STATISTICAL SIGNIFICANCE**

A test of statistical significance starts with a ‘null hypothesis’ about the wider population to which the findings of the study will be extrapolated (e.g. that there is no association between occupational lifting and hip osteoarthritis in this wider population). With the assumption that this null hypothesis applies, it then calculates the probability of obtaining findings as or more extreme than those observed in the study sample, simply through chance variation in sample selection. If this probability ($p$-value) is low, the null hypothesis becomes less tenable, and may be rejected in favour of an alternative (e.g. that occupational lifting is truly associated with hip osteoarthritis).

**CONFIDENCE INTERVALS**

A confidence interval around an estimate of a parameter gives a range within which, in the absence of bias, the parameter might normally be expected to lie. Most often, 95 per cent confidence intervals are derived. These are
calculated in such a way that, in the absence of bias, 95 per cent of study samples would be expected to produce confidence intervals that included the true value of the population parameter. Because they are less likely to be unrepresentative by chance, larger samples tend to give tighter confidence intervals.

CONSISTENCY WITH OTHER STUDIES

Importantly, assessment of the possible contribution of chance to the findings of a study depends not only on statistical analysis of the data obtained in the study, but also on the weight of relevant evidence from other research, both epidemiological and in other disciplines. For example, an association between a chemical and cancer might be attributed to chance even though it was statistically significant (i.e. carried a low p-value), if other similar epidemiological studies had found no association and toxicological testing in animals did not suggest that the chemical was a carcinogen.

CONFOUNDING

A further consideration in epidemiological studies of causation is the potential for confounding. Confounding affects inferences about causation from observed statistical associations. As an example, driving a lorry might be associated with an elevated risk of bladder cancer not because the occupation is hazardous, but because lorry drivers smoke more heavily than the average. In general, confounding occurs when a confounding factor is associated with the risk factor under investigation, and independently determines or predicts risk of the health outcome. Depending on the nature of its association with the primary risk factor and of its relation to the health outcome, the effect of a confounding factor can be either to inflate or reduce estimates of causal impact. Various techniques are used to reduce or eliminate confounding effects in epidemiological studies, including restriction of recruitment so that exposure to a confounding factor within the study sample is uniform (e.g. recruiting only non-smokers), matching participants according to their level of exposure to the confounder, and statistical adjustment in analysis.

EFFECT MODIFICATION

Sometimes confused with confounding is effect modification. This occurs when the strength of the association with one risk factor (usually quantified in terms of a relative risk) varies according to the presence or level of another factor (the effect modifier). For example, the relative risk of non-melanoma skin cancer from occupational exposure to sunlight differs according to skin colour, being lower in those with higher skin pigmentation that those with less pigmentation, e.g. in Afro-Carribeans compared to Caucasians. Effect modification is one reason why two studies of the same exposure and health outcome may produce differing estimates of risk.

STUDY DESIGNS

The most natural way to test a causal hypothesis or to quantify the impact of a cause on an outcome is to conduct a planned experiment. For ethical reasons, human experimental studies are not widely used in occupational health research – it is not usually acceptable deliberately to expose a volunteer to a hazardous agent. However, experimental studies have been used to assess the benefits of strategies to prevent illness, to investigate determinants of exposure when handling hazardous materials, such as pesticides (using an innocuous surrogate marker such as a dye), and to explore biochemical consequences of exposure to hazardous chemicals at levels well below those at which any adverse effects on health would be expected. More often, occupational studies are observational in nature. In other words, the investigator does not change participants’ exposures as part of the investigation, but rather studies people as they happen to have been exposed. Some observational studies analyse data at a population level (ecological studies), but most collect and analyse information about individuals.

Randomized controlled experimental studies

The most widely applied experimental design in medical research overall is the randomized controlled experiment. Studies of this sort entail comparison between two or more alternative exposures, one of which may be a control involving no intervention by the investigator. Subjects who meet predefined criteria of eligibility for study are identified, and if they consent, are randomly assigned to one of the exposure groups. They are then followed up systematically, and outcomes (both beneficial and adverse) are compared according to the exposure to which they were allocated. Effects can be summarized by various measures, including attributable and relative risks/benefits. Depending on the nature of the intervention, there may be scope to reduce bias by ‘blinding’ participants and/or investigators to the exposure that individuals receive until the relevant health outcomes have been assessed.

Where for some reason not all participants receive the exposure to which they were assigned according to the study protocol (e.g. because of non-compliance with the requirements of the intervention), it is particularly important that outcomes be compared according to the original exposure allocation. This is because those who drop out may have withdrawn because of an adverse effect of the exposure under investigation, which otherwise would be underascertained. However, it is usually helpful to carry out a secondary analysis according to the exposure actually received. Interpretation would be circumspect if the benefits from allocation to an intervention were limited entirely to subjects who did not receive the assigned exposure as planned.

The particular strength of randomized controlled experiments is that randomization, if carried out on a sufficiently large scale, tends to ensure that exposure groups are similar
with regard to potential confounding factors (including even those of which the investigator is unaware). However, if desired, even tighter control on confounding can be ensured by stratifying subjects before randomization, according to important determinants of outcome, and by ‘blocking’ the randomization so that within each stratum, there is always a close balance between the numbers of subjects assigned to each exposure. For example, exposures to two interventions might be randomly allocated within successive blocks of six (three to each intervention). In this way, within the matching stratum, the difference in numbers assigned to each exposure would never be greater than three.

**Randomized crossover studies**

A special type of randomized experiment is the randomized crossover study, a design in which each subject serves as his or her own control. The method is appropriate for investigation of short-lived effects of exposure. Again, subjects who meet specified eligibility criteria are identified and recruited (after giving informed consent). Each participant then receives each of the exposures under investigation sequentially, but in a randomly determined order (often with a ‘wash-out’ period between successive exposures). Outcomes are assessed during or immediately after each exposure, and are compared. Because comparisons are within rather than between participants, the method is particularly suited to investigation of subjective outcomes such as levels of pain, especially if the subject can be blinded to the exposure received.

**Non-randomized controlled experiments**

The benefits of randomization in control of confounding are only realized when the randomization is carried out on a sufficiently large scale. If 200 subjects are randomly allocated, half to one exposure and half to another, it is unlikely statistically that there will be a major imbalance of confounding factors between the two exposure groups. However, this does not apply where the number of units randomized is small. For example, in a study to evaluate an ergonomic intervention involving the installation of new lifting equipment in workplaces, only six workforces might be available for study. If three workforces were randomly allocated to the intervention and three to serve as a control, there could easily be important differences between the workers in the two exposure groups just by chance. In this situation, it would be better to use a non-randomized experimental design, in which allocation of the intervention to workforces was carefully planned in a way that minimized such differences between the intervention and control groups.

Sometimes non-randomized controlled experiments can be further enhanced by including a comparison of exposure groups both before and after the experimental exposure is introduced. If there are differences between the intervention and control groups before exposure, perhaps because of unrecognized confounders, these can then be controlled statistically when evaluating the impact of the intervention.

**Ecological studies**

Ecological studies are observational investigations which collate and analyse information about exposures and/or health outcomes at a population level. For example, a study might compare death rates from pleural mesothelioma in different countries according to their historical rates of importing asbestos and asbestos products. In occupational epidemiology, ecological studies are most often based on populations defined geographically, by occupation, by time or by combinations of these variables. They have the advantage that the data used are often readily available from routinely published statistics. However, because the information is only for populations and not individuals, it may be difficult to control for possible confounding effects. The main applications of ecological studies are in monitoring trends, and in the generation and early exploration of causal hypotheses.

**Cohort studies**

In a cohort study, individuals who differ in their exposure to known or suspected risk factors for a health outcome are identified. They are then followed up systematically to ascertain the subsequent occurrence of the outcome, which is compared according to the earlier presence or level of the risk factors. For example, a ‘cohort’ of pregnant women might be identified when they attend hospital for antenatal care, and their exposure to occupational activities during the first trimester of pregnancy assessed. They could then be followed up systematically to term, and the prevalence of outcomes, such as preterm delivery and low birthweight, compared according to their activities early in pregnancy. Where the outcome in a cohort study is the incidence of a disease (or a proxy for incidence such as mortality) estimates can be made of both attributable and relative risk.

The subjects in a cohort study may be selectively sampled according to their exposure to risk factors of interest. For example, a study might follow up a group of workers chosen because they were known to have high exposure to lead and a control group who were unexposed to the metal in their work. Alternatively, the cohort may be selected from the general population without regard to likelihood or levels of exposure. A well-known example of this approach is the Framingham study, which has followed up adult residents of the town of Framingham in Massachusetts over many years, collecting information about a wide range of risk factors (including occupational exposures) and health outcomes.\(^1\)
Various sources of information can be used to characterize exposures in cohort studies, including employment records (giving data on job history), questionnaires, direct observation (e.g. of physical activities at work), environmental or personal monitoring of exposure to chemical or physical hazards, and measurement of relevant biomarkers in tissues and body fluids. Sometimes, the assessment of exposure is made at a single point in time and sometimes information about exposure is collected on repeated occasions over a period of time. Often in occupational cohort studies, the classification of exposures combines information on individual occupational history with generic data on patterns of exposure in different jobs (and perhaps time periods) held in the form of a ‘job–exposure matrix’. Where possible, information is collected about potentially confounding exposures, as well as the risk factors of primary interest. Their effects can then be taken into account statistically when the study is analysed.

Methods for ascertaining health outcome vary according to the nature of the outcome. They include the use of health records (e.g. cancer registrations), death certificates (which give causes of death), questionnaires, physical examination and clinical investigations (e.g. spirometry, radiographs or biochemical measurements).

A major strength of the cohort study method is the assessment of exposures, which is the starting point for the investigation and often more reliable than with other study designs. The method is relatively efficient for the investigation of rare exposures, since participants can be selectively sampled according to their known or likely exposures. Furthermore, if desired, the same study can often be used to examine multiple health outcomes with little additional effort. For example, a cohort study using cancer registrations to ascertain outcome, could provide information about risk for each of a number of malignancies. On the other hand, cohort studies are less efficient for the investigation of rare health outcomes, since large numbers of people must be followed for long periods in order that the number of observed cases is sufficient for meaningful statistical analysis. Prolonged follow up may also be required where a hazardous exposure only increases the risk of a health outcome after a long latent interval. For example, most occupational cancers do not occur in excess until ten or more years after people are first exposed to the relevant carcinogen.

Two modifications to the cohort study method sometimes help to address these limitations. One involves the use of incidence or mortality rates in the general population as a comparator for disease experience in a cohort exposed to a risk factor. For example, the incidence of leukaemia in a cohort of hospital employees exposed to the sterilant, ethylene oxide, has been compared with that expected from cancer registration rates in the national population. This approach is reasonable where relevant exposures in the general population are trivial in comparison with those experienced by the study cohort, and it has the advantage that the rates for the general population that are used for comparison are readily available and statistically stable (because they are based on large numbers of cases). However, it is important that the method for ascertaining cases in the study cohort is similar to that for the general population (e.g. both based on cancer registrations) or risk estimates will be liable to bias. A further limitation may be a lack of information about important confounders in the general population.

In cohort studies that compare mortality or cancer incidence with rates in the general population, risk estimates are often presented in the form of standardized mortality ratios (SMRs) or standardized incidence ratios (SIRs) based on a person-years analysis. This involves computing the time that each cohort member was at risk (i.e. under follow up and eligible to become a case if he/she developed the relevant health outcome) for different combinations of sex, age and calendar period. The person-years at risk for each combination are summed across all cohort members, and multiplied by the corresponding sex-, age- and calendar period-specific outcome rates in the comparison population to give an expected number of cases for that combination. These expected numbers are then summed across all combinations of sex, age and calendar period to derive an overall expected number of cases. The ratio of the number of cases observed to the number expected is the SMR or SIR.

The second modification is to conduct the cohort study retrospectively. With this approach, the cohort is defined according to historical criteria (e.g. all of the workers who were employed at a particular manufacturing plant for at least six months during a specified period), and eligible subjects are identified from preserved records. Health outcomes are then examined in the time since each subject fulfilled the criteria for entry to the study. To be amenable to this approach, the relevant health outcome must be ascertainable at the time the study is conducted. For example, in many countries, mortality by cause of death can be established retrospectively from death certificates and cancer incidence from records of cancer registrations. In other studies, the assessment of outcome may depend on being able to trace and contact a sufficiently large and representative proportion of the original cohort so that they can be questioned about their health during the follow-up period or examined for changes in health measures, such as pulmonary function. Importantly, the identification of the cohort should not depend on factors associated with subsequent health outcome. For example, a retrospective cohort study of lung cancer at a coke oven could be seriously biased if the records of ex-employees who were known to have died had been selectively removed from archived files.

While the main use of cohort studies in occupational medicine is to identify and characterize occupational causes of disease, they may also inform decisions in case management. For example, systematic follow up of a cohort of patients presenting with a first epileptic seizure could provide information on the risk of further seizures that was useful in deciding whether and when such individuals should be allowed to drive professionally or work at heights.
Case–control studies

In a case–control (also known as case–referent) study, people who have developed a health outcome (cases) are identified, and their past exposure to known or suspected determinants of the outcome (risk factors) is compared with that of controls who do not have the outcome. This allows estimation of odds ratios for each risk factor. For example, to assess the risk of knee osteoarthritis from prolonged kneeling, past histories of occupational kneeling might be compared in patients listed for knee surgery because of osteoarthritis and controls who do not have knee complaints.

The case–control design is best understood if it is viewed as sampling subjects from a larger, usually hypothetical, cohort study. In most cohort studies, only a small minority of subjects develop the health outcome of interest during follow up. This imbalance between cases and non-cases is statistically inefficient. In effect, a case–control study increases statistical efficiency by collecting information about all (or a substantial proportion) of the cases in a cohort, but about only a representative sample of the non-cases.

In choosing a population in which to conduct a case–control study, three criteria must be considered. First, there must be a satisfactory way of identifying and recruiting adequate numbers of cases. Second, there must be adequate heterogeneity of exposure to risk factors in the study population. Third, there must be a satisfactory way of ascertaining exposures in cases and controls. If the number of cases studied is too few or the exposures of participants are all very similar, the study will have little statistical power to detect associations with risk factors. If it is only possible to ascertain a proportion of the cases that occur in the study population over the period of investigation, then the cases studied should be representative with respect to the risk factors under investigation. If exposures cannot be ascertained satisfactorily, the study will be uninformative or misleading.

The aim in selecting controls is that their exposures to the risk factors under investigation should be representative of those in the real or theoretical cohort from which the cases derived (i.e. those people who could have been included in the study as cases had they developed the health outcome under investigation). In addition, the exposures of controls should be ascertainable in the same way and with similar accuracy as for cases. Ideally, exposures would be assessed with complete accuracy in both cases and controls, but in practice this is rarely achievable. However, if errors in exposure assessment are non-differential (i.e. similar in cases and controls), any resultant bias will be conservative (tending to obscure associations rather than to give spuriously elevated estimates of risk).

The assessment of exposures is by definition retrospective. Various sources of information may be used, including documented records, questionnaires and measurement of biomarkers. However, where biomarkers are employed, they must be indicative of exposures before the health outcome developed and unmodified by its subsequent occurrence. For example, measurement of a urinary metabolite as a marker of exposure in a case–control study of glomerulonephritis would be inappropriate if excretion of the metabolite were altered by the presence of the disease.

Suspected confounding factors can be addressed by measuring them and then adjusting statistically for their presence or level. This adjustment can sometimes be made more efficient by matching controls to cases, either individually or as a group, according to their exposure to the confounder. However, in a case–control study, matching does not of itself eliminate confounding effects and appropriate statistical analysis is still required. Where matching is employed, controls should have exposures that are representative of those in members of the source cohort from the same stratum of the matched variable.

Case–control studies have the advantage that they are statistically more efficient than cohort studies, particularly in the investigation of rare health outcomes. Moreover, they can be limited by difficulties in achieving unbiased retrospective assessment of exposures, especially where the ascertainment of exposure relies on subjective recall. Also, while they provide estimates of odds ratios, and therefore of approximate relative risks, they cannot be used to estimate attributable risks without additional information from other sources.

NESTED CASE–CONTROL STUDIES

As indicated above, case–control studies are sometimes ‘nested’ within a larger cohort investigation. This is normally done to increase efficiency or because it would be impractical to collect complete data on exposure to risk factors for all members of the cohort. For example, in a prospective cohort study of cancer incidence among workers exposed to dioxins, blood samples might be collected at baseline that could be used to measure dioxin levels in the study participants. However, because the assay for dioxins is relatively expensive, rather than performing it in every blood sample, it might be preferable to store the samples, and then carry out the measurement of dioxins only for the cancer cases that occurred during subsequent follow up and for a group of appropriately chosen controls. This could reduce costs substantially with little reduction in statistical power.

Case–cohort studies

Like nested case–control studies, case–cohort studies are a way of making cohort investigations more efficient. As in a nested case–control study, information about exposures is obtained for all of the cases that occur during the follow-up period, but for only a sample of non-cases. However, instead of sampling controls from the non-cases that were ‘at risk’ when each case occurred, the person-years at risk
in each exposure category (and thereby the expected numbers of cases) are estimated by sampling controls at random from the total cohort.

Apart from its efficiency, especially when the assessment of individual exposures is relatively costly, the case–cohort method has the advantage that it is readily amenable to simultaneous investigation of multiple health outcomes. Furthermore, if follow up is subsequently extended, only the exposures of the new cases are required to update the analysis (this is in contrast to the nested case–control design, in which exposure would have to be characterized also for additional controls selected to match the new cases). However, bias could arise if the method for assessing the exposures of new cases differed from that carried out earlier for the baseline sample of cohort members. One reason why this might occur is that where exposure assessment is limited only to new cases, the assessor cannot easily be ‘blinded’ with regard to health outcome.

Case–crossover studies

Case–crossover studies are used to investigate known and suspected causes that have only a short-lived impact on the risk of a health outcome. The method is in some ways similar to that of a case–control study, but instead of comparing cases with non-cases, the exposures of cases immediately before development of the health outcome are compared with those of the same individuals at some other time. Thus, each subject serves as his or her own control (rather like in a randomized crossover experiment). A case–crossover design might be used, for example, to assess the risk of road traffic accidents from using a mobile phone while driving. Drivers who were involved in accidents would be asked about their use of a mobile phone in the minutes before the accident, and during one or more earlier control periods of similar duration.

The method is not as well developed and has not been as widely implemented as the other study designs described in this chapter. In particular, more thought is needed on the criteria by which control periods are optimally specified. By analogy with the case–control method, one might expect the control period to be representative (in terms of relevant exposures) of the times when the subject was ‘at risk’ of becoming a case. However, statistical efficiency may be increased if control periods are matched to case periods for one or more potential confounders. Control periods should then be representative of ‘at-risk’ times within the relevant stratum of matching.

A further challenge is that the subject will almost always be aware of when the relevant health outcome occurred. Thus, assessment of exposures that depends on the subject’s recall cannot be blinded. This could bias estimates of risk if exposures in different time periods were not uniformly remembered. It would not be a problem, however, where the assessment of exposures was from contemporaneous records rather than from memory.

A major advantage of the case–crossover method is that, because the subject serves as his or her own control, it eliminates the potential for confounding by long-term characteristics that might complicate interpretation of a case–control study.

Cross-sectional surveys

In a cross-sectional study, information is collected from a sample of individuals at a single point in time, about health outcomes and/or exposure to possible determinants of health. The information obtained may relate to the subject’s health or exposures at the time of the survey, or at some time in the past. For example, a cross-sectional study might be used to assess the current prevalence of sensorineural deafness in a sample of adults from the general population, and also their lifetime prevalence of exposure to noisy working conditions. The people studied in a cross-sectional survey may be selected without regard to their exposure, or they may be chosen because they have known exposures (e.g. to allow a comparison of health between exposed and unexposed groups).

Where information is collected about both exposures and health outcomes, the study can be used to investigate their statistical association. However, care is needed in interpretation. Because of the cross-sectional design, there may be difficulty in distinguishing the direction of cause and effect. For example, if barmen were found to drink more alcohol than other occupational groups, that could be because work in a job with ready access to alcohol encourages higher consumption. On the other hand, it could reflect a tendency for people who enjoy alcohol preferentially to seek work in bars. Also, there is a danger that selection effects may distort associations. For example, a cross-sectional comparison of the prevalence of asthma between people working with laboratory animals and unexposed controls could be misleading if people who developed allergies to animal proteins tended selectively to move to other jobs because of their symptoms. Such people would be under-represented in a cross-sectional sample of laboratory workers, leading risks to be underestimated.

Despite these limitations, cross-sectional surveys can be a valuable source of information about the occurrence of occupational illness and its causes.

ROUTINE SURVEILLANCE OF OCCUPATIONAL DISORDERS

One of the major applications of occupational epidemiology is in the routine surveillance of work-related illness and disease. Information about the occurrence of occupational disorders is used to target and prioritize control measures, and to monitor the success of preventive strategies.

The methods used to assess the frequency of occupational disorders vary according to the way in which they are
related to work. Some diseases occur only as a consequence of occupational exposure (e.g. coal workers’ pneumoconiosis, silicosis). For disorders of this type, the burden of disease attributable to work is indicated by its overall frequency in the population of interest. If the disease is commonly fatal, the required information could come from analysis of death certificates. If the disease normally attracts social security compensation, its incidence may be indicated in social security statistics. Otherwise, some form of reporting scheme may be required (see below).

Other disorders, although not specific to work, can nevertheless be attributed to occupation with confidence in the individual case, either because of specific clinical features (e.g. the demonstration of skin sensitization to an agent found only in the workplace), or because the relative risk and AF_{exp} for an occupational exposure are sufficiently high that attribution can reasonably be assumed in any case that has been exposed. In these circumstances, it is sufficient simply to ascertain and enumerate attributable cases. Again, social security statistics may be a useful source of information if the disorder is compensable (provided that the uptake of compensation by eligible cases is sufficiently high and does not vary importantly over time). Alternatively, attributable cases may be ascertained through a reporting scheme designed specifically for surveillance purposes. For example, in the UK, the University of Manchester has for some years operated a scheme in which cases of various occupational diseases are centrally notified by nationally representative panels of physicians.

More challenging is the situation in which a disorder is caused by occupational exposures, but cannot be attributed to work with confidence in the individual case. For example, lung cancer is a hazard of work in coke ovens, but the relative risk is not so high that attribution can be assumed simply because a person with the disease has at some time worked in a coke oven. Moreover, there are no special clinical features that can establish coke ovens as the cause of lung cancer in an individual case. For hazards of this type, the burden of illness or disease that is attributable to work can be established only by controlled comparisons of risk. For example, the burden of lung cancer nationally from work in coke ovens could be estimated from a large case–control study of a nationally representative study population. Alternatively, the attributable risk of lung cancer from work in coke ovens might be estimated by comparing mortality rates in coke oven workers with those in other occupations (e.g. in a cohort study) and this risk estimate then combined with information on the national prevalence of employment in coke ovens. In practice, assessment of disease burden in this way is often far from straightforward. In particular, since individual risk varies according to the level and timing of relevant exposures, it may be difficult to extrapolate risk estimates from cohort studies of workforces, which often have been chosen for study because they have experienced unusually high exposures to a hazardous agent, to the patterns of exposure to the same agent that occur nationally. Nevertheless, if findings are interpreted with appropriate caution, useful conclusions can be drawn.

While it can be helpful to know the overall burden of a disease or illness that is attributable to an occupational exposure, it is often useful also to break down the total by, for example, occupation, industry or geographical region. This is possible with all of the approaches to monitoring that have been described.

### Routine analyses of occupational mortality

One important source of information in the surveillance of occupational diseases is the routine analysis of occupational mortality at a national or regional level. Analyses of this sort have been carried out periodically in the UK for many years, and have been performed also in the United States. Their value lies not only in monitoring well-established occupational causes of mortality, but also in generating clues to previously unrecognized hazards. For example, an increased risk of infectious pneumonia following occupational exposure to metal fume first came to light in routinely generated statistics of mortality by cause among welders.

Two methods of estimating risk have been applied in the routine analyses of occupational mortality carried out in the UK. In the first, the analysis focuses on deaths occurring in a period of up to five years surrounding a national census. Information about the number of deaths in a particular occupation from a specific underlying cause is obtained from death certificates (which in the UK include a record of the deceased’s last full-time job). This is then compared with an expected number of deaths, calculated by applying sex- and age-specific rates for the country as a whole to the estimated numbers of people in the occupation nationally in the corresponding sex and age strata. These estimates of the populations at risk in each sex and age group are derived from information supplied by a representative subset of participants in the census. The ratio of observed to expected deaths gives a cause-specific SMR for the occupation under study.

The other method uses only information obtained from death certificates. The number of deaths by cause in each occupation is derived in the same way as for the SMR calculation described above. However, the expected number of deaths for a given occupation and cause of death is calculated by multiplying the sex- and age-specific proportions of deaths in all occupations combined that are ascribed to that cause by the number of deaths from all causes in the occupation of interest in the corresponding sex and age bands. In this case, the ratio of observed to expected deaths is a proportional mortality ratio (PMR).

Each of these methods has its strengths and limitations. A weakness of the SMR method is that data on occupation for the numerator and denominator of the risk estimate come from different sources, and this can lead to bias. For
example, there is a tendency for the next of kin to promote their deceased relative when registering his or her death. Thus, a shopkeeper might be described as a company director. Where this occurs, the effect will be to inflate SMRs for more prestigious jobs. Another limitation is that SMR analyses can only be carried out for periods surrounding a census year. The PMR method is not restricted in this way, but has the disadvantage that PMRs are influenced not only by mortality from the cause of interest, but also by the overall death rate in an occupation. For example, if an occupation had unusually low death rates from common causes, such as heart disease and cancer, its PMR for a rarer cause, such as fibrosing alveolitis, could be elevated even when it was not a hazard of the occupation. These limitations must be taken into account when interpreting SMRs and PMRs from routine statistics of occupational mortality.

Similar methods of analysis can be applied to data on occupation from cancer registrations to generate standardized or proportional registration ratios (SRRs or PRRs). However, this is only possible where reliable information about occupation is available for at least the majority of cancers registered.

**HEALTH OUTCOMES OTHER THAN DISEASE OR ILLNESS**

In most occupational epidemiology, the health outcome investigated is a disease, illness or associated disability. However, the same study methods can often be used to look at other outcomes.

One application is in the investigation of factors influencing levels of exposure to hazardous agents. For example, a cross-sectional design might be used to explore the relation of working methods to individual uptake (dose) of a chemical pollutant, the outcome being assessed by measurement of a relevant biomarker. In this way, it was shown that a major determinant of occupational exposure to organophosphate sheep dip was whether the operator handled the concentrated product before it was diluted—a finding that led to the redesign of containers with wider necks to reduce the risk of splashing.

Another area now being developed is the study of risk factors for biological effects such as cytogenetic abnormalities, that are thought to lie on, or be markers for processes on the pathway to serious disease. For example, one of the considerations that led the International Agency for Research on Cancer (IARC) to classify ethylene oxide as a human carcinogen was the demonstration that the frequency of chromosome aberrations is increased in exposed workers. Such studies have the advantage that they may highlight a need to control hazardous occupational exposures at an early stage, before cases of overt disease have started to appear. Also, they may have greater statistical power than conventional studies to detect adverse effects and characterize exposure–response relationships.

### EVIDENCE-BASED OCCUPATIONAL MEDICINE

Like other medical disciplines, occupational medicine is both an art and a science. While practitioners always bring their own unique personal skills and expertise to their work, their handling of occupational health problems should at the same time be consistent with the sum of relevant scientific evidence. Over recent decades, output from medical research, and specifically occupational health research, has grown rapidly, making it much more difficult for the individual practitioner to keep abreast of and assimilate new information as it becomes available. Even with the help of computerized literature searches and electronic publication of papers, there is a limit to the material that one individual can review for himself.

To address this problem, increasing emphasis is now given to formal secondary research, which attempts systematically to identify, collate and interpret published (and sometimes unpublished) scientific evidence on questions that are relevant to occupational health policy and practice. Reviews of this type initially focused mainly on the assessment of hazard and risk from occupational exposures, and were used to underpin regulatory policy, for example on exposure limits. More recently, however, the application of systematic reviews has extended to questions relevant to individual clinical decisions in the prevention and management of occupational disorders.

### Methods of systematic review

As with any research study, the first step in a systematic review is to define the questions that will be addressed. An attempt is then made to identify all available evidence within prescribed limits (e.g. published in peer-reviewed papers or in specified languages) that pertains to these questions. The starting point for this is normally a search of one or more computerized databases that cover publications relevant to the focus of the review. Databases listing reports relevant to occupational medicine include Embase, Medline, PubMed, NIOSHTIC, PsycInfo and TOXLINE. The search is made by combining a series of search terms, using Boolean operators. An initial check is made to ensure that the numbers of publications identified and their titles seem appropriate, and if necessary, the search criteria are revised. The lists of publications from each database are then amalgamated, and duplicates eliminated.

Next, the titles and abstracts of the listed publications are scrutinized and those that are clearly irrelevant are eliminated. This may be done as a single exercise or in two stages (titles and then abstracts). For those publications that remain, the full text is retrieved and checked for relevance. In this way, a shortlist of relevant reports is compiled and the reference lists of these reports are checked for any additional publications that were not picked up by the original computer search. Again, abstracts and, if necessary, full texts are scanned to check for their relevance and
where appropriate, the additional reports are added to the shortlist. This exercise not only guards against omission of important publications, but also serves as a check on the performance of the original search criteria. The identification of large numbers of new reports may suggest that the search criteria need revision. Each of the reports in the shortlist is then examined and summarized. The information abstracted is that which relates to the study questions and often this abstraction is facilitated by the use of a standardized format in which to record the information.

To reduce the chance of error, all stages of the process that are not automated are normally carried out independently by at least two members of the study team and any differences reconciled by discussion.

Once the required information has been abstracted, it is evaluated and synthesized. In some cases, the synthesis may extend to a formal meta-analysis in which summary estimates of outcome measures are calculated with confidence intervals. However, this is only appropriate where the design of the primary studies is sufficiently uniform, a requirement that is more often met for randomized controlled experiments than for the observational studies that are more common in occupational health research. Where studies addressing the same question produce apparently discordant results, possible explanations should be considered systematically (Table 6.1).

Some systematic reviews specify criteria in advance that will be used to grade the quality of studies, and greater weight is then given to findings from those that are classed as stronger. An attraction of this approach is that it helps to standardize assessment and interpretation, making it more reproducible. Thus, if a different group of researchers carried out the review to the same protocol, they should come to the same conclusions. However, there is a danger that evidence will be given inappropriate weight in the quest for repeatability. For example, a study showing a positive association between an exposure and disease might suffer from a bias, the effect of which was to reduce risk estimates. If the findings from this study were downgraded because of the bias, the evidence for a hazard could be assessed as weaker than it really was.

Some guidelines for systematic review have attempted to grade the strength of evidence provided by different study designs, with for example, randomized controlled experiments ranking higher than cohort studies and cohort studies higher than case-control studies. However, while in general, cohort studies are less prone to bias than case-control investigations, this is not universally true. Thus, it is better if the strength of evidence from each study is evaluated on its own merits rather than according to simple rules of thumb.

**Translation into practice**

Once an evidence-based review is completed, its value will only be realized if its findings are translated into policy or practice. Where the express purpose of the review is to inform regulation, this is usually straightforward, but where the aim is to guide the practice of individual healthcare workers or managers, a planned communication exercise may be required. The methods used will depend on the target audience, but may be assisted by early involvement and commitment of representatives from the groups whose practice will be affected. These representatives can then advise on the optimal methods of communication and assist in conveying findings to their constituency. A good example of this is the set of evidence-based guidelines published by NHS Plus on the management of chronic fatigue syndrome in relation to work. These were drawn up following a review process that involved practising occupational physicians, and these individuals subsequently helped to disseminate the findings to their colleagues.

**FURTHER READING**

For readers seeking a more detailed account of epidemiological methods and the use of statistics in interpretation of epidemiological data, a number of textbooks are available.

**Key points**

- Epidemiology is the branch of science that is concerned with the distribution and determinants of health outcomes in populations.
- Epidemiology is used in occupational medicine to identify, confirm and characterize health hazards in the workplace; monitor the
effectiveness of controls aimed at reducing health risks; prioritize research and interventions; inform decisions in clinical management; and determine eligibility for compensation because of occupational diseases.

- Planning of epidemiological studies and interpretation of their findings must take into consideration the possibility that results will be unrepresentative by chance or because of systematic bias or confounding.
- Various study designs are commonly employed, including randomized and non-randomized controlled experiments, ecological studies, cohort studies, case–control studies, case–cohort studies, case–crossover studies and cross-sectional surveys.
- Assessment of the overall balance of epidemiological evidence on a topic is often facilitated by formal systematic review, for which methods are now well developed.

Attribution of disease

ANTHONY NEWMAN TAYLOR AND DAVID COGGON

INTRODUCTION

Attribution of a disease to a particular cause in an individual is usually a matter of informed judgement. The judgement is based on the degree of certainty required, together with knowledge of causation in relation to the particular disease and the particular circumstances of the case. The level of certainty commonly applied, in medicine and the law, is ‘on the balance of probabilities’ or ‘more likely than not’. As Lord Denning put it, ‘If the evidence is such that the tribunal can say “we think it more probable than not”, the burden of proof is discharged, but if the probabilities are equal it is not’.

Attribution of disease in the individual case implies a sufficient knowledge of causation to answer the questions:

1. Is the agent a cause of the disease, at least in certain defined circumstances?
2. If so, were the circumstances of the individual case such that the factor is more likely than not to have caused the disease to occur?

This chapter will address these two questions: disease causation and attribution in the individual case. The development of epidemiology during the past 60 years has refined our understanding of the ways in which causes relate to disease outcome, which has informed medical and legal understanding of causation and attribution.

CAUSATION

Observation can only tell us that certain events regularly follow other events. The rest is subjective inference.

David Hume, 1739

Whenever I look at my watch and see the hand pointing to ten, I hear bells beginning to ring in the church close by; but I have no right to assume ... the movement of the bells is caused by the position of the hands of my watch.

War and Peace, Tolstoy

Cause of disease: Something that at least in some circumstances, makes a disease more likely if it is introduced or less likely if it is removed.

Coggon and Martyn

The characteristics which allow inference of causation have been the subject of long-standing disagreement and debate, as exemplified by the quotations above from Hume and Tolstoy. For our purpose the definition, proposed by Coggon and Martyn, provides a practical foundation: ‘something which at least in some circumstances makes a disease more likely if it is introduced or less likely if it is removed’. Cigarette smoking is a cause of lung cancer and high blood pressure a cause of stroke; stopping smoking reduces the risk of lung cancer and lowering blood pressure reduces the risk of stroke.
No condition has a single cause; rather all conditions have multiple causes, some of which act through one another. Aristotle distinguished necessary from sufficient causes, a distinction which can be applied to disease causation. In the absence of a necessary cause, a disease will not occur. Infection with *Mycobacterium tuberculosis* is necessary for the disease tuberculosis, as cases of tuberculosis do not occur in its absence. Similarly, inhalation of respirable crystalline silica dust is a necessary cause of silicosis. However, infection with *M. tuberculosis* is not a sufficient cause of tuberculosis: only some 10 per cent of those infected with *M. tuberculosis* will develop tuberculosis. Other factors including poverty, malnutrition, age, overcrowding, HIV infection and silicosis increase the risk for those infected with *M. tuberculosis* of developing tuberculosis. While the focus of physicians in individual cases of tuberculosis will be on the successful application of antituberculous chemotherapy, the importance of these other factors in determining the risk of tuberculosis in the population is appreciable. English mortuary registers in the 1830s showed clear evidence of the socioeconomic determinants of tuberculosis: ‘the proportion of consumptive cases in gentlemen, tradesmen and labourers was 16, 28 and 30 per cent, respectively’. McKean showed that during the twentieth century, by the time streptomycin was introduced around 1950, the death rate had fallen to about 20 per cent of its level in 1900, an improvement he attributed primarily to improved nutrition in the population.

Identification of a cause or combination of causes sufficient to cause a disease is uncommon other than for single gene disorders and chromosomal abnormalities. The presence of two abnormal haemoglobin genes (HbS) is sufficient to cause sickle cell disease and three copies of chromosome 21 sufficient to cause Down syndrome.

The majority of diseases are caused by a combination of factors (both genetic and environmental) which, when present, can be shown to increase the frequency of the disease, or when absent to reduce it, but which alone are neither necessary nor sufficient. Cigarette smoking is a potent cause of lung cancer, but not all cases of lung cancer have smoked cigarettes (cigarette smoking is not necessary), and only a minority of smokers develop lung cancer (cigarette smoking is not sufficient).

Investigation of a factor as a potential cause of a disease would ideally be undertaken in a representative population, half of whom were randomly allocated without their knowledge to exposure to the factor in question. This is the basis of the randomized controlled trial, whose major strength is in minimizing the problem of confounding biases (recognized and unrecognized), which can lead to false inferences of causation. Randomized controlled trials are now the bedrock underpinning decisions about the efficacy of therapeutic interventions and, in a few cases, about adverse effects of drugs. Not least for ethical reasons, such studies are usually not feasible in addressing questions of disease causation, which normally rely upon inferences from observational studies.

There are two common approaches to observational studies of disease causation:

1. Demonstration that those exposed to the putative cause develop the disease more frequently than those not exposed.
2. Demonstration that those with the disease have more frequently been exposed to the putative cause than those without the disease.

The first forms the basis of the cohort design; the second, the basis of the case–control (case–referent) design of epidemiological study.

**Threats to the inference of causation**

In general epidemiological studies, particularly analytical studies, are concerned with cause and effect. The essence of an epidemiological investigation is comparison within or between population samples to determine whether differences in frequency of disease are associated with the exposure or factor of interest. Cohort studies are designed to ensure that, to the extent possible, like is compared with like in all respects other than for the factor under investigation. In case–control studies, the aim is that exposure to the risk factor in the controls should be representative of exposure in the population at risk of becoming cases. Bias in a study is a systematic tendency to overestimate or underestimate a characteristic of interest, because of deficiencies in study design or execution. Bias can lead to false inferences about causation.

In thinking about potential bias in a study, it is helpful to consider three questions:

1. In what way does the study sample (healthy or unhealthy) differ from the population from which it was drawn?
2. What is the potential for inaccurate information about study participants (e.g. from errors in measurement or recall)?
3. How might such differences affect the results?

An informative example is of osteoarthritis of the hip in farmers. Farmers were over-represented among hospital patients with osteoarthritis of the hip. This did not necessarily imply that the incidence of osteoarthritis of the hip was increased among farmers, as hospital cases are not representative of the population as a whole. Cases coming to hospital are likely to include a higher proportion of more severely affected cases, and might over-represent farmers, whose livelihood depended on their physical capacity. In fact, subsequent population studies confirmed farming to be an important risk factor for osteoarthritis.

Three important sources of bias are recognized in epidemiological studies, as discussed below.
Selection bias

This arises when the sample of subjects for whom information is collected is systematically unrepresentative of the wider population about which conclusions are to be drawn with regard to the parameter (e.g. odds ratio or disease prevalence) being estimated in the study. An important example of this is the health of workforces as compared to the general population. In general, those who enter work are likely to be healthier than those not in work (healthy selection effect) and those who remain in work are healthier than those who leave work (healthy survivor effect). In a study of workers engaged in the manufacture of polyvinyl chloride (PVC), Fox and Collier quantified the magnitude of these contributions to a lower than expected mortality in the workforce:

- Selection of a healthy population for employment. The mortality experience within five years of starting work in a factory where PVC was made was 37 per cent expected for circulatory and 21 per cent expected for respiratory disease. The standardized mortality ratio (SMR) for these conditions progressively increased with increasing duration of employment, becoming similar to the general population after 15 years.
- Survival in employment of healthier males. Those who had left the industry during the 15 years from first employment experienced an SMR 50 per cent higher than those who remained employed in the industry.

For cardiovascular and respiratory disease, valid comparisons of mortality experience between a workforce and the general population are likely to be difficult, particularly during the first 15–20 years of employment.

Information bias

Information bias arises from error in measuring exposure or disease. Retrospective investigation of risk factors for congenital malformations from answers to questions to their mothers is likely to be subject to recall bias: mothers whose children have congenital malformations are more likely than those whose children are without congenital malformations to recall drugs taken, infections acquired or workplace chemical exposures experienced during pregnancy.

Confounding and modifying factors

A confounder is an extraneous factor which is associated with the risk factor under investigation and which independently determines the risk of disease outcome.

A confounding factor is therefore one which:

- is associated with the disease;
- is associated with the exposure;
- is not simply an effect of the exposure.

In contrast, effect modification occurs when the strength of the association with one risk factor varies according to the presence or level of another factor (the risk modifier). For example, in a study of the association between occupational lifting and low back pain, risk estimates differed according to stature. In the shortest males, the estimated relative risk was 4.5, in those of intermediate height it was 1.6–2.4, and in the tallest males it was 1.0. A similar pattern was observed in females, suggesting that stature modifies the risk of low back pain from lifting.

Observational studies are inevitably subject to potential for bias and therefore to false inference. For this reason, no single study is usually considered definitive and conclusions are therefore based on the overall weight of the evidence accumulated from several studies.

Robert Koch, the discoverer of the tubercle bacillus as the microbial cause of tuberculosis formulated four postulates which needed to be met before a causal relationship could be inferred between a particular microbe and disease:

1. The agent must be shown to be present in every case of the disease, by isolation in pure culture.
2. The agent must not be found in cases of other diseases.
3. Once cultured, the agent must be capable of reproducing the disease in experimental animals.
4. The agent must be recovered from the experimental disease produced.

The criteria are apt in the consideration of necessary, infectious causes of disease, but are not appropriate for determining non-infectious causality in chronic diseases, such as chronic obstructive pulmonary disease (COPD) where, for example, inhaled coal dust is a cause, but is not a necessary cause.

Others have explored alternative criteria, more appropriate to cancer and chronic disease. Bradford Hill is responsible for the best known criteria on which to base judgements about causal inferences from the findings of observational studies. However, he emphasized that these criteria should not be applied rigidly and recognized that concepts of causation are necessarily provisional, dependent on knowledge at that time.

Of the Bradford Hill criteria, the most important are:

1. Strength of the association, i.e. the ratio between the incidence of disease in those exposed to the putative cause and those not exposed – relative risk (or, in case–referent studies, the ratio of the odds of being exposed in those with the disease to those without the disease). In general, the greater the relative risk or odds.
ratio, the less likely it is that the observed association is due to confounding.

2. **Exposure–response gradient.** A positive relationship between disease incidence and the level of exposure to the putative cause (i.e. risk increases with higher exposures) strengthens the inference of causation from association.

3. **Consistency of findings between different studies,** undertaken in different places by different people at different times using different populations, carries considerably more weight than a single observational association.

4. **Biological plausibility.** Is there a biological mechanism through which the putative cause could cause the disease? While this is helpful, potential mechanisms have been identified for some suspected causes which have proved artefactual, and some agents can cause disease through previously unknown mechanisms.

5. **Experiment.** Can disease incidence be reduced by a reduction in exposure to the putative cause? This is the nub of a causal inference, providing the most important test of cause and effect.

The final question to be addressed having taken these others into account is: Is there any alternative hypothesis that can explain the observations equally well or better?

Demonstration of disease causation is clearest, and attribution in the individual case most confidently made, where the cause is necessary or nearly so. In these circumstances, the cause is described as specific for the condition. Such conditions include chemical poisonings, such as by lead and mercury, pneumoconiosis caused by inhaled coal and silica, mesothelioma caused by inhaled asbestos, and haemangiosarcoma of the liver caused by inhaled vinyl chloride monomer. For these diseases, the probability of causation for those exposed at work in sufficient concentration to the particular agent is comparable to that for an acute occupational injury and can approach certainty. It is not surprising that the earliest diseases to be recognized in the United Kingdom under the Workmen’s Compensation Act in the early part of the twentieth century included a number of such disorders.

Other diseases (such as lung cancer, COPD, osteoarthritis (OA) of the hip), which now form the majority of diseases of occupational cause, are not specific to exposures in the workplace, but the outcome of multiple causes, none necessary or sufficient. In these circumstances, evidence for attribution to an occupational cause depends on inference from observational studies of workforces which consistently demonstrate a sufficient increase in disease incidence, not explained by chance, bias or confounding. No studies are perfect and determination that an observed association is causal is a matter of judgement, based on the strength and consistency of the evidence and its coherence. The strongest evidence for causation is a reduction in disease incidence following avoidance or removal of exposure (Figure 7.1).\(^7\)

![Figure 7.1 Reduction in the risk of lung cancer in British doctors in years after stopping cigarette smoking in comparison to the risk in doctors who continued to smoke. Data from Ref. 7.](image)

### ATTRIBUTION

Attribution of disease to a particular cause in the individual case depends on whether:

- the agent or exposure can cause the disease at least in some circumstances (causation);
- the circumstances of the individual case are such that the agent or exposure caused or made a sufficient contribution to the development of the disease.

The answer to the first will be based on judgement of the strength of the scientific evidence and the answer to the second will be based on the level of probability required to accept attribution in the individual case. For this purpose, we can distinguish five levels of probability:

1. almost certainly true (‘beyond reasonable doubt’);
2. more likely than not (‘on the balance of probabilities’);
3. as likely as not;
4. less likely than not;
5. almost certainly false.

In general, the level of probability adopted for the purposes of attribution is ‘more likely than not’ (on the balance of probabilities).

The question of causation has been addressed in the previous section. The question of attribution will depend on potency of the causal agent in the particular circumstances of the individual case. These will include the nature and level of exposure and the presence of modifying factors.

Some diseases, such as lung cancer, can be considered as ‘all or none’ diseases. The effect of a cause in these conditions is to increase the probability of the occurrence of the disease. Others, such as hypertension or COPD, are ‘more or less’ diseases. Whereas ‘all or none’ diseases are or are not present, ‘more or less’ diseases occur in a continuum of severity, where the question is not, ‘Do you or do you not have the disease?’, but ‘How much of the disease do you have?’.
For ‘all or none’ diseases, the contribution of a particular cause in the individual case can be quantified by the attributable fraction in the exposed \((AF_{\text{exp}})\). This is the difference in incidence rate in the exposed and unexposed as a proportion of the incidence rate in the exposed.

\[
AF_{\text{exp}} = \frac{\text{Incidence in exposed} - \text{incidence in unexposed}}{\text{Incidence in exposed}}
\]

It can also be considered as the proportion by which the incidence rate in the exposed would be reduced if the exposure were eliminated.

\(AF_{\text{exp}}\) can also be derived from knowledge of the relative risk (RR) by the formula:

\[
AF_{\text{exp}} = \frac{RR - 1}{RR}
\]

It can be seen from this that an attributable fraction in the exposed of greater than 50 per cent corresponds to an RR > 2. Thus, if the RR = 2,

\[
AF_{\text{exp}} = \frac{RR - 1}{RR} = \frac{2 - 1}{2} = 50\%
\]

RR > 2 implies that in these circumstances the occurrence of the disease in an exposed person can be attributed to the particular cause on the balance of probabilities, i.e. more likely than not: where the RR is <2, there is a less than 50 per cent chance that the particular case of disease would have been prevented if the exposure had not occurred.

This test of more likely than not has been the basis for attribution used by the Industrial Injuries Advisory Council (IIAC) in determining whether a disease should be prescribed for the purposes of statutory compensation and by the UK courts in determination of negligent damage.

An informative example is the relationship of lung cancer to asbestos exposure. In the absence of any specific identifying characteristics to distinguish a case of lung cancer caused by asbestos from one which would have occurred in the absence of asbestos exposure, attribution of lung cancer to asbestos in the individual case can only be based on the attributable fraction in the exposed and therefore the relative risk in comparison to those not exposed to asbestos. The relative risk of lung cancer for an asbestos textile worker employed in the 1950s and 1960s is more than doubled in those employed for ten years or longer, implying that 50 per cent or more of the cases of lung cancer which occurred in these workforces would not have occurred had they not worked with asbestos in these factories. Although it is not possible to be certain whether or not the individual case would not otherwise have occurred, it is more likely than not, in these circumstances, that it is attributable to asbestos exposure.

The attributable fraction (and RR) can vary in relation to the level of exposure, usually, as with asbestos and lung cancer, increasing with increasing cumulative exposure (intensity × duration) (Figure 7.2).

**Figure 7.2** Increasing risk of disease \(AF_{\text{exp}}\) and relative risk (RR) with increasing cumulative exposure to the causal agent. At low exposure, while the risk is increased, attribution remains less likely than not (i.e. among three exposed cases it would have occurred anyway in two). At intermediate level exposure, the attribution becomes as likely as not (i.e. among four exposed cases it would have occurred in two anyway). Only at the highest level is attribution more likely than not (i.e. among five exposed cases, it would only otherwise have occurred in two).

### 'More or less' diseases

Lung cancer is an ‘all or none’ disease with a clear distinction between cases and non-cases. The same is not true of diseases, such as hypertension (high blood pressure) and COPD (chronic obstructive pulmonary disease characterized by low forced expiratory volume in 1 second or FEV\(_1\)) which have a continuum of severity without a clear distinction between cases and non-cases. Blood pressure and FEV\(_1\) (a measure of limitation of airflow) are unmodally distributed in the general population and disease represents the extreme of the distribution curve. As Geoffrey Rose put it, for these conditions the question is not ‘does he have it?’ (an appropriate question for lung cancer), but ‘how much does he have?’.

COPD can be defined (somewhat arbitrarily) in relation to the lower extreme of distribution curve. In its prescription of COPD in coal miners, IIAC took as a case definition of COPD an FEV\(_1\) of 1 L or more below the average (mean) value for a person of the same age and height. This represented an impairment of lung function sufficient on average to be associated with a significant level of disability (inability to keep up with others of the same age when walking on the level). Studies in the United Kingdom had
shown that the proportion of miners with this level of FEV\textsubscript{1} loss increased with increasing cumulative coal dust exposure and that at the highest levels of exposure the probability of this occurring was more than doubled (Figure 7.3).\textsuperscript{8} From knowledge of the levels of coal dust exposure in coal miners, underground and on the surface in the UK, it was possible to identify the circumstances of exposure where the risk of this level of FEV\textsubscript{1} loss was more than doubled (\(AF_{\text{exp}} > 50\) per cent). This was found to occur in coal miners who had worked underground for 20 years or more, which became the basis for the prescription.

More recently, it has been shown that comparable cumulative levels of exposure are also experienced by surface workers employed on the screens for 40 years (i.e. the levels of exposure are on average about one half of those underground) and prescription of COPD in coal miners has been amended to reflect this.

**ATTRIBUTION IN THE INDIVIDUAL PATIENT**

These principles can be applied to the question of attribution of disease to a particular cause in patients seen in clinical practice. For this purpose, it can be helpful to consider attribution of disease to an occupational cause as a hierarchy of probability of causation and associated difficulty of attribution (Figure 7.4).

Demonstration of disease causation and attribution in the individual case can be made most confidently for diseases which have followed a clearly defined accident (e.g. chemical pneumonitis following an acute inhalation accident) or for diseases with specific clinical features that link them to exposure: these include pneumoconioses and occupational asthma. Others, which now form the majority, occur at increased incidence among those with relevant occupational exposures as compared with the general population; many, such as COPD and OA hip, are common in the general population with cases of occupational cause representing a small minority. Attribution in such cases requires knowledge of the epidemiological evidence for the potency of the cause in different circumstances and whether, in the particular circumstances of the case, attribution is more likely than not. This is easier for otherwise unusual diseases, such as mesothelioma, caused by levels of exposure of asbestos above background, than for lung cancer, COPD and OA hip, where the doubling of risk occurs only in well-defined circumstances of exposure. Before attribution can be made, knowledge is needed of these circumstances together with the circumstances of exposure experienced by the individual case.

**ATTRIBUTION AND DISEASE REGISTERS**

The strength of good epidemiological studies is their study of populations (or a representative sample) at risk, which allows valid estimation of the level of increased risk of disease in relation to exposure. Disease registers, in contrast, depend on reporting by physicians of cases they have seen, which they consider attributable to occupation. Clearly, only cases seen by the physician and, of these, only those considered by the physician attributable to occupation,

will be reported. This can lead to two potential sources of bias, whose magnitude can be difficult to estimate: **ascertainment bias** and **attribution bias**.

The reasons for referral of cases to physicians may vary considerably between different sources of referral at different times, and physicians themselves may be unaware of this. Such differences can lead to changes (up or down) in the numbers of cases of particular conditions which come to their attention. Diseases whose relationship to occupation is more specific are more likely to be reported. Reports to the Surveillance of Work and Occupational Respiratory Disease (SWORD) voluntary reporting scheme, by chest and occupational physicians, identify many cases of occupational asbestos-related pleural disease (diffuse pleural thickening and malignant mesothelioma), but few cases of lung cancer or COPD. This is probably because diffuse pleural thickening and mesothelioma are uncommon among those not exposed to asbestos and therefore readily attributable to asbestos. In contrast, lung cancer and COPD are common in the general population and primarily attributable to a non-occupational cause, cigarette smoking. Lung cancer, particularly in cigarette smokers, is less likely to be recognized or reported as caused by asbestos than mesothelioma.

Reporting schemes, such as SWORD, have provided and continue to provide valuable information about the relative importance of diseases of occupational cause in the UK, but their limitations should be appreciated. This is of particular importance when changes in disease incidence based on reporting schemes are used for analysis of trends over time. Such changes may occur not because of changes in disease incidence, but because of alteration in the proportion of cases presenting to physicians or judged by them to be attributable to occupation.

### References

### Key points

- Attribution of disease in the individual case requires answers to the questions:
  - Is the agent a cause of disease at least in certain circumstances?
  - If so, did the circumstances of the individual case make causation likely?
- A cause of a disease can be considered as something which makes a disease more likely if introduced or less likely if removed.
- Few diseases have a single cause, but are multifactorial. For some diseases, e.g. poisonings and pneumoconiosis, the cause is specific. For the majority of disease, inference of causation comes from judgement about findings from population studies, taking due account of the potential of these studies for bias and confounding.
- In general, attribution is based on the balance of probabilities: evidence that in the particular circumstances of the case the putative cause was ‘more likely than not’. This implies a relative risk of more than 2, an attributable fraction in the exposed of more than 50 per cent.
Compensation schemes

ANTHONY NEWMAN TAYLOR AND DAVID WALTERS

INTRODUCTION

Statutory compensation for industrial accidents and diseases was enacted first in Germany and then in the United Kingdom in the late nineteenth and early twentieth centuries, and subsequently during the twentieth century in the great majority of countries of Western Europe, as well as in North America. The moral basis of these schemes is that workers contributing to the national good through their work should not be economically disadvantaged as a result of accident at, or disease caused by, their work. One of the earliest proponents, the nineteenth century German Chancellor Bismarck, also recognized that such a scheme could enable social peace by ameliorating potential conflict between workers and employers.

The current schemes in each country provide no fault compensation, for accidents and diseases attributed to work. However, between the United Kingdom and mainland Western European countries, there are important differences in coverage and funding.

The majority are self-governed social insurance schemes, with mandated funding by employers, based on the scheme introduced by Bismarck in Germany in the Worker’s Accident Insurance in 1884, which created the first modern system of ‘no fault’ worker’s compensation. Workmen’s Compensation in the United Kingdom was also based on this principle, until the Industrial Injuries Act (1946) when government took responsibility for funding the scheme as part of the social security system. Increasing costs, particularly in relation to asbestos, have recently led several other countries to provide government funding to supplement social insurance funding.

The intention of the majority of schemes is replacement of lost earnings (at least in part) because of the inability to work, as a consequence of accident or disease caused by work. Again the UK system is different, providing benefit for physical and mental disablement, although some other countries’ schemes now also include this. Coverage of many European schemes has now also broadened to include prevention and rehabilitation, as well as compensation. This is most developed in Germany where the employer’s liability insurers constitute an important element of the mandatory regulatory system, as well as taking a lead in prevention and rehabilitation initiatives. A ‘first principle’ of the German system is ‘rehabilitation before pension’, with the intention of permanent reintegration into the workforce to the extent that the individual’s disability allows. Sadly in the United Kingdom, despite considerable urging for more than a decade, the government has yet to introduce the means for vocational rehabilitation into the Industrial Injuries Scheme.

Which diseases are compensated can in principle be decided on the basis of ‘individual proof’ – attribution of disease to occupational causation in the individual case – or from a list of ‘prescribed diseases’, where the scientific evidence of causation in particular circumstances is sufficient to allow claimants the ‘benefit of presumption’. In practice, a combination of these principles is found in
differently. In all European countries, diseases compensated through the scheme are covered in a list. There is also a European community list. Which diseases are included in the list varies between countries, both on the basis of their determination and in their comprehensiveness. In Sweden for instance, only infectious diseases are listed; eligibility for other conditions is open and based on individual proof. Finland has an indicative list, but its system does not exclude other conditions, effectively allowing individual proof in addition to the listed conditions. On the other hand, the United Kingdom and France are more prescriptive in generally only allowing listed diseases, although in the United Kingdom individual proof exists for some conditions, such as occupational asthma (in addition to the listed prescribed causes) and dermatitis.

Eligibility of the self-employed for compensation also varies between countries. In general, social insurance schemes are more open to inclusion of the self-employed, with eligibility based on their payment of insurance premiums. The self-employed are excluded from the United Kingdom scheme.

INDUSTRIAL INJURIES COMPENSATION IN THE UNITED KINGDOM

The current scheme for the statutory compensation of accidents and diseases attributable to occupation in the United Kingdom is the Industrial Injuries Scheme, initially enacted under the National Insurance (Industrial Injuries) Act, 1946. It differs in many important respects from comparable schemes in Europe and North America.

The United Kingdom Industrial Injuries scheme is a no-fault, government-funded compensation scheme, for employed earners, which provides benefits to those disabled by accidents or suffering from listed ‘prescribed diseases’, i.e. attributable to occupation. In some circumstances, claimants for a prescribed disease have ‘the benefit of presumption’:

Where a person has developed a disease which is prescribed in relation to him ... that disease shall, unless the contrary is proved, be presumed to be due to the nature of his employment, if that employment was in any occupation (listed in the Schedule) and he was employed on or at any time within one month immediately preceding the date on which he is treated as having developed the disease.

The 1946 Industrial Injuries Scheme provided two major benefits:

1. Industrial Injuries Disablement Benefit (IIDB), payable for ‘loss of faculty’ (in proportion to loss of health, strength and the power to enjoy life attributable to industrial accident or prescribed disease’) for:
   a. Accidents ‘arising out of and in the course of employment’ (an accident has been defined as ‘an unlooked for mishap or untoward event which is not expected or designed’, Lord McNaughton: Fenton v Thorley 1903).
   b. Prescribed diseases
      i. which are a recognized risk to workers in an occupation or exposed to a particular agent.
      ii. where the disease can be attributed to occupation or an agent at work on the balance of probabilities, i.e. more likely than not.

   In general, attribution of a disease to a specific cause can be based on:
   a. Specific clinical features
   b. By inference from the results of population studies to causation in the individual patient.

2. The second important benefit introduced in the 1946 Act was Special Hardship Allowance (SHA), subsequently renamed Reduced Earnings Allowance (REA). Arguably the most enlightened part of the Industrial Injuries Scheme, SHA (later REA) provided an earnings replacement benefit to enable those with occupational disease, whose health would be adversely affected by remaining in their current job, to move to other less well paid work. It provided the means to prevent disease progression to a severe and irreversible level of disability. Reduced Earnings Allowance was abolished by the government of the day in 1990, although claimants in relevant employment before 1990 remain eligible to claim.

CURRENT PATTERN OF CLAIMS FOR INDUSTRIAL INJURIES BENEFIT IN THE UNITED KINGDOM

At present some 350 000 people are in receipt of IIDB, REA or both, at a total cost of £776 million p.a. The current (2009) maximum weekly benefit is £127.10 for IIDB and £50.84 for REA. IIDB payments range from £25.42 to £127.10, the amount received based on the level of disablement that arises from the accident or prescribed disease. IIDB is not normally paid where the level of disablement is less than 14 per cent. However, for pneumoconiosis, byssinosis or mesothelioma, IIDB is paid with a minimum disablement assessment of 1 per cent. Since 2002 awards for mesothelioma and since April 2006 awards for asbestos-related lung cancers, have been paid at 100 per cent. Some 13 000 new claimants receive benefit each year, three-quarters of whom are of working age. Ninety-four per cent of accident claims,
which constitute 60 per cent of new claims, are of working age, whereas 60 per cent of new claimants for prescribed disease, which constitute 35 per cent of new claims, are over state age pension. Eighty per cent of those currently in receipt of benefit are male, with women constituting 30 per cent of new claims for prescribed disease and 7 per cent for accidents, reflecting the predominantly male workforces in industries and occupations in which the majority of accidents and prescribed diseases have occurred.

The pattern of current payments for IIDB and REA in the United Kingdom reflects the industrial history of the country during the second half of the twentieth century. Accidents are most likely to occur in manufacturing, construction and mining industries with 26 per cent of major accidents occurring in manufacturing, 16 per cent in construction and 13 per cent in mining and quarrying.1 New benefit recipients for IIDB and REA in industries with more than 300 claims in 2005–2006 are shown in Figure 8.1.

New claims for prescribed diseases are dominated by diseases associated with mining and asbestos. Some two-thirds of new benefit recipients for a prescribed disease are for pneumoconiosis or mesothelioma. The number of new claims for the most common prescribed diseases put into benefit in 2002–2003 and 2005–2006 is shown in Figure 8.2.

Although the incidence of pneumoconiosis is falling in the United Kingdom, the incidence of mesothelioma is increasing and the long latency of both diseases makes it likely they will continue to form a large proportion of IIDB benefit recipients for many years.

THE DEVELOPMENT OF UK COMPENSATION SCHEMES

Two main types of compensation for accidents and diseases caused by work are available in English law: damages at common law in tort and benefits under the statutory industrial injuries scheme. Whereas success in the former requires proof of negligence or breach of statutory duty, the latter is a no-fault scheme, which in many instances provides the benefit of presumption in the individual case.

Statutory compensation in the United Kingdom for accidents and disease attributable to work has been available since the Workmen’s Compensation Act of 1897. This scheme was replaced in 1946 by the Industrial Injuries Scheme which, in a modified form, exists today. During the long century from 1897 to the present day, workmen’s compensation in the United Kingdom has adapted to the changing nature of hazardous exposures at work, the diseases associated with them and to the advances in medical technology (e.g. diagnostic x-rays), which have allowed the differentiation of occupational disease (e.g. pneumoconiosis from tuberculosis). In addition, advances in understanding the nature of occupational disease, in particular the occupational contribution to the incidence of diseases common in the population, have, more recently, allowed the inclusion of non-specific diseases (e.g. chronic obstructive pulmonary disease (COPD) in coal miners and osteoarthrosis of the hip in farmers) in addition to the diseases specific to occupation, such as poisoning by lead or mercury, which have been included since 1906. The scheme of compensation has also been influenced by the development of public policy and statute: in 1897 with the first Workmen’s Compensation Act, making employers liable for compensation for accidents at work, without the need to prove negligence; and the 1948 Industrial Injuries Act, which transferred responsibility for payment and administration of benefit from employers and their insurers to government, and provided benefit primarily for loss of faculty, and associated disablement, in place of loss of earnings.
Workmen’s Compensation Acts (from 1897)

Statutory compensation for accidents at work and industrial diseases in the United Kingdom originated in the late nineteenth century as a statutory remedy for the failure of civil courts to provide compensation to workers injured or killed by accidents at work. At that time, fatal accidents in the United Kingdom numbered some 5000 each year, with about 1000 each year in the mining industry.

The Workmen’s Compensation Act of 1897 reflected an extension of the principle of automatic compensation for those serving in the armed forces injured in war, which had its origins in Elizabethan England. Joseph Chamberlain, the architect of the 1897 Workmen’s Compensation Act, referred in a speech at Birmingham Town Hall in 1894, to the victims of industrial accidents as the ‘wounded soldiers of industry’. Later in the same speech, he stated that in his opinion, ‘the cost of every accident in every employment is rightly a charge on the cost of production’. The subsequent 1897 Act embodied this radical new principle of automatic compensation for employees for industrial accidents, without the need to prove his employer’s negligence.

Prior to the 1897 Act, employees had the right to seek compensation from their employers through the courts for accidents in the course of employment, by demonstrating negligence or breach of statutory duty. However, during the nineteenth century, the courts had accepted a number of defences which provided considerable barriers to successful action by workers. These included three in particular, known as the ‘unholy trinity of defences’. (1) Violent non fit injuria: accidents were an ordinary hazard of employment and by taking the job the workman was accepting the risk, expressly or by implication; (2) contributory negligence: negligence or want of ordinary care on the part of the workman, i.e. in order to succeed the workman had to prove his freedom from negligence; and (3) common employment: the employer was not liable where an injury was due to the negligence of a fellow worker in the same employment.

Of these, the defence of common employment was the most important and aroused the most antagonism and hostility. In practice, it meant an employee had a claim only if the employer had been personally negligent. In companies with a large number of employees such as railways and mines, which had the highest rates of accidental injury and death, the workman was left without the means to pursue a successful claim. Steps were first taken to abolish the defence of common employment by Act of Parliament in 1880, but it was not effectively overcome until 1897. It was during debates in and outside parliament during the 1890s that Joseph Chamberlain first advanced the principle of automatic compensation by employers for accidents at work, irrespective of cause and without the need to prove negligence. He was the architect of the first Workmen’s Compensation Act of 1897, of which this was the underlying principle, taking compensation out of the courts for accidents, ‘arising out of and in the course of employment’, effectively abolishing legal barriers to employee’s compensation.

The principle of a duty of employers to compensate employees for loss of earnings due to accidents at work, introduced in the 1897 Workmen’s Compensation Act, was revolutionary in its implications: it provided the employee with the legal right to compensation at no cost to himself; it imposed on the employer a legal obligation to compensate workers for loss of earning capacity as a result of accidents at work, with the cost to be regarded as a cost of production, comparable to depreciation of capital assets; employer liability was irrespective of any negligence on the part of the employer or of the employee; and for the common law, strict liability, i.e. liability without imputation of fault was written into statute. Beveridge later described the Workmen’s Compensation Act of 1897 as ‘the pioneer system of social security in Britain’.

The 1897 Act did not cover industrial disease, but this omission was soon remedied. The Workmen’s Compensation Act of 1906 listed six diseases for which compensation was payable: anthrax, ankylostomiasis (hookworm), poisoning by lead, mercury, phosphorus or arsenic, and their sequelae. Workers were entitled to compensation if they could establish that the disease was due to the nature of their employment and they had been engaged in that employment at any time during the 12 months preceding the date of disablement. The Home Secretary, who was responsible for the administration of the Act, was empowered to add further diseases to the schedule. In the absence of specified criteria to enable this, he set up a review committee under Herbert Samuel.

The Samuel Committee, which reported in 1907, proposed three criteria for the addition of new diseases under the Act:

- outside the category of diseases already covered by the Act;
- such as to incapacitate a worker for more than one week;
- so specific to the employment that causation could be assumed in the individual case.

The important implication of the third criterion was that diseases undoubtedly associated with certain industries would not be scheduled if they were also fairly common in the general population. The committee did recognize that where a disease was common to a particular trade, but also occurred rarely outside the trade, it could be included in the schedule.

The committee used bronchitis in flax workers as an example of the difficulties of adding a disease common in the population to the schedule:

Bronchitis, for example, is a trade disease among flax-workers; a larger proportion of that class suffer from it than of other people; but it is not specific to the
employment, for numbers of people who are not flax-workers contract it also. Unless there is some symptom which differentiates the bronchitis due to dust from the ordinary type, it is clearly impracticable to include it as a subject of compensation; for no one can tell, in any individual case, whether the flax-worker with bronchitis was one of the hundreds of persons in the town whose bronchitis had no connection with dust irritation, or whether he was one of the additional tens or scores of persons whose illness was due to that cause. To ask a court of law to decide would be to lay upon it an impossible task. If the workman were required to prove his case, he might be able to show that a larger percentage of his trade suffer from bronchitis than do the rest of the population, but he could never show that he himself was a unit in the excess, and not in the normal part, of that percentage. If it were the employer who was required to disprove a claim, he could rarely, if ever, show that the workman did not contract the illness through his employment, and he would be compelled to compensate not only those labourers whose bronchitis was in no degree an industrial disease.

The problem of statutory compensation for diseases common in the population whose risk was increased in some occupations, was the subject of continuing debate and disagreement, which was only resolved in the last quarter of the twentieth century.

On the basis of their original criteria, the Samuel Committee recommended a further 18 diseases should be included in the scheme and a further three in 1908. The diseases recommended included conditions such as chronic ulceration and scrotal cancer in chimney sweeps. It did not include ‘fibrous phthisis’ (silicosis and silico-tuberculosis). Although recognized as a hazard of stonemasons, grinders, potters and tin miners, they considered the long latency of the disease would make it difficult to apportion liability among different employers. The committee also considered asbestosis, but were unable to include it because of lack of evidence. Further diseases were subsequently added, including silicosis in 1919 through a special scheme, Workmen’s Compensation (Silicosis) Act 1918, which required employers to contribute to an insurance scheme, overcoming the problem of identifying which employer was liable.

However, the operation of the Workmen’s Compensation Acts was the subject of increasing dissatisfaction. Employers insured against their liability for compensation. This led to claims for compensation under the Act becoming adversarial, with high administrative costs, delay in settlement and workers being bought off by low value lump sum payments.

A Parliamentary report in 1944 expressed this dissatisfaction:

For nearly half a century the compensation of workmen for industrial injury has been a liability, imposed by law, on their employer. Under the existing scheme (the Workmen’s Compensation Acts) it has been open to the employer, and in some cases obligatory on him, to insure himself against this liability; while it has been for the workman to make his claim and to take steps to enforce it, if challenged in the Courts of Law. Inevitably compensation has thus become a disputable issue between the two parties or their representatives. In his report, Beveridge recognized this ‘disputable’ system imposed a disproportionate cost of administering the scheme compared with the payment issued in benefit to sick and injured workers.

**Industrial Injuries Act, 1946**

Beveridge proposed that social security should be an insurance, rather than a tax-based scheme, funded from National Insurance contributions made by employers and employees. His proposals included a new industrial injuries scheme. Enactment of the Beveridge report, including a new Industrial Injuries Act, was the responsibility of the Minister for National Insurance, Jim Griffiths, who personally initiated the inclusion of Special Hardship Allowance as an earnings replacement, in addition to disablement benefits, consequent upon ‘loss of faculty’. The new Act transferred responsibility for payment and administration of benefit from employers and their insurers to government. Benefit was payable for accidents and prescribed diseases for ‘loss of faculty’ (‘in proportion to loss of health, strength and the power to enjoy life attributable to industrial accident or prescribed disease’) in place of lost earnings replacement. Loss of earnings was compensated in one provision of the Act – Special Hardship Allowance – introduced as an earnings replacement for those unable to return to prior employment. An early example of the value of Special Hardship Allowance was in making up lost earnings for those with category 2 simple coal workers’ pneumoconiosis (and therefore at significant risk of progressive massive fibrosis (PMF)) who moved to ‘dust approved conditions’, with a reduced risk of disease progression, but less well paid work.

The 1946 Act maintained the distinction between accidents ‘arising out of and in the course of employment’ and prescribed (i.e. listed) diseases. The Act allowed that:

A disease or injury may be prescribed ... in relation to any insured persons, if the Minister is satisfied that:

- it ought to be treated, having regard to its causes and incidence and any other relevant considerations, as a risk of their occupation and not a risk common to all persons
- it is such that, in the absence of special circumstances, the attribution of particular cases to the nature of employment can be established or presumed with reasonable certainty.
The development of disease prescription, particularly in relation to broadening the scope of prescription to include diseases not specific to occupation, can be shown in three examples.

**Workmen's compensation and coal**

The Samuel Committee had been unable to recommend prescription for silicosis, in part because it was not possible at that time to distinguish silicosis from other pulmonary diseases, particularly tuberculosis. The development of the chest radiograph in the early twentieth century allowed the differentiation of silicosis from other respiratory diseases. Silicosis was recognized as an industrial disease under the Workmen’s Compensation (Silicosis) Act, 1918. The Act required employers to contribute to an insurance scheme, from which compensation would be paid, overcoming the problem, highlighted by the Samuel Committee, of identifying employer liability. It also introduced regular medical examinations authorizing medical examiners to suspend workers compulsorily at the early stages of disease, to prevent the development of incapacitating disease. Coal miners were included in the scheme in 1928, when they could demonstrate exposure to dust of silica rock and were ‘totally disabled’. The scheme was further extended to include ‘partially disabled’ workers three years later. In 1934, the scheme was extended to include any coal miner with silicotic nodules, whether or not they were working with rock. All coal miners with radiological evidence of pneumoconiosis from coal dust exposure were included in the scheme in 1943.

Workers compensated for Coal Worker’s Pneumoconiosis (CWP) were ‘certified’ with benefit of a weekly payment or a lump sum and compulsory suspension from mining to protect workers from further lung deterioration. The certification of large numbers of workers resulted in unforeseen social problems in South Wales as identified in 1948 by Fletcher. By the end of 1945, 12,000 men had been certified in South Wales and new cases were being certified at a rate of 100 men per week. Most of these men (66 per cent) were under 50 years old and 25 per cent were under 40 years old. The majority of the men had been coal hewers and faced the prospect of being out of work with no training for alternative employment. In 1951, Hugh Jones and Fletcher noted that ‘at present some 5000 men with pneumoconiosis, three quarters of whom are probably capable of work, under normal industrial conditions, are unemployed’.

The nature and progression of coal worker’s pneumoconiosis had become better by the 1960s. Inhaled coal dust reaching the peripheral gas exchanging parts of the lungs is
removed, primarily through engulfment by scavenging macrophages, which migrate centrally to the mucociliary escalator. If the dose of respirable dust overwhelms this removal mechanism, coal dust accumulates in the lungs as centriacinar macules, which appear as rounded nodules on chest radiographs. The nodules themselves, composed of retained dust, do not cause impairment or disability. This form of the condition, characterized by retained coal dust in the lungs, was classified as simple pneumoconiosis. The severity of pneumoconiosis was graded according to the size and profusion of nodules seen on the chest radiograph. Some cases of simple pneumoconiosis developed progressive massive fibrosis, which was associated with significant disability and reduced life expectation. During the 1940s and 1950s, PMF had been considered an atypical form of tuberculosis. However, Cochrane provided substantial evidence against this hypothesis and showed that the risk of PMF was related to the category of simple pneumoconiosis, i.e. correlated with the quantity of coal dust in the lungs.10 His findings implied that if workers with category 2 pneumoconiosis were removed from further dust exposure, the risk of progression to PMF would be reduced. Jacobsen et al. subsequently showed that on average coal dust inhaled over a 35-year working lifetime with exposures of 4 mg/m² were associated with a 4 per cent risk of developing category 2 pneumoconiosis. Measures were put into place to reduce dust concentrations to 4 mg/m² and workers with category 2 pneumoconiosis moved to less dusty (‘dust approved’) working conditions. Special Hardship Allowance helped facilitate the redeployment of workers to less dusty conditions, by providing compensation for loss of earnings consequent on the move to less hazardous work. Special Hardship Allowance, which later became Reduced Earnings Allowance, was arguably the most enlightened part of the Industrial Injuries Scheme, enabling workers to remain in work while preventing further health deterioration.

Asbestos and asbestosis, lung cancer and mesothelioma

In the late nineteenth and early twentieth centuries, asbestos became increasingly widely used, primarily because of its thermal insulating properties. Subsequently, its uses broadened to include reinforcement of boarding and cement. Inhaled asbestos fibres of ≥5 μm in length, too long to be engulfed by scavenging macrophages in the lung, accumulate in the lungs to cause fibrosis (asbestosis). Asbestos fibres are also carcinogenic causing lung cancer and mesothelioma. The chronology below shows the evolution of knowledge about adverse health effects associated with asbestos:

1899: Montague Murray reports a post-mortem case of pulmonary fibrosis in an asbestos worker in the UK.
1900: Cooke reports the case of 33-year-old Nellie Kershaw who died of pulmonary asbestosis after working 20 years in the Turner and Newall asbestos textile factory in Rochdale, Lancashire, UK.11
1930: Merewether and Price12 report the increased prevalence of asbestosis in the Rochdale workforce of asbestos textile workers.
1947: Merewether13 reports excess lung cancer deaths in those with asbestosis compared to those with silicosis.
1955: Doll14 provides definitive evidence of the increased risk of lung cancer in the Rochdale asbestos textile workforce.
1960: Wagner et al.15 provides evidence of the association between mesothelioma and occupational and non-occupational exposure to blue asbestos (crocidolite) in NW Cape Province, South Africa.

ASBESTOSIS

Merewether and Price12 reported an increased risk of fibrosis in asbestos textile workers, which increased in prevalence with longer duration of employment (Table 8.1).

Although remarkably high by modern standards, the number of prevalent cases of fibrosis was almost certainly an underestimate of the true size of the problem, as employees whose health was most affected by asbestos were likely no longer to be at work because of disease severity or death.

Statutory compensation of asbestosis

Asbestosis was enacted in the Workers’ Compensation (Silicosis and Asbestosis) Act, 1930, which extended the provisions of the Workmen’s Compensation (Silicosis) Act to asbestosis, i.e. compulsory employer liability insurance and regular medical examinations with the powers of suspension.

Asbestosis continues to be compensated as a pneumoconiosis.

MESOTHELIOMA

Mesothelioma is an uncommon respiratory cancer. Wagner et al.15 first reported the association between mesothelioma and exposure to crocidolite (blue) asbestos

</table>
in the North Western Cape Province of South Africa in 1960. They observed the long latent interval between first exposure (usually >20 years) to asbestos and the onset of the disease and a short survival time post-diagnosis (<1.5 years). They also identified its occurrence both in those occupationally exposed in its extraction and use (insulation), as well as in those not occupationally exposed, who had encountered it in the neighbourhood of the mines (Table 8.2).

In the United Kingdom, there has been a high incidence of cases of mesothelioma clustered in areas historically associated with asbestos work, where railway (e.g. Swindon) and ship (e.g. Devonport and Barrow) manufacture and repair were undertaken. Before the 1960s, the Devonport dockyards used considerable quantities of crocidolite and amosite asbestos. However, from the mid-1960s, alternative insulation material was used and respiratory protection provided. Hilliard et al. showed that these measures have been associated with a decrease in the number of cases of mesothelioma since the early 1990s. However, these preventative and protective measures were not implemented in the UK construction industry until the 1970s or 1980s. The incidence of mesothelioma in the United Kingdom is continuing to increase, with an increasing proportion of cases in electricians, carpenters and plumbers in the construction industry rather than in the traditional asbestos workforces in dockyards and insulation. Peto et al. estimated that the peak of the UK epidemic of mesothelioma will not yet be reached until 2015–20, continuing until 2050, with some two-thirds of the cases in the UK epidemic yet to occur. A similar continuing increased incidence of mesothelioma, although at a lower level, is occurring throughout Western Europe.

### Statutory compensation of mesothelioma

The prescription of mesothelioma is based on the specificity of asbestos as the cause of the disease. Mesothelioma can be caused by relatively low levels of exposure to asbestos, which is reflected in the current prescription – ‘exposure to asbestos, asbestos dust or any admixture of asbestos at a level above that commonly found in the environment at large’. Claims for mesothelioma are now fast-tracked by the Department for Work and Pensions: there is no 90-day waiting period, claimants are automatically awarded 100 per cent assessments and there is no absolute requirement for corroborative evidence of occupational exposure.

### LUNG CANCER

Prescription for lung cancer due to asbestos has been complex. There is a clear excess of cases of lung cancer in those with asbestosis, which was observed by Merewether in his report as HM Inspector of Factories in 1947. He noted a considerably greater proportion of deaths in certified cases of asbestosis than silicosis (Table 8.3). Subsequently Doll, in a landmark study in 1955, reported a marked excess of lung cancer deaths in men employed before the 1931 Asbestos Regulations (which had followed the Merewether and Price report) in the Turner and Newall Rochdale textile factory. All cases of lung cancer were in men with asbestosis (Table 8.4).

### Statutory prescription of lung cancer in asbestos workers

Lung cancer was formally prescribed in 1985 in cases of asbestosis and in cases with diffuse pleural thickening. The case for prescription of lung cancer in asbestos workers without asbestosis was more difficult due to the lack of specific clinical features to differentiate cases of lung cancer from those in the general population. It was clear, unlike mesothelioma, that the increased risk of lung cancer occurred at relatively high levels of cumulative exposure. Initially, diffuse pleural thickening was used as a surrogate for sufficient exposure to be associated with a doubling of risk of lung cancer. However, subsequent evidence indicated...
this was not the case but that in certain workers, such as asbestos textile workers, there was a doubling of the risk of lung cancer in those working with asbestos.

In 2006, lung cancer in the absence of asbestosis was prescribed for 'exposure to asbestos for at least five years before 1975 and ten years after 1975 in the following occupations (i) workers in asbestos textile manufacture, (ii) asbestos sprayers and (iii) asbestos insulation work, including those applying and removing asbestos-containing materials in shipbuilding’. Since 2006, cases of asbestos-related lung cancer have received 100 per cent disablement benefit.

**Chronic obstructive pulmonary disease and coal workers**

Cancer is an ‘all or none’ disease: you have cancer or you do not. In contrast, some other diseases may be ‘more or less’, with degrees of disease such as high blood pressure or airway narrowing in chronic bronchitis and emphysema.

Lung function can be assessed by measuring the amount of air a person can exhale during a forced expiratory manoeuvre. The total volume of air that can be exhaled is the forced vital capacity (FVC) and the volume of air that can be exhaled in 1 second is the forced expiratory volume in 1 second (FEV1). A person with airflow limitation will have a lower FEV1 and lower FEV1/FVC ratio than a normal individual. In a study in 1961, Cochrane and Higgins found that miners and ex-miners had lower lung function than non-miners. However, no gradient of lung function loss was observed in miners and ex-miners with increasing category of simple pneumoconiosis. In contrast, lung function was decreased in miners and ex-miners with PMF, with lung function loss increasing with increasing severity of PMF. On this basis, Cochrane considered that coal dust did not cause airway obstruction, but recognized he was using the category of simple pneumoconiosis measurements as a surrogate for airborne coal dust exposure. In 1982, Cockcroft et al. found evidence that emphysema at post-mortem was considerably more frequent in coal miners than in non-miners, in individuals referred for post-mortem because of sudden death (i.e. a reason for post-mortem unrelated to occupation overcoming potential selection bias), with an odds ratio of 10.35 after adjusting for age and cigarette smoking. In a large study of UK coal miners, Marine et al. in 1988 showed the proportion of coal miners with a FEV1 < 65 per cent was more than doubled in those with high, as compared to low, exposure to coal dust, in both smokers and non-smokers. This evidence together with other similar observations, particularly from the United States, provided the basis for prescription for chronic bronchitis and emphysema (now COPD) in coal workers.

In considering the terms of prescription for coal workers with COPD, the Industrial Injuries Advisory Council addressed the following questions:

- What is a disabling loss of FEV1? A study of miners found an FEV1 of 942 mL less than average for a man of the same age and height was associated with shortness of breath when walking with others on the level.

- Is there evidence of at least a doubling of risk of this FEV1 loss? Evidence indicated that a doubling of risk of this level of FEV1 loss occurred at cumulative exposures to coal dust of 60–120 mg/m2 per year.

- What is the nature of occupational exposure in which this occurs? Hygiene data from the Institute of Occupational Medicine (IOM) in Edinburgh showed exposures for UK miners to be:
  - Coal face workers: 2.5–6.5 mg/m2
  - Development operations: 1.5–5.5 mg/m2
  - Other underground workers: 1.0–3.0 mg/m2
  - Surface workers: 0.2–0.7 mg/m2

- Can this be translated into job titles and duration of employment for purposes of prescription? IIAC translated this into 20 years employment underground in a coal mine.

Chronic bronchitis and emphysema was prescribed in 1992 as an FEV1 of 1 L less than the average value for a man of similar age and height, in coal miners who had worked underground for 20 years, who had Category 1 Simple Coal Workers Pneumoconiosis on a chest radiograph. The requirement for Category 1 pneumoconiosis was later withdrawn. More recently, on the basis of additional evidence from IOM about coal dust exposure to surface workers, prescription has been extended to include surface screen workers, employed for 40 years, allowing a 2:1 aggregation of duration of exposure below ground and on the surface, i.e. 15 years underground plus ten years on the screens above ground qualifies for prescription.

**OTHER UK COMPENSATION SCHEMES**

**Pneumoconiosis (Workmen’s Compensation) Act, 1979**

This is a state-funded scheme which provides lump sum payments to those who have developed respiratory disease through their employment, for workers unable to recover compensation through the courts or through a private no-fault compensation scheme, because their employer is no longer in business. The Act originally covered pneumoconiosis, byssinosis and mesothelioma, but has since been extended to include lung cancer with asbestosis or prescribed in relation to asbestos and bilateral diffuse pleural thickening.

To succeed, the claimant has to satisfy three criteria:

1. Disablement benefit must be payable under the industrial injuries scheme in respect of the disease in question.
2. Every relevant employer must have ceased to carry on business.
3. No action must have been brought or any claim compromised by common law.
Successful claimants under the scheme are paid lump sum compensation in addition to IIDB. The average lump sum under the scheme is £13 000 with payments made on a sliding scale based on age and level of disablement.

**Diffuse Mesothelioma Scheme, 2008**

The Diffuse Mesothelioma Scheme, which commenced on October 1, 2008, extends coverage for compensation for mesothelioma to those exposed to asbestos in the UK, who are otherwise unable to claim compensation. This includes the self-employed exposed to asbestos in their work and those exposed to asbestos in the home from asbestos brought home on a worker’s clothes. It excludes employed earners able to claim IIDB under the 1979 Pneumoconiosis Act. Compensation is made as a lump sum payment.

In order to qualify under the scheme:

- There must be evidence to show the claimant has a malignant mesothelioma.
- The claimant must have been exposed to asbestos in the United Kingdom.
- The claim must be made within one year of diagnosis or in the case of a claim made by a dependant, within one year of the date of death.
- The third requirement, to claim within one year of death, does not apply to those diagnosed before the introduction of the scheme.

**COMPENSATION SCHEMES IN CONTINENTAL EUROPE**

There are broadly two main bases for the compensation systems found in continental Europe. One is modelled on the German approach with self-governed sectoral insurance associations funded by employers’ contributions, providing a comprehensive prevention, rehabilitation and compensation service. In the second form, the state administers the system for compensating occupational injuries and disease as part of its wider provision for social security and levies contributions from employers to finance it.

There are further differences in the arrangements and in those responsible for governance and administration in different countries. The degree of federalization and regional autonomy differ with some countries such as Sweden and France having highly regionalized administrative structures and others, such as Germany, having a well-developed sectoral focus in addition to regionalization. The mix of public and private insurance organizations that make up the systems vary between countries. In many countries, there is now a mixture of these two approaches, with participation of both the state and private insurance systems.

In Belgium, there is a separate scheme for occupational accidents, based on private employers’ insurance, and a state system for occupational diseases for industrial and commercial sector workers. This is also true in Portugal. In Denmark, private insurers carry the risk for occupational accidents, while occupational diseases are insured by specific funds financed by contributions from employers. In Norway and Finland, insurers carry the risk for both accidents and disease, but in Norway there is a state system and a private employers’ insurance system which ‘tops up’ the state system. In some countries, the usual system of social insurance for incapacity resulting from occupational injury and disease, designed to replace lost earnings, is supplemented by additional schemes, usually resulting from agreements between trade unions, to provide additional benefits for their members. In Sweden, higher pensions are available through the labour market insurance scheme known as AFA Insurance.

Coverage of the original social insurance systems was intended for employed people in private sector industry, which remains the basis of coverage. While coverage has been extended to provide benefits for public sector employees, for part or all of those in agriculture and, in some cases, the self-employed, many of these still remain outside the general coverage of this form of social insurance and are subject to separate schemes in many countries. Workers who are unable to demonstrate a legal form of employment in relation to a claim for benefits for accident or disease while engaged in work remain ineligible for these types of benefits under most systems.

In many countries, work injury/disease insurance systems are now also involved in prevention and rehabilitation. This is most developed in Germany where the employer’s liability insurers constitute an important element of the mandatory regulatory system, as well as taking a lead in prevention and rehabilitation initiatives. A ‘first principle’ of the German system is rehabilitation before pension, with the intention of permanent reintegration into the workforce to the extent that the individual’s disability allows.

In all European countries, diseases that are compensated are covered in a list. There is also a European Union list. Which diseases are included in the list varies between countries, both on the basis of their determination and in their comprehensiveness. In Sweden, only infectious diseases are listed; eligibility for other conditions is open and based on individual proof. Finland has an indicative list, but its system does not exclude other conditions, effectively allowing individual proof in addition to the listed conditions. On the other hand, the United Kingdom and France are more prescriptive in generally only allowing listed diseases, although in the United Kingdom individual proof exists for some conditions, such as occupational asthma (in addition to the prescribed listed causes) and dermatitis.

The role of the list in determining specific cases of compensation also varies. There are two extremes of the legal and administrative principles of the different systems concerned. At one extreme is the ‘open system’, in which each claim for an occupational disease is treated on its own merits, as in Sweden where the occupational disease list includes only infectious diseases, with all other conditions treated individually. At the other extreme, the French list of 112 occupational diseases appended to its social security
code specifies symptoms or pathological lesions required to be present, the type of work that is known to cause the condition and the time limits for compensation claims. In theory, any disease meeting the medical, occupational and administrative criteria in the list is presumed to be occupational in origin. In the other 15 EU countries, the function of the ‘list’ falls somewhere between these extremes in decisions concerning the eligibility of conditions. A trend evident in many countries has been the increasing recourse to ‘open’ systems in recent years. Despite this, well over 90 per cent of diseases recognized as occupational remain on the basis of their inclusion in the national list.

Whether the condition is on a list or identified individually as part of a mixed system, the process by which evidence is assessed and decisions taken as to its ‘occupational’ cause in most cases concerns two issues – the extent to which the disease can be ascribed to an occupational cause and the extent to which a claimant can show they have experienced relevant exposures. The means by which the first of these issues is resolved in most countries, as in the UK, is defined in legislation or the guidance to it. Determining the recognition of occupational associations with the cause of conditions involves review of epidemiological and other scientific/medical evidence and the achievement of broad expert agreement concerning increased risk in relation to occupational exposure. Practice in other European countries does not follow exactly the rule adopted in the UK, where decisions for prescription are based on robust epidemiological evidence of a greater than doubled risk of the disease in an exposed occupational group compared to a comparable unexposed group or the general population. However, there are broad similarities in the approach in all countries in so far as there is emphasis on the need for robust evidence of occupational risk and agreement of expert opinion.

In Belgium, Italy and Luxembourg, both the occupational risks of a disease and the occupations in which such risks occur are defined on the list of prescribed diseases appended to legislation, as in the UK. As in France, it is sufficient for individuals in these countries to demonstrate that they are suffering from a disease on the list and that they have been exposed to a relevant hazard or undertaken a job on the list. In Austria, Denmark, Finland, Germany, Switzerland, Portugal, Spain and Switzerland, the list serves as a guide to insurance organizations investigating the claim that the disease is occupationally caused; the insurance companies will seek to establish if the disease in question could have been caused by a causal agent marked on the national list, while at the same time excluding any non-occupational factors that could have caused the disease. These lead to differences in the number of claims for compensation for occupational diseases and the recognition rates for such claims between different countries.

Some clear differences emerge when comparing arrangements for work injury/disease benefits in other countries with the IIIDB scheme in the UK. Partly as a consequence of its different origins, the UK approach provides for considerably lower benefits than other European systems and represents lower proportional expenditure on this form of support than is found elsewhere. Whereas the majority of schemes provide partial earnings replacement, the UK scheme compensates loss of faculty and associated disablement. Also in contrast with some other countries, it makes no provision at present for either prevention or rehabilitation. However, there are also similarities. The legacy of the industrial era is found in most systems. As long as conditions that are eligible for compensation are based on lists primarily based on the ‘classic’ industrial diseases, the number of claims (and therefore costs of compensation) are unlikely to increase greatly. The gender distribution of successful claimants under these systems will be predominantly male. How compensation systems deal with the predominant and very different current conditions of ill health associated with work is a major issue for all systems. While in some countries musculoskeletal disorders now feature more prominently, stress-related conditions still represent a significant challenge. The move to ‘open’ systems may partly address this problem, but evidence to date suggests that it does not do so entirely.

A trend evident in several countries is some reorientation of ‘no-fault’ compensation systems towards a closer fit with civil law models. Perceived inadequacies in levels of compensation available through social insurance combined with perceptions of injustice over employer immunity from redress under the civil law have led to these changes.

The traditional protection from actions in civil law that being part of such schemes afforded to employers in many countries, in contrast to the UK, is increasingly seen as inappropriate. At the same time, the level of individual employer contributions has become increasingly debated. Tensions in existing systems are evident and movement towards a closer alignment with the benefits available under civil law is a common international trend.

Current data on occupationally related ill health compared with the number of claims made for occupational disease and those claims recognized suggest that only a minority of those whose health is affected by their work seek compensation and in any European system, recognition of such claims rarely exceeds 50 per cent. Several explanations have been proposed, which include the limitations of the experience and ability of doctors to recognize occupational causes, ignorance of workers concerning both the hazards of their work and their entitlements to compensation and the complexity of the administration of the system for compensation. It is also important to appreciate that not only does the complexity of making a claim exclude many, but the claim process itself may also have negative consequences for recovery and return to work. While one of the great virtues of ‘no-fault’ systems for compensation is that they act to eliminate adversarial approaches to claims, the use of experience rating by some insurance systems destroys this advantage since it provides a strong incentive for employers to contest claims. It is also argued that the growth in precarious employment in advanced market economies has eroded the coverage of workers’ compensation systems, creating administration
difficulties, undermining the coverage and objectives of compulsory insurance, as well as weakening processes for making claims. There is also evidence that the costs of compensating injured workers are being shifted from workers’ compensation systems to those concerned with public health or social security.

As is the case in the UK, recognition of some of these problems means that reform of the present system is planned or called for in most countries. Generally, the main thrust of such reforms is to seek to address issues of affordability and efficiency, while at the same time dealing with perceived weaknesses in cover and redress of harm. It seems unlikely that these changes to existing systems will lead to greater access to benefits for potential claimants.

**COMPENSATION SCHEMES IN THE UNITED STATES**

The development of workers’ compensation in the United States has its origins as a response to the development by employers of defences to litigation by employees, for accidents at work, very similar in kind to ‘the unholy trinity of defences’ employed in the UK. These included contributory negligence, the ‘fellow servant’ rule (comparable to the defence of ‘common employment’) and the ‘assumption of risk’ (equivalent to *violenti non fit injuria*). Not surprisingly, therefore, much of the early development of workers’ compensation in the United States was based on principles derived from the German and UK schemes.

Although workmen’s compensation schemes in the United States are now insurance-based schemes, organized state by state, the federal government took the lead in the early twentieth century in providing compensation to its workforce for accidents at work. The Federal Employers’ Liability Act of 1908 covered federal employees engaged in hazardous work and employees of certain carriers engaged in interstate and foreign commerce. It was adopted at the urging of President Theodore Roosevelt, who in a speech to Congress said that the ‘burden of accident falls upon the hapless man, his wife and children’ which was ‘an outrage’.

The turning point in the development of worker’s compensation legislation in the United States was the adoption by Wisconsin in 1911 of Worker’s Compensation, which was the subject of considerable debate. Employers lobbied successfully for what has become known as the ‘great trade off’. Employers agreed to provide medical and wage replacement benefits in exchange for the employee giving up his/her right to sue the employer. Several states subsequently adopted this model. However, it took until 1976 for all 50 states to have some form of coverage for occupational disease.

Workers’ compensation schemes in the United States are no-fault schemes: in return for relinquishing the right to sue his or her employer, the employee has the right to fair and timely compensation.

The basic structures of workers’ compensation in the United States and Canada are similar. A board or commission sets the rules; an insurer provides coverage on the basis of the payroll for eligible workers; cases are adjudicated in the first instance by the insurer and subsequently, if contested, by an appeals system. Despite the original intention to avoid litigation, legal advocacy remains part of the process, particularly in complicated or disputed appeals. Because of deadlines by which time an insurer must decide claims, many requests for compensation are initially rejected, forcing claimants to retain legal counsel and file lengthy appeals. The consequences for the worker can include uncompensated legal expenses and economic hardship.

Federal schemes include the Black Lung Programme for coal miners, the Longshoremen and Harbour Workers’ Compensation Programme, the Federal Employers’ Compensation Act, the Radiation Exposure Compensation Act and the Energy Employees’ Occupational Illness Compensation Program Act. In several instances, these federal programmes replace or are intended to complement state-based compensation programmes.

In the majority of states, compensation is limited to two-thirds of previous wages and coverage of medical costs. Funding of the schemes by employers, of whom the majority are insured, is intended to internalize the cost of work-related accidents and disease, providing an incentive to employers to ensure job safety and health. However, risk pooling, the basis of insurance, blunts the financial consequences of accidents and diseases caused by work, diminishing the impact of such incentives.

All claims for compensation schemes are handled by state compensation boards. Insurers are entitled to dispute permanent disability claims. In any contested claim, the burden of proof is on the worker. This can cause considerable difficulty in substantiating the claim, particularly for conditions of long latency, where the relevant exposure occurred many years before.

Apart from federal schemes, workers’ compensation varies from state to state. This is particularly the case for diseases. State schemes cover accidents without regard to fault unless self-inflicted or caused by intoxication. In most states, disease coverage was originally covered by schedules, which provided guidance for compensation boards and courts. However, the continuous need to update the schedules, and their being considered restrictive and inflexible, has led to their being generally abandoned.

Many states only compensate diseases which are ‘peculiar to’ or ‘characteristic of’ occupation, i.e. specific to occupation. This creates particular difficulty for conditions which have multiple causes and are of long latency, when it can be difficult to identify the particular workplace where the relevant exposure occurred. This is particularly true of respiratory tract diseases, such as lung cancer, which has a predominant non-occupational cause, cigarette smoking, as well as several well-recognized occupational causes, including asbestos, which is compensated uncommonly. This contrasts with mesothelioma caused by asbestos, haemangiosarcoma of the liver caused by vinyl chloride monomer and leukaemia caused by benzene, the first two
of which, particularly, are more specific to occupation and more widely accepted than lung cancer. Disputes often revolve around the 'apportionment' when a worker has multiple causes of a disease, such as the estimated contribution of a worker’s asbestos exposure and cigarette smoking to the development of lung cancer.

Workers’ compensation in the United States is primarily a state responsibility, which has developed in a more piece-meal manner than in the UK. Its potential strengths lie in the incentives in the scheme to improve workplace health and safety through employers’ insurance and rehabilitation from the responsibility for payment of medical costs. Its problems, as a fair and timely means of compensation, lie in the variation in occupational disease coverage, which in some states remains mainly restricted to diseases specific to occupation, and the frequency with which workers must appeal claims that have been rejected by insurers.

Key points

- Statutory no fault compensation schemes for accidents at work and diseases caused by work are provided in the UK, Western Europe and North America. The Industrial Injuries Benefit Scheme in the UK is funded by taxation, whereas in other countries funding is usually by social insurance schemes.
- Accident at work are in general readily recognized. Attribution of disease to work creates more problems. In the absence of specific clinical features, attribution is usually made 'on the balance of probabilities' or 'more likely than not' (i.e. an attributable fraction of more than 50 per cent).
- Diseases can in principle be compensated on the basis of 'individual proof' or from a list of 'prescribed diseases'. Different countries use different combinations of these two principles. In the UK, the great majority of compensatable diseases are set out in a prescribed list, which identifies both the disease and the circumstances in which attribution to work can be made.
- Different countries vary in the nature of the diseases they compensate. In the United States, in many states only diseases 'peculiar to' or 'characteristic of', i.e. specific to occupation, are compensated. In the UK, diseases such as lung cancer and chronic obstructive pulmonary disease are prescribed where the risk of their occurring in the workforce is at least doubled.
- Statutory compensation in the UK has developed during the past century from the prescription of disease specific to work to one of widening the inclusion of disease attributable, but not specific, to work.

INTRODUCTION

The need for a medical opinion is a daily requirement of those who work in the field of compensation for personal injury. In disputes between employers and employees, the doctor may be asked to decide whether the employee is fit for work and, if not, whether he is likely to be able to return in the foreseeable future. Doctors also regularly appear in criminal courts to give an account of the victim’s injuries or to advise on the time and cause of injury. They may be asked for an opinion on the mental state of a person accused of crime. In other areas, they may be drawn into a case where relatives doubt the validity of a will signed by a testator who was allegedly incompetent, or they may become involved in child care cases. In a growing number of cases, it is the doctor who stands accused of negligence and must rely on other doctors to support what he has done, or omitted to do. This chapter will centre on medicolegal reports requested by a lawyer in a case of personal injury arising out of a work-related accident or disease and will then deal with the role of the expert medical witness appearing in a court of law.

The medical expert will be confronted with a totally different regime: a world of reasonable probabilities and reasonable doubt which is foreign to his scientific training. He may sometimes be asked to give evidence that may damage his patient, and be unable to refuse. It is important that he understand a little of the legal process and of the needs of the courts.

CIVIL AND CRIMINAL LAW

Criminal law is concerned with offences against society as a whole. Prosecution is therefore brought in almost all cases by a public official (Crown Prosecution Service in England and Wales, Procurator Fiscal in Scotland). Prosecutions for offences against the criminal law of health and safety at work are brought by the Health and Safety Executive or local authority. Crimes are divided according to the seriousness of the alleged offence. The less serious crimes are tried summarily by the magistrates courts in England and Wales, the district and sheriff courts in Scotland. The most serious crimes, such as murder and rape, are tried by a judge and jury in the Crown Court in England and Wales and the High Court in Scotland. When a defendant is found guilty by the criminal court he is punished by imprisonment, fines, probation orders etc., but although the criminal courts now also have power in some cases to order compensation to the victim, this is very much secondary to the primary function of punishment. The Criminal Injuries Compensation Board awards compensation out of public funds to the victims of crimes of violence.

Civil law is concerned with the adjudication of property rights and the award of compensation to those injured by another’s unlawful act. A civil action is brought by the person who has suffered injury: the claimant (formerly known as the plaintiff) in England and Wales, the pursuer in Scotland. In England, cases of major importance are tried in the High Court; where less money is at stake, the County
other institutions, but a reference may be made from an unfair advantage in an open market. Each member state must be recognized in other states. The criminal and other professional qualifications obtained in one member state must prove the defendant’s guilt beyond a reasonable doubt, whereas in the civil action the burden is to prove liability on a balance of reasonable probabilities (‘more likely than not’).

In addition to the civil courts, there are a number of administrative tribunals which deal with cases in a limited area. Examples are the employment tribunals for employment disputes and the first tier tribunals for disputes over entitlement to welfare benefits. Of particular interest to doctors are medical appeal tribunals, whose work includes the determination of issues of medical assessment related to claims for industrial injuries benefits.

A vitally important distinction between the criminal and civil process is that in the criminal courts the prosecution must prove the defendant’s guilt beyond a reasonable doubt, whereas in the civil action the burden is to prove liability on a balance of reasonable probabilities (‘more likely than not’).

In both civil and criminal courts, the British procedure is adversarial rather than inquisitorial. Each side must call evidence to support its case. The judge acts as a referee to see fair play and to make the final decision. Experts are called by both sides, not appointed by the judge, as in the civil law system adopted in most other European countries, derived from Roman law. In the United Kingdom, the coroners’ courts, which deal with sudden, accidental and unnatural deaths, exceptionally follow an inquisitorial procedure.

Membership of the European Union has added an extra dimension to English and Scottish law. Since the aim of the community at its inception was primarily to create an economic community, domestic laws relating to compensation for personal injury have been unaffected. In other areas, however, where laws directly or indirectly restrict competition, sweeping changes have been directed by the Council of Ministers, the legislature of the Community. Medical and other professional qualifications obtained in one member state must be recognized in other states. The criminal law of health and safety at work and laws relating to product safety now stem mainly from Brussels, since a country which failed to achieve minimum safety standards at work or which imposed unnecessarily strict standards for consumer goods to exclude foreign imports would have an unfair advantage in an open market. Each member state must enforce Community law through its own courts and other institutions, but a reference may be made from domestic courts to the Court of Justice of the European Communities in Luxembourg.

THE ROLE OF THE DOCTOR IN PROVIDING MEDICO LEGAL REPORTS

There are two main circumstances where a medical report might be requested:

1. When a doctor has been involved in a case as an active participant and is asked to give evidence based on his knowledge of what has occurred. He may have treated the victim of a crime or accident in his surgery (office) or in hospital.
2. When the doctor is asked after the event to bring his professional skill and knowledge to bear as to how an injury was caused, its effect on the person injured or the prognosis for the future. Here, the doctor acts as an expert witness, not as a participant in the event being scrutinized by the court.

Witnesses of fact

The duty of confidentiality enshrined in the Hippocratic Oath yields to a conflicting duty to give evidence of events when called upon to do so by a court of law. Doctors, unlike lawyers, have no privilege against disclosure of their patients’ secrets. A doctor who refused to obey the court’s order could be punished for contempt. However, courts will sometimes rule that a doctor need not give evidence of confidential material if it is not necessary to assist the court to make a decision. The judge may be asked to peruse the relevant material in order to permit its non-disclosure.

Sometimes a claimant will be unable to decide whether he has a cause of action at all until he has seen medical evidence. He may have been told by fellow workers that he is exhibiting classic symptoms of an occupational disease, but be unsure of the medical details of his condition or of the doctor’s diagnosis. Under the Civil Procedure Rules, he may apply to the court for an order that records be disclosed. The court has a discretion to restrict disclosure to the plaintiff’s legal or medical advisers.

A health professional, including an occupational physician, is obliged by the Data Protection Act 1998 to disclose health records to the subject of those records, unless such disclosure would damage his physical or mental health or reveal the identity of a third party who wishes to remain anonymous. This also applies to records held by the National Health Service and foundation trusts and private hospitals, and to all medical records, both manual and held on computer.

A report of this kind should begin with factual information about the doctor, his qualifications and position, and the patient. It should state how the doctor met with the patient, giving time, place and general circumstances, together with
the names of any other people present at the time. It should go on to give details of the results of the examination, and end with a summary of conclusions. At this stage, the doctor may give an opinion — for example, as to the cause of the injury or the likely prognosis for the future. This evidence may be vital later when the court has to apportion blame for the accident or fix the amount of damages.

**Expert witnesses**

Expert witnesses are called upon, not because they know anything about the facts of the case but because they can give an opinion as to a relevant issue. It is for the judge to decide whether someone is truly an expert. In medical cases, formal qualifications are of course important, as is experience in the relevant specialty. Any expert report, therefore, should be prefaced with the qualifications and status of the doctor. In 2000, a voluntary system of accreditation of experts of all kinds was created with the launch of the Council for the Registration of Forensic Practitioners (CRFP). The impetus for this was a number of criminal convictions which were quashed on appeal as unsafe and unsatisfactory because of the quality of expert evidence. Registration, which depends on demonstrated competence against defined standards, is voluntary. The council ceased trading in 2009. There are two other well-respected voluntary organizations created to represent and advise experts, the Expert Witness Institute and the Academy of Experts.

In 1999, a major revolution occurred in the system of civil justice in new Civil Procedure Rules (CPR), implementing reforms recommended by Lord Woolf in his report: Access to Justice. Before this, lawyers and their clients managed litigation for the most part. It was for the parties to decide which witnesses they wished to call, and experts often regarded themselves as ‘hired guns’, tending to be partisan in their evidence. Under the new rules, it is for the court to further the overriding objective of dealing justly with the case. This involves active management by identifying the issues at an early stage, encouraging parties to cooperate, fixing timetables and giving instructions about evidence. As regards expert evidence, though parties remain free to instruct experts as they think fit, the court has complete control over the use of evidence in court. Where the court has not sanctioned the appointment of an expert, the party may not be able to recover the costs of the expert’s report, and will not be permitted to rely on it in the proceedings.

Rule 35.1 states that expert evidence shall be restricted to that which is reasonably required to resolve the proceedings. Courts may refuse to give permission for any expert evidence to be called, may order that it be given in writing rather than orally in the proceedings, may limit the number of expert witnesses, or order that expert evidence may only be given by a single joint expert. This is a matter for the judge to decide and not for the parties and their lawyers. Sometimes, a party asks the judge for permission to instruct a new expert because of loss of confidence in an existing expert. In *Beck v Ministry of Defence* (2003), a Flight Lieutenant in the RAF developed psychiatric illness. He was treated by an RAF general practitioner and consultant psychiatrist. He alleged that the treatment was negligent. The MOD instructed an expert psychiatrist, but lost confidence in him because he had insufficient knowledge of the MOD psychiatric referral system. They wanted a new expert, but the claimant refused to be psychiatrically examined a second time. The MOD applied to the court for permission to instruct a new expert. The Court of Appeal held that this would be granted only on condition that they disclosed to the claimant’s lawyers the report of the first expert. Otherwise, the court would be encouraging the practice of ‘expert shopping’. A claimant can reasonably object to having to be examined again if this is, or may be, because the conclusions of the first expert have proved more favourable to him than the defendants had anticipated.

In 2005, the Civil Justice Council approved the Protocol for the Instruction of Experts to Give Evidence in Civil Claims (the Protocol) and it was annexed to the Civil Procedure Rules as guidance for the courts. This sets out the duty of experts. They have an overriding duty to the court, which takes precedence over any obligation to the person instructing or paying them. ‘Experts must not serve the exclusive interest of those who retain them.’ Experts should provide opinions which are independent. A useful test of independence is that the expert would express the same opinion if given the same instructions by the opposing party.

Experts should confine their opinions to matters which are material to the disputes between the parties and provide opinions only in relation to matters which lie within their expertise. They should take into account all material facts before them at the time they give their opinion. Their reports should set out those facts and any literature or other material on which they have relied in forming their opinions. They should indicate whether an opinion is provisional, or qualified, and whether further information is required to express a final opinion.

Experts should inform those instructing them without delay (and preferably not in the middle of giving evidence) of any change in their opinions on any material matter and the reason for it. As Lord Justice Stuart-Smith said in *Vernon v Bosley (No 2)* (1997):

> If a doctor whom it is proposed to call to give evidence relating to the plaintiff’s expectation of life writes in any accompanying letter or subsequently that he has discovered that the plaintiff is suffering from a life-threatening disease unrelated to the accident, that letter must clearly be disclosed, if the doctor is to be called to give evidence on the question of expectation of life.

It would be the doctor’s ethical duty to refuse to give evidence if he knew that a material fact was being withheld from the other side and that his evidence would therefore
be misleading. The Protocol advises that experts should not be asked to, and should not, amend, expand or alter any parts of reports in a manner which distorts their true opinion, but may be invited to amend or expand their reports to ensure accuracy, internal consistency, completeness and relevance to the issues and clarity. In Noble v Robert Thompson (1979), a psychiatrist wrote a report on a depressed mother with the hope that it would assist her in obtaining access to her children. The doctor wrote that access should not be enforced against the wishes of the children themselves. He refused to delete this when asked to do so and sued for his fee when the solicitors refused to pay. The judge gave judgement for the psychiatrist: ‘It would be of no assistance to the courts if doctors were encouraged to abandon their professional approach and write reports designed to achieve particular objects, at the behest of the patient or anyone else’.

It is now mandatory for all reports to be signed and to contain the following declaration:

I confirm that insofar as the facts stated in my report are within my own knowledge I have made clear what they are and I believe them to be true, and that the opinions I have expressed represent my true and complete professional opinion.

Part 35 Practice Direction

In addition, where there is a range of opinion on the matters dealt with in the report, the expert must summarize the range of opinions and give reasons for his own opinion. The report must also contain a statement that the expert understands his duty to the court and has complied and will continue to comply with that duty.

The House of Lords held in Bolitho v City and Hackney Health Authority (1998), a clinical negligence claim, that as a general rule a consensus of opinion among distinguished experts in a specialty that a doctor has taken reasonable care will be accepted by the courts, that the court has to be satisfied that such an opinion has a logical basis. As Lord Browne-Wilkinson put it:

In particular, in cases involving, as they so often do, the weighing up of risks against benefits, the judge before accepting a body of opinion as being reasonable, responsible and respectable, will need to be satisfied that, in forming their views, the experts have directed their minds to the questions of comparative risks and benefits and have reached a defensible conclusion on the matter.

Experts should be aware that any failure by them to comply with the Civil Procedure Rules or court orders or any excessive delay for which they are responsible may result in the parties who instructed them being penalized in costs and even, in extreme cases, being debarred from placing the expert’s evidence before the court. The judge can also make orders for costs directly against expert witnesses who cause significant expense to be incurred flagrantly and reckless disregard of their duties to the court (Phillips v Symes (2005)).

Although Rule 35 obliges a party to disclose to the other an expert report on which he intends to rely at the trial, this does not extend to draft reports prepared at a preliminary stage to assist the lawyers to advise their client. The law of litigation privilege is that disclosure will not be ordered of any report prepared with a view to legal proceedings, unlike the patient’s medical records which, as has already been discussed, do not attract the same privilege. In Lee v SW Thames Regional Health Authority (1985), a child with severe burns was transported from one hospital to another in an ambulance. He was found to have suffered brain damage, probably caused by lack of oxygen. The plaintiff’s lawyers asked the court to order disclosure of a memorandum prepared by the ambulance crew which had been sent to the health authority with a view to obtaining legal advice on liability. It was held that the court had no power to do this: the report was privileged. However, an accident report prepared partly to make a finding as to causation and future preventive measures and partly to prepare for legal proceedings is not privileged against disclosure (Waugh v British Rail (1980)). The Protocol recognizes that from time to time parties instruct experts before proceedings are commenced or at any early stage in order to assess the strengths and weaknesses of a claim, without the intention of relying on those reports in litigation. Such reports are confidential and do not have to be disclosed to the other side, neither do preliminary reports made in preparation of the final report. In Johnson v Marley Davenport Ltd (2004), the claimant suffered an accident on a construction site in which he badly damaged his head and spinal cord. A professor of forensic pathology was instructed by the claimant’s solicitors to give expert advice on the possible cause of the accident, of which the claimant could remember nothing. He wrote a preliminary draft report for the purpose of a conference with the lawyers and a final report which was disclosed to the defendants. The defendants asked the court to order disclosure of the draft report, but disclosure was refused by the Court of Appeal.

Rule 35.10 removes from the ambit of privilege the lawyers’ instructions to the expert, who is now required to set out in his report ‘the substance of material instructions whether written or oral’. In Lucas v Barking Havering and Redbridge Hospitals NHS Trust (2003), it was held that this did not give a right to the opposing party to see every document referred to in the expert’s summary of his instructions (as, for example, a witness statement), as long as the expert’s summary was complete and not misleading. However, if the expert is relying on published or unpublished literature, this must be disclosed.

A novel situation arose in W v Egdell (1990). W was detained as a patient in a secure hospital without limit of time as a potential threat to public safety after he shot and killed five people. Ten years later, he applied to a mental
health review tribunal to be discharged or transferred to a regional secure unit. His responsible medical officer, who had diagnosed him as suffering from schizophrenia which could be treated with drugs, supported the application. His solicitors instructed Dr Egdell, a consultant psychiatrist, to examine W and report on his mental condition with a view to using the report to support his application to the tribunal. In the event, Dr Egdell strongly opposed the transfer. The solicitors decided that as the report was unfavourable they would not place it before the tribunal and withdrew the application for time being. The doctor sent a copy, in breach of confidence, to the health authority, the Secretary of State and the tribunal, and the solicitors withdrew the application for the time being. It was held by the Court of Appeal as follows:

A consultant psychiatrist who becomes aware, even in the course of a confidential relationship, of information which leads him, in the exercise of what the court considers a sound professional judgment, to fear that decisions may be made on the basis of inadequate information and with real risk of consequent danger to the public is entitled to take such steps as are reasonable in all the circumstances to communicate the grounds of his concern to the responsible authorities.

In Kapadia v London Borough of Lambeth (2000), the claimant was pursuing a claim for disability discrimination against his employer in an employment tribunal. The employer’s solicitors instructed an expert occupational physician to examine Kapadia and write a report. Kapadia gave his consent in writing, but when the case went to the tribunal he objected to the report being shown to his employer without his having the opportunity to read and approve it first. It was held that by consenting to be examined on behalf of the employers he was consenting to the disclosure in legal proceedings to the employers of a report resulting from that examination.

The Civil Proceedings Rules do not apply to employment tribunals, but the Employment Tribunals (Constitution and Rules of Procedure) Regulations 2004 follow a similar pattern. In De Keyser v Wilson (2001), the claimant commenced proceedings against her employer in the employment tribunal for constructive dismissal. She alleged that she had a depressive illness which had been caused by stress at work. Solicitors for the employers asked that she undergo a psychiatric examination by an expert occupational physician. The letter of instruction set out a number of facts about the claimant, for example the death of her brother, a contested custody case, an adulterous affair and the criminal conviction of a man described as her lover, and invited the doctor to conclude that her illness had been caused by these events rather than her employment. The Employment Appeal Tribunal directed that the case should be allowed to proceed, but that another expert should be appointed, to be instructed in more general terms, because the instructions contained material that was irrelevant and abusive.

THE PURPOSE OF EXPERT MEDICAL REPORTS

It is suggested that the doctor should always keep clearly in mind what it is that must be proved to the court. In an action for damages for personal injury, for example, the claimant has to prove, on a balance of reasonable probabilities, first that the defendant was negligent or in breach of his statutory duties, second that the negligence of the defendant caused the claimant’s injury and third that the claimant suffered some material injury to his physical or mental health. The amount of the damages (the legal term is ‘quantum’) will depend on the state in which the claimant is left after the accident. If a young healthy girl aged 17 years is very severely brain damaged in an accident at work caused by the negligence of her employer and dies almost immediately, her parents will receive only the statutory amount for bereavement, currently £10 000. However, if the doctors say she will live for another 20 years, though paralysed and insentient, she will be able to claim damages of £1 million or more for the necessary nursing care, special accommodation and the loss of the earnings she would have made if she had not been injured. Courts now have power to award periodic payments of damages rather than a lump sum (Courts Act 2005).

When a claimant has suffered such catastrophic injury and the damages are large, defendant insurance companies consider structured settlements. Until recently, these had to be agreed between the parties, but the Courts Act 2005 gives a discretion to the judge to order periodic rather than lump sum payments. A structured settlement involves the purchase of an annuity which then guarantees the claimant a sufficient income for the rest of his or her life, with no danger of damages running out if the doctors’ predictions of life expectancy prove to be incorrect. The Inland Revenue has agreed that these payments will not be subject to income tax.

In another case, a man in his 50s is diagnosed as suffering from asbestosis due to exposure to asbestos by his employer. He is breathless and unable to work. There is a possibility that he may contract mesothelioma or lung cancer. He has been a moderate cigarette smoker all his adult life. The lawyers need from the doctor an estimate as to the percentage of disability caused by the cigarettes and a forecast of what may happen to him in the future.

Because the course of disease and injury is often unpredictable in the early stages, the doctor may write in his first report that he wishes to examine the patient again after a specified period has elapsed. Settlement of the claim may be deferred, not through lawyers’ delays but to allow the full extent of the damage to become apparent. When the development of a further disability, such as epilepsy, is possible only in the longer term the lawyers may apply for an award of provisional damages. Such a settlement allows the claimant to return for more if his medical condition deteriorates after his award of damages. However, it was held in Willson v Ministry of Defence (1991) that the mere progression of a particular disease was not appropriate for a
awards of damages. Time when employers could not reasonably be expected of the loss had occurred in the first years of exposure at a
corporation, but if they have gone out of business and no
ages. The company held liable can then sue the others for a
claimant can sue any one of them for the whole of his dam-
The effect is that, where companies A, B and C have all
for which they were responsible, but this was reversed for
of the damages related to the extent of the exposure
(on a lump sum basis.

Damages are of two kinds: special damages to compen-
sate for losses up to the date of settlement or trial, and gen-
eral damages to make up for future loss. By section 22 of the
Social Security Act 1989 (amended in 1997), the defendant
must deduct from the damages for loss of earnings paid to
the claimant in respect of an accident or injury occurring
after January 1, 1989 the gross amount of any relevant social
security benefits paid or likely to be paid to the victim. The
defendant then reimburses the Secretary of State with this
sum. Relevant benefits for this purpose include attendance
allowance, disablement benefit, income support, incapacity
benefit, disability living and working allowance and job-
seeker’s allowance up to the end of the period of five years
following the accident.

Causation is a particularly difficult area in which med-
eical evidence may be vital. In cases of occupationally
induced disease, evidence of research may be more import-
ant than examination of the claimant. The rate of hearing
loss of workers exposed to high levels of noise in the ship-
yards was a central part of the evidence in Thompson v
Smiths Shiprepairers (1984). The court decided that most
of the loss had occurred in the first years of exposure at a
time when employers could not reasonably be expected to
guard against it – a ruling that considerably lowered the
awards of damages.

In Fairchild v Glenhaven Funeral Services Ltd (2002),
(a worker who had been exposed to asbestos dust or fibres
while working for several different employers had died of
mesothelioma, a cancer caused by one or more asbestos
fibres entering the pleura (or peritoneum). Did the fatal
fibre or fibres which caused the cancer arise from the neg-
ligence of defendant A or defendant B or defendant C? It
was impossible to identify the source of the rogue fibre and
if the law demanded that degree of proof, the claimant
would be bound to fail. The House of Lords held that, in
such a case, it is enough for the claimant to prove that the
employer’s negligence materially increased the risk of con-
tracting the disease. All the employers who had negligently
exposed the claimant to asbestos were potentially liable. In
Barker v Corus (2006), it was held that each employer’s
insurance company could be liable only to pay a propor-
tion of the damages related to the extent of the exposure
for which they were responsible, but this was reversed for
mesothelioma claimants by the Compensation Act 2006.
The effect is that, where companies A, B and C have all
been negligent in exposing a claimant to asbestos fibre, the
claimant can sue any one of them for the whole of his dam-
ages. The company held liable can then sue the others for a
contribution, but if they have gone out of business and no

THE FORM OF THE EXPERT REPORT

The report should begin with the name and qualifications of the expert, the date and circumstances of his examination. The first section should deal with the history of the disease or injury. The date of birth of the patient should always be given. In an occupational injury case, the work is as important as the victim, but the lawyers will probably be asking for a separate report from an engineer on the tech-

ical aspects. In the past, lawyers were concerned about the non-admissibility of hearsay evidence, that is evidence of which the witness has no personal knowledge, but which has been reported to him. The Civil Evidence Act 1995 now permits hearsay evidence in civil proceedings, subject to safeguards.

The second section of the report should elucidate the present state of the injury. Obviously, this will be made up partly of what the patient says and partly of objective examination, such as radiographs or scans. At this stage, the doctor should consider whether there is any indication that the patient is inventing all or some of the symptoms and signs. Accusations of malingering should not be made lightly, although the patient cannot sue the doctor for defamation if he makes such an allegation. Later reports when injuries appear not to have responded to treatment may contain references to ‘functional overlay’ or ‘compensationitis’. The law is that genuine psychological consequences of an injury do not preclude the award of damages: only if the patient is consciously inventing or exaggerating his symptoms is he not entitled to compensa-
tion. Defendant insurance companies may hire a photo-

gapher to catch such a claimant up a ladder repairing his
roof when he is supposed to be in agony from a bad back.
Courts have held that such covert surveillance is not a
breach of the Human Rights Act 1998 (Jones v University of
Warwick (2003))).

At this stage in the report, the doctor should give an
opinion as to the cause of the symptoms, setting out any
possible alternative causes and any causes related to the
conduct of the patient (e.g. obesity or cigarette smoking).
As previously indicated, it is important to try to put a
percentage figure on alternative causes, for example, ‘the
patient’s smoking has contributed 50 per cent to his reduced
lung function’. To write a fully comprehensive report, it is
important to gain access to the patient’s general practi-
tioner and hospital records. The patient’s written consent
will, of course, be necessary. Some doctors follow the policy
of writing a report and accompanying it with a covering
letter pointing out inconsistencies or weaknesses in the
patient’s case. ‘The patient says he has been in pain for
months, but he has never visited his general practitioner
during that time, nor has he been off work’. This practice is
not to be encouraged. The doctor’s duty to the court means that his report must be as objective as possible.

The next section should assess the effect of the disability on the patient both now and in the future. The following are important factors:

- Is there pain? Will it continue?
- Is there loss of mobility? Will it continue?
- Has the patient lost work? If still off work, how long will this continue? Will the patient be able to resume his job, or will he be permanently unfit? What job will he be able to do, if any?
- What jobs around the house is the patient unable to do? Child care? Housework? Gardening? Do-it-yourself? Will the situation improve?
- What hobbies is the patient now unable to enjoy? Will the situation improve?
- How has the disability affected the patient’s general quality of life? Relationships? Enjoyment of life? What is the future likely to hold?

The report should state clearly what future complications are possible in the medical condition, if any. Arthritis? Epilepsy? Cancer? Again, the degree of risk should be estimated and the possible time scale for example, ‘80 per cent likelihood of arthritis within five years’. If an injury has brought forward the onset of a condition that would otherwise have remained dormant, an estimate should be made of the number of years of dormancy lost. The likely expectation of life should be given.

A typical expert report prepared for a civil court in a personal injury claim should contain the following elements:

- A coversheet with the name of the case and the case number, the name of the expert and the name of his instructing solicitors
- A table of contents
- A brief curriculum vitae of the expert
- A summary of conclusions
- The expert’s instructions
- Documents examined (e.g. medical records) and other sources of evidence (e.g. any examinations or tests carried out)
- Chronology
- Scientific or technical background, with reference to relevant literature
- Opinion
- Literature citations
- Declaration that the expert acknowledges that his first duty is to the court, and the statement of truth as set out in the Practice Direction (above).

GOING TO COURT

Most actions for damages for personal injury are settled out of court. The costs of legal proceedings are such that most defendants, who are usually insurance companies, are willing to settle any claim which contains some merit. However, some claims have to be fought, because they are regarded as being without any justification or, more often, because they are in some way a test case on which other cases may depend.

The best medical expert witness from a lawyer’s point of view is one who writes fair and balanced reports which he is able to defend under cross-examination. Such experts are likely to have long waiting lists. In some cases, doctors give up their medical practice in order to concentrate on medicolegal work. This may eventually be counterproductive, if the other side is able to argue that the expert is out of date or lacks recent ‘hands-on’ experience.

Experts are encouraged to agree reports if this is possible. It would be unusual for two eminent doctors to have totally opposing views of a particular case. The Woolf Report on civil proceedings recommends that every attempt should be made to resolve any conflict of evidence between doctors before the trial. The court may limit the parties to one expert if that is all that is necessary.

As has been previously stated, the expert’s role should be that of an independent adviser to the court. Lack of objectivity is to be avoided, especially if it arises from improper pressure by solicitors. As Lord Wilberforce said in Whitehouse v Jordan (1981): 19

It is necessary that expert evidence presented to the court should be, and should be seen to be, the independent product of the expert uninfluenced as to form or content by the exigencies of litigation.

It is not the function of the expert to comment in evidence about the parties’ credibility as witnesses, merely to assess the likelihood of the truth of their story by objective criteria.

If the case does go to court, and the expert is called, certain practical points must be borne in mind. The first is that the expert must be available to give evidence, which may necessitate complicated arrangements if he or she is still in practice. Some solicitors follow the policy of subpoenaing their own witness, to be certain of his presence. Courts will be sympathetic to the needs of patients, but the
doctor may have to wait for a considerable time before being called.

Obviously, an expert should try to make a good impression on the judge. Attire should be sober, and hands should be kept out of pockets and away from jewellery. When giving evidence, it is important to address the judge, not merely the advocate who is asking the questions. If there is to be reference to reports, these should be held in a paginated bundle, of which the judge and the other side should also have a copy. The expert should be positive and firm, yet reasonable, in approach and keep calm, especially under cross-examination. He should remember that counsel may attempt to cast doubt on his credibility by making him lose his temper or contradict himself. If the expert does not understand a question, or needs time to consider it, he should ask for it to be repeated. If he does not know the answer to a question, he should say so and not be tempted to venture speculative opinions which cannot be substantiated. It may be that in the course of the proceedings the expert’s opinion has changed, because new facts have come to light. If this is the case, it is vital for him to inform his barrister before giving evidence. He should never try to tell jokes or upstage the judge when in the witness box. The judge will respect expert medical qualifications, but only if he is treated with respect.

In civil proceedings, the witness is first subjected to an examination by his own counsel. Although this should be a friendly process, it is important to answer questions, rather than volunteering information. Counsel will have planned how best to elucidate the evidence he needs. This is followed by cross-examination by counsel for the other side who is, of course, likely to be more hostile, though not discourteous, since bullying a witness can be counterproductive. Finally, a re-examination is permitted to clarify points which have been raised in cross-examination, but not to repeat the original evidence.

No one can be liable for defamation or negligence in respect of anything done in the course of judicial proceedings, which are protected by absolute privilege, that is even if the witness giving oral or written evidence to a court spoke maliciously without belief in the truth of what he was saying he cannot be sued for it, although he can be prosecuted for the crimes of perjury and contempt of court if he makes a false statement without an honest belief in its truth. It was established by the House of Lords in Watson v M’Ewan (1905)\(^\text{20}\) that the same immunity attaches to statements made by the expert witness while preparing for trial.

In Stanton v Callaghan (2001),\(^\text{21}\) the Court of Appeal considered how far that immunity extends. The claimant owned a house which had suffered subsidence damage. Partial underpinning was carried out, paid for by insurance, but this failed to stabilize the property. An expert surveyor, Mr Callaghan, was engaged by the claimant and reported that partial underpinning had been an inappropriate solution. He recommended total underpinning, but the insurers rejected the claim. The claimant therefore commenced proceedings against the insurance company, and Callaghan was instructed as an expert witness. Some time after the issue of proceedings, Callaghan agreed with the insurance company’s expert that another and cheaper solution would be equally effective and as a result the claimant was forced to settle the claim for an amount of money which covered his legal costs, but not the costs of the remedial work. He therefore sued Callaghan for negligence. It was held that an expert is not immune from an action for negligence in respect of advice as to the merits of a party’s claim in litigation, but that in this case, where the surveyor’s advice was for the principal purpose of his eventually giving evidence in court, he did have immunity from civil liability.

In Hughes v Lloyd’s Bank plc (1998),\(^\text{22}\) in contrast, the plaintiff was injured in a road accident. She attended her general practitioner who was asked to report on the severity of her injuries for the purpose of a claim for compensation. He wrote that her condition was not serious, on the faith of which the plaintiff settled her claim for £600. It then became apparent that the injury was far more severe than the doctor had predicted and the plaintiff sued him for negligence. The Court of Appeal held that he was not immune from civil liability. When he made his report he was not an expert witness, merely a paid adviser at a preliminary stage. If he had failed to take reasonable care, he could be sued for compensation.

In Phillips v Symes (2004),\(^\text{23}\) Mr Justice Peter Smith held that an expert witness can be ordered to pay costs where he has been guilty of ‘flagrant reckless disregard of his duties to the court’.

The question later arose as to whether expert witnesses have immunity from the disciplinary powers of professional bodies, such as the General Medical Council (GMC). Sally Clark, a solicitor, was convicted in 1999 of the murder of two of her three infant children. At the trial, Sir Roy Meadow, an eminent paediatrician, gave evidence for the prosecution that the risk of two children in the same household dying from accidental ‘cot death’ was 1 in 73 million. Mrs Clark’s conviction was later quashed because the prosecution had not disclosed relevant medical evidence to the defence (not because Professor Meadow’s evidence was misleading), but Professor Meadow was referred to the GMC’s Fitness to Practise Panel by Mrs Clark’s father. They concluded that he had gone outside his field of expertise and given erroneous and misleading statistical evidence. Although he had acted in good faith, he was convicted of serious professional misconduct and his name was erased from the medical register. Professor Meadow appealed to the High Court. Mr Justice Collins held that he was not guilty of serious professional misconduct and restored his name to the register. He also held that an expert witness should, in general, be immune from fitness to practise (FTP) proceedings unless the trial judge found his shortcomings so serious that he should be referred to his professional body, if he or she had one. The GMC appealed to the Court of Appeal which held that expert witnesses did not have immunity from FTP proceedings, but agreed that Professor Meadow, though guilty of misconduct in going
outside his area of expertise, was honest, though mistaken, and could not be held to be guilty of serious professional misconduct (General Medical Council v Meadow (2006)).

Key points

- The criminal courts are primarily concerned with the punishment of offences against society as a whole, the civil courts with the adjudication of property rights and the compensation of those injured by another’s unlawful act.
- Doctors are called to give evidence in courts and tribunals either as witnesses of fact, because they were involved in the case as an active participant, or as expert witnesses, called upon to give an opinion as to a relevant issue, for example, the cause of an injury and the likely prognosis.
- Although doctors, in general, owe a duty of confidence to patients and others who confide in them, courts and tribunals have power to order them to reveal confidential information without consent. The General Medical Council recognizes that disclosure in response to a court order is one of the exceptions to the duty of confidence.
- Reforms of civil procedure brought about by the Civil Procedure Rules 1999 (as amended) restrict the right of the parties to call expert evidence. In many cases, the court may order that only a single joint expert should be instructed. The 2005 Protocol sets out the duties of experts, whose overriding duty is to the court, not to the party instructing them.
- Expert witnesses have immunity from liability for defamation and negligence in respect of anything said in the course of legal proceedings, and statements made while preparing for a trial.
- However, doctors acting as an expert witness do not have immunity from Fitness to Practise Proceedings before the General Medical Council.

INTRODUCTION

Occupational physicians are frequently involved in the assessment of health risks associated with exposure to chemicals in the workplace and this responsibility increasingly includes the public environment. Interaction with chemicals in the environment is a necessity for any living organism and human beings are no exception. As a consequence, a range of complex biochemical mechanisms has evolved in humans to protect against absorbed toxic compounds. Whenever there is a risk of exposure to hazardous chemicals, it is important that the factors affecting the absorption and distribution of chemicals in the body, the processes involved in detoxification and elimination and the influence of susceptibility are taken into consideration. An understanding of toxicology (the study of ‘poisons’) is essential for occupational physicians in their role as health risk managers or when investigating the exposure of workers to hazardous chemicals. Toxicology is growing rapidly as a science and demonstrates increasing relevance to the activities of all healthcare professionals. A range of standard reference texts is now available.\(^1\)

Paracelsus is regarded as the ‘father’ of toxicology and credited with first recognizing the association between absorbed dose and toxicity – the dose–response relationship.\(^2\) Although he undoubtedly understood the concept of potency, his comments on the relationship of toxic effects to the amount of chemical ingested were, in fact, intended to increase consumer confidence in the safety of novel remedies that he was marketing (he was an early snake-oil salesman!).

The dose–response relationship is a useful indicator of the toxicity of a chemical. Toxic doses in man may range from \(\mu\text{g}\) to \(\text{g/kg}\) body weight and chemicals may be classified according to their probable lethal human dose (Table 10.1).

In addition to intrinsic toxicity and mode of action, the dynamics of absorption, metabolism, distribution and elimination are important variables in the development of a toxic effect. Exposure in the workplace environment can be to many different chemicals, simply or as mixtures, and

the occupational physician must be able to recognise hazardous situations, know about the absorption and detoxification of chemicals and have a detailed knowledge of their potential toxic effects.

An additional factor is the interindividual variation in specific detoxifying enzyme activities which may differ markedly (greater or lesser) between individuals within a population. These variations constitute subgroups, or genetic polymorphisms, in the population; some subgroups are small in size (poor metabolizers of debrisoquine constitute about 10 per cent of the general population) or large (the general population are more or less equally divided into either fast or slow acetylators). Subgroups with greater activity may produce toxic metabolites more rapidly (fast acetylators are more likely to develop isoniazid hepatotoxicity), whereas poor metabolizers may be at more risk because they are unable to detoxify a chemical adequately (slow acetylators are more likely to develop an isoniazid neuropathy and poor debrisoquine metabolizers a perhexiline neuropathy). The role of interindividual variation in susceptibility to toxicity requires greater general consideration, since, in certain combinations of circumstances, it may contribute to the ‘dirty worker’ phenomenon. At present, most work on genetic polymorphisms relates to drug metabolism and toxicity, but the relevance to non-drug chemicals is increasingly recognized.

Within species differences in susceptibility are usually of a lesser magnitude than the variation between species. Most toxicity data are derived from animal toxicity tests and the models generated subsequently applied to man. Apart from the ethical considerations related to this use of animals, serious scientific problems may arise in extrapolating from animal models to human health risks. Ideally, data generated from animals should be supplemented or replaced with information derived from human studies.

**ABSORPTION AND DISTRIBUTION OF CHEMICALS**

Foreign compounds (also referred to as exogenous chemicals or xenobiotics) must be absorbed from the surrounding environment and transported to a target site in the body for a toxic effect to occur. The chemical may have to cross the many cell membranes which form a lipoprotein barrier to the extracellular environment, as well as maintaining the integrity of the cell. Specific transport mechanisms evolved to facilitate the absorption and distribution of nutrients, rather than toxic chemicals, and most xenobiotics are transported by simple methods and not complex carrier-associated processes (some compounds do enter cells on such carriers, e.g. paraquat transport into lung cells). A carrier is usually specific for an endogenous substance and unless the xenobiotic compound has a very similar structure, it will not usually be able to bind to the carrier (paraquat has a similar structure to endogenous diamines, such as putrescine).

Lipid solubility is a major factor determining the extent and rate of simple diffusion through a lipoprotein membrane: lipophilic molecules diffuse more readily than those that are hydrophilic. The rate of transport is dependent on the partition coefficient (i.e. the ratio of solubility in octanol/water). Non-ionized molecules are often more lipophilic and ions generally more hydrophilic, so the movement of electrolytes, such as organic acids and bases, is related to the degree of ionic dissociation and the lipid solubility of the non-ionized form of a compound.

The extent of dissociation is expressed in the Henderson–Hasselbach equation:

\[ pK_a = pH - \log([A^-]/[HA]) \]

or

\[ pH = pK_a + \log([\text{base}]/[\text{acid}]) \]

where [HA] is the concentration of the non-ionized form, \([A^-]\) is the concentration of the ionized form and pK_a is the negative log of the dissociation constant.

The cell membrane controls the movement of chemicals in or out of the cytoplasm and several methods have been identified by which xenobiotics are transported across membranes:

- **Simple diffusion** down a concentration gradient is the most common and simple method, does not require expenditure of energy and is the principal mechanism for the transport of most lipid soluble, non-ionized compounds.
- **Filtration** allows water, ionic and hydrophilic molecules of appropriate size to pass through small pores (about 0.4 nm in diameter) in the cell membrane.
- **Facilitated diffusion** is carrier-mediated, transports chemicals with specific common structures across the cell membrane and at high concentrations may become saturated.
- **Active transport** allows the absorption of substances against a concentration gradient, but requires the expenditure of energy and so is linked to the metabolic activity of the cell.
- **Phagocytosis** and pinocytosis enable particulates and solutions to be taken into a cell by the extrusion or invagination of an area of the membrane and engulfing of part of the extracellular environment.

These absorption processes, although at a cellular level, influence the degree and nature of absorption through the lungs, skin and gastrointestinal tract and are, therefore, relevant at the macro level of hazard assessment.

**TOXICOKINETICS**

Toxicokinetics is the study of the dynamic (kinetic) relationships between the concentration of a chemical (toxicon)
in body fluids and tissues and its biological effects (toxicodynamics). The investigation and management of an individual exposed to toxic chemicals require a basic knowledge of toxicokinetic concepts, alongside understanding of the mechanisms by which chemicals gain entry to the body and are biotransformed into non-toxic or possibly toxic metabolites. Toxicokinetic analysis produces a mathematical description of the dynamics of absorption, distribution and elimination of a chemical. Although this involves the descriptive use of mathematical expressions and models, it does have a practical use in evaluating the significance of blood concentrations obtained from biological monitoring and then determining the nature of exposure control (i.e. risk management). (Pharmacokinetic analysis quantifies the dynamic changes in the concentration of a drug (pharmacy) and has been incorporated into toxicokinetics as there are no fundamental differences between a drug and a toxin – the major toxic effect of a drug is often the main reason for its therapeutic use.)

The kinetic profile of a chemical can be used to estimate the body burden following workplace exposure and to predict the time required for near total elimination of a chemical from the body. Similarly, the rate at which a compound is absorbed or eliminated from the body can be quantified and applied to occupational health practice.5,6

Toxicokinetic concepts

The body is composed of a multitude of real ‘compartments’ in the form of cells, tissues and organs. However, the analysis of kinetic data necessarily models a limited number of theoretical compartments. These models are one solution to the analysis of data but it must always be remembered that models are fitted to data rather than data to models. It is sometimes difficult to be certain that a specific model accurately describes the processes involved; one method of validating a model is to perturb the system and see if the effect mirrors a similar change in the real world (e.g. decreased ventilation, hepatic metabolism, renal blood flow, etc.). Toxicokinetic concepts have led to the development of complex multicompartment models for the absorption, distribution and elimination of chemicals by the body. The simplest of these is, obviously, a single compartment model which considers the body as a homogeneous unit. More sophisticated analysis uses two, three or, occasionally, many more compartmental models (see Figure 10.1).

The rate of absorption ($K_{abs}$) is dependent on many parameters that are often difficult to measure individually so in the initial analysis of blood concentration data the rate of elimination ($K_{el}$) is determined as this often appears to be the simpler process (e.g. via the kidney). The majority of chemical substances are eliminated from blood by an apparent first-order process which is seen as an exponential decay (see Figure 10.2) and described by the mathematical equation:

$$C_t = C_0 \cdot e^{-\beta t}$$

where $C_t$ is the plasma concentration at time $t$, $C_0$ is the plasma concentration at $t = 0$, $e$ is the natural number (2.7182) and $\beta$ is the elimination rate constant ($K_{el}$).

The elimination of some chemicals (e.g. phenytoin, ethanol) is non-linear and demonstrates zero order
(saturation) kinetics. In first-order kinetics, a constant fraction of the chemical is eliminated in unit time. In zero-order kinetics, a constant mass of the chemical is eliminated in unit time and, consequently, the process can become saturated and toxic effects occur following a very small increase in dose.

The half-life \( t_{1/2} \) of a chemical is the time period during which the blood concentration decreases by one-half and is inversely related to the elimination rate constant \( \beta \):

\[
t_{1/2} = \frac{0.693}{\beta} \text{ (where 0.693 is } \log_e(\ln 2).)
\]

The half-life can be determined from the slope (elimination rate) of the log plasma concentration/time graph following a single dose of a compound (Figure 10.2).

The concept of a half-life is useful for studying the uptake and elimination of compounds as it can be shown that after 3.3 half-lives the plasma concentration reaches 90 per cent of the equilibrium concentration, and 95 per cent after five half-lives. Hence, \( 5 \times t_{1/2} \) is the time taken for 95 per cent of a dose of chemical to be eliminated from the body after absorption, or to reach 95 per cent of its steady-state value. The half-life is also the minimum time interval between chemical exposure (or drug administration) that avoids progressive accumulation. Data about the elimination half-life of a compound can be used to assess the importance of the duration of exposure and increase the value of either blood or breath monitoring of exposed workers.

The volume of distribution \( V_D \) is a theoretical estimate of the extent of the distribution of a chemical in the body, provides a measure of the relative magnitude of differential tissue uptake and is expressed in units of litres or litres/kg:

\[
V_D = \chi/C_0
\]

where \( \chi \) is the total amount of chemical (i.e. body burden, if bioavailability is 100 per cent) and \( C_0 \) is the plasma concentration at \( t_0 \).

Compounds with a large volume of distribution are widely and extensively distributed throughout the tissues of the body and the plasma concentration constitutes a small fraction of the total body burden. A small volume of distribution implies limited tissue distribution and indicates that the plasma concentration is a good indicator of the total amount in the body (chemicals with a \( V_D \) approximating to blood volume (3–5 litres) are almost totally restricted to systemic circulation); \( V_D \) is apparent and not real, so a chemical which is concentrated in a tissue (such as fat) and has a low blood concentration, will have a \( V_D \) so high that may markedly exceed the total volume of the body (e.g. >200 litres for some organic solvents).

Clearance (\( Cl \)) is the volume of the \( V_D \) that is completely cleared of a chemical per unit time (i.e. \( \text{mL/min, litre/hour} \)). Clearance is a more independent measure of elimination than half-life since it is a physiologically meaningful measure of the efficiency of elimination from the body. It provides the most reliable measurement of the elimination of a compound since clearance by a particular organ can be estimated (similar to measuring renal clearance of insulin, etc.).

In simple terms,

\[
Cl = V_D \times K_d
\]

Changes in the \( V_D \) may alter the \( t_{1/2} \), but leave clearance unaltered. Chemicals with a large \( V_D \) may have a high clearance yet persist in the body and have a long \( t_{1/2} \) of elimination.

The total systemic clearance is dependent on the specific clearances of each organ:

\[
Cl_{\text{systemic}} = Cl_{\text{renal}} + Cl_{\text{hepatic}} + Cl_{\text{other routes}}
\]

The clearance of a chemical by an organ \( (Cl_{\text{organ}}) \) can be measured and is principally dependent on blood flow and the degree of extraction (extraction ratio, ER) of the chemical from blood:

\[
Cl_{\text{organ}} = Q \times ER
\]

where \( Q \) is the organ blood flow and \( ER \) is the extraction ratio.

The ER is determined from the arterial and venous concentration difference across an organ:

\[
ER = \frac{C_A - C_V}{C_A}
\]

where \( C_A \) is the concentration in blood flowing into organ (arterial) and \( C_V \) is the concentration in blood flowing out of organ (venous).

For those organs with a high ER (e.g. liver, kidney), clearance will be high and directly dependent on organ blood flow. Chemicals with a high liver clearance undergo extensive first-pass metabolism (e.g. nitrites). Organs with a low ER (e.g. muscle, bone) have a clearance that is not dependent on blood flow.

**KINETICS OF EXPOSURE**

The principal routes of exposure in the workplace are by inhalation or skin absorption.

**Inhalation kinetics**

The lungs enable the efficient transfer of gases between the body and the environment. The tissue barrier separating air and blood is only 0.5–1.0 \( \mu \)m thick and the 300–400 million alveoli provide a large surface area for diffusion. In addition, the media on either side of this barrier are continuously renewed; the air is changed 12–15 times per minute and the pulmonary blood flows at a rate of 3.5–5 litre per minute at rest. It is not surprising, therefore, that volatile chemicals can be both efficiently absorbed from, and eliminated in, the breath.

Analysis of expired air has been used to diagnose diabetes and uraemia and, more extensively, to detect ethanol.
consumption in motorists (although only about 1 per cent of the total body burden of ethanol is eliminated via this route). Real-time monitoring of the breath of workers exposed to volatile compounds in industry is a potentially useful non-invasive technique for determining the degree of absorption, but does require that the factors affecting the absorption, distribution, metabolism and elimination (i.e. the toxicokinetics) of compounds have been previously determined for this route in man.\(^8\)

A number of volatile organic compounds can be identified in the breath of the normal general population\(^9,10\) at concentrations of parts per billion (in hospital practice the inhalation kinetics of volatile compounds are of importance to the anaesthetist); in industrial workers the concentrations are generally in parts per million. Breath analysis has been used in experimental toxicology to study lipid peroxidation and in the investigation of defective intestinal absorption, but monitoring of marker metabolites in the expired breath remains a relatively unexploited technique. However, there is renewed interest in the potential of breath monitoring in the diagnosis of certain disease states.

Routine monitoring of the workplace usually assumes the level of contamination of air with a compound is a reliable indicator of worker exposure and, by implication, probable absorption of the chemical. However, this is not a direct relationship; the environmental concentration merely indicates the potential for absorption. Under continuous exposure, any change in the inhaled air concentration will have a corresponding effect on the alveolar air concentration. Increasing the duration of exposure produces a progressive increase in blood concentration towards a plateau value (equilibrium is reached). A progressive saturation of blood and tissues with the compound involves a reduction in the difference between arterial and venous blood with less of the inhaled compound moving from the alveoli to capillary blood. For volatile compounds that are highly lipophilic and selectively taken up by fatty tissues, tissue saturation is never reached in the normal exposure period in the workplace. In contrast, the elimination of such compounds from the body is extremely slow and the potential exists for progressive accumulation following frequent modest exposures.\(^11\)

Other factors influencing the inhalation kinetics of a volatile compound include the environmental air concentration, duration of exposure, rate of alveolar ventilation, cardiac output, blood and tissue solubility and the degree of metabolism of the chemical. Volatile compounds are usually inhaled as a gas mixture with air and most are completely miscible in all proportions. The concentration of gases and volatile compounds in a mixture is expressed in terms of partial pressures, which are often incorrectly considered equivalent to concentrations; the relative concentrations of dissolved materials can be expressed in terms of partial pressures which add up to a total pressure of 100 per cent. However, a limit is set on the concentration (wt/unit vol) which this represents by the solubility of the volatile materials. Solubility is inversely related to temperature and proportional to the pressure of the chemical in the surrounding gas. The partial pressures of constituent volatile compounds vary with the absolute pressure but, at a fixed pressure, the concentration of each gas or vapour varies directly with its partial pressure and indirectly with the total pressure of the gas/vapour mixture. A gas or vapour present at a partial pressures of 100 per cent can still have its concentration (wt/unit vol) varied over a range that is determined by the absolute pressure.

The rate of delivery of an inhaled mixture of air and a volatile compound depends upon alveolar ventilation. A doubling of alveolar ventilation from 4 litre/min to 8 litre/min produces a minimal increase in the blood concentration of a poorly water soluble substance, but an appreciable increase for highly water-soluble substances. Cardiac output has an opposing effect on alveolar concentration and this is most noticeable for highly water soluble, or extensively metabolized substances, rather than poorly soluble compounds. An increase in cardiac output results in a larger amount of the inhaled substance passing from the lungs to the blood. A decrease has the opposite result and causes a rise in alveolar concentration.\(^12\)

An insoluble substance that does not pass into the bloodstream will increase in alveolar concentration until it is equal to the environmental air concentration, the time taken being equivalent to the lung wash-in time. A substance with an infinite solubility could in theory never increase the alveolar concentration and, although such substances do not exist, there is a broad range of solubilities. The concentration in alveolar or expired air, expressed relative to the environmental air concentration is inversely proportional to the blood solubility of a compound. Relative concentrations of >0.5 are poorly soluble and those <0.5 are highly soluble. The effect of solubility on alveolar concentration is seen in Figure 10.3.

The aerodynamic particle sizes of aerosols, mists and sprays also affect their accessibility to alveoli and large particles may be deposited in the larger airways, or in the pharynx, and swallowed.

The arterial concentration of an inhaled compound can be estimated from the alveolar concentration using the blood–air partition coefficient of the chemical (if partial pressure equilibrium is attained rapidly). This is not attained immediately, but requires a finite time that depends on the half-life of the compound:

\[
 t_\frac{1}{2} = 0.693 \times \frac{P_c}{F}
\]

where \(V\) is the tissue volume, \(P_c\) is the tissue–blood partition coefficient and \(F\) is the rate of blood flow to the tissue.

A high relative alveolar concentration is found for compounds that undergo little metabolism. As the degree of biotransformation increases so does the level of metabolites in pulmonary blood. The combined effects of metabolism and solubility affect the blood kinetics of a
chemical. Extensive metabolism can significantly undermine the usefulness of biological monitoring of exhaled breath, unless a volatile marker metabolite predominates and there is no phenotypic variation in biotransformation within the population.

Routine measurement of the breath concentrations of industrial or therapeutic chemicals is poorly utilized for monitoring exposure or assessing body burden. Rigorous kinetic analysis is essential to establish its value and reliability as a non-invasive method of assessment. The necessary technology is widely available and still simply requires more consideration.

**Dermal absorption**

The skin is an effective barrier to many environmental chemicals because the stratum corneum, acting to control the loss of water from the body, also functions as the principal barrier to dermal penetration by chemicals. Direct absorption through the skin is a major route of exposure to pesticides and other workplace chemicals and accidental skin contamination by spillage or deposition on the skin surface can be followed by rapid systemic absorption. The lipid solubility of a chemical determines how easily it can cross the stratum corneum, the epidermis and upper dermis, and then enter the systemic circulation. Compounds with a molecular weight exceeding 500 Da cannot easily pass through the lipid layers of the stratum corneum, and hence are absorbed to a much lower extent than smaller molecules. However, perturbation of the stratum corneum barrier by mechanical means, or by chemicals such as solvents, will increase percutaneous absorption. Similarly, individuals with poor barrier function originating from disease states, such as atopy, may exhibit a higher degree of percutaneous absorption. Highly lipophilic chemicals can penetrate the stratum corneum, but further penetration is limited by low solubility of the penetrant in the aqueous environment of the viable epidermis. However, lipophilic chemicals may accumulate in the stratum corneum, potentially forming a reservoir for systemic absorption after the surface dose has been removed. Direct absorption through skin is utilized for pharmaceutical compounds which are rapidly metabolized by first-pass metabolism in the gut wall or liver following oral administration. The drug, in a suitable formulation, is applied to the skin and enters the systemic circulation directly bypassing initial first-pass metabolism in the liver.

Dermal absorption has been considered a passive process limited only by the physical barrier function of the stratum corneum. The skin, however, is capable of metabolizing a range of xenobiotics and studies, with whole skin homogenates and subcellular fractions, have demonstrated significant metabolic activity, albeit less than that found in liver (about 10 per cent hepatic activity). Monooxygenases (including cytochromes P450, flavin-containing monooxygenases and NAPD(H)-quinone reductases), oxireductases, conjugation pathways and esterase activity have all been identified in skin. Consequently, many compounds that penetrate the stratum corneum may undergo biotransformation to active metabolites before entering the systemic circulation. A limited number of in vivo studies in humans have indicated that metabolism takes place in the skin in vivo during absorption of some compounds (e.g. aldrin, glycerol trinitrate, synthetic prostaglandins and amines in oxidative hair dyes). A number of in vitro models of percutaneous absorption, using excised human or animal skin, have been developed in recent years, the most popular being based on static or flow through diffusion cells. A substantial number of studies have confirmed that these techniques are relatively robust and give good predictions of percutaneous absorption in vivo. The in vitro skin absorption test was formally adopted as a test guideline by the Organisation for Economic Co-operation and Development (OECD) in 2004.

**DETOXIFICATION AND ELIMINATION**

Most toxic xenobiotics have no nutritional value and are metabolized primarily to reduce their potential toxicity and facilitate elimination from the body. The majority of compounds that gain entry most easily to the body are lipophilic and likely, therefore, to be retained. Before they can be excreted they must be converted into a form that is more easily eliminated. The liver is the major organ for the metabolism (biotransformation) of such compounds. There is, however, increasing evidence that other organs such as the skin, lungs, kidney and skeletal muscle may have an important capability for biotransformation, albeit at a lower level of activity than the liver (Table 10.2). Detoxification does not always occur and, for some chemicals, toxicity may be enhanced as a result of biotransformation.

The metabolism of xenobiotics is carried out by a group of relatively non-specific enzymes. The key enzyme in this system is cytochrome P450, the active site of which contains...
Detoxification and elimination

An iron atom that can change between divalent and trivalent oxidation states. This enzyme combines with the substrate and molecular oxygen as part of a process through which the substrate is oxidized. The group of enzymes are classified as mixed function oxidases, the specific oxidizing enzyme, cytochrome P450, having a characteristic peak in the reduced form at 450 nm in a carbon monoxide adduct difference spectrum (hence P450). The enzyme requires an electron transport chain for its reduction. This consists of a flavoprotein enzyme, cytochrome c reductase (cytochrome P450 reductase) that transfers electrons (e⁻) from the flavine to cytochrome P450. Cytochrome c reductase requires NADPH as a coenzyme; microsomal oxidation requires both NADPH and O₂. Cytochrome P450 exists as a family of isoenzymes with differing and overlapping specificities and more than eight gene families have been identified.

Cytochrome P450 is abundant in the liver, which is the primary site of protection against systemic poisons, but may occur in other parts of the body, such as the kidney, ovaries, testes and olfactory mucosa. The presence of the enzyme in the lungs, skin and gastrointestinal tract reflects a defensive role in these organs against local toxic xenobiotics. Oxidase enzyme activity is mainly associated with the smooth endoplasmic reticulum. When tissues, such as liver, are homogenized, the ER is broken down to form small vesicles known as microsomes. Microsomes are the fraction collected from centrifugation of tissue homogenate at about 100 000 g and, essentially, contain the rough and smooth endoplasmic reticulum and Golgi apparatus. There is evidence that the microsomal enzymes are associated with a lipid membrane and are lipid-dependent. Sonic vibration, or the use of hypotonic solutions, fail to solubilize them, whilst the use of microsomes with deoxycholic acid, which solubilizes lipid membranes, destroys the activity of oxidative enzymes.

Biotransformation of xenobiotics usually consists of two phases: phase 1, which involves oxidation (via the cytochrome P450-dependent mixed function oxygenases), reduction or hydrolysis of the parent compound, and phase 2, in which the metabolite is conjugated to glucuronic acid, glutathione, glycine, sulphate or some other endogenous compound.

In phase 1, a polar reactive group is introduced into the molecule to increase water solubility and make the compound suitable for phase 2 where the altered molecule is combined with an endogenous substrate to produce a water-soluble conjugate that is more readily excreted in the urine. Consequently, the principal function of biotransformation is to facilitate the elimination of a foreign agent by its conversion to a more polar (water soluble) metabolite and is, therefore, a detoxification mechanism. In some cases, the intermediate metabolites or final products may be more toxic than the parent compound (i.e. an entoxification). Such metabolites may be systemically toxic or, because they are produced locally by an organ, have toxic effects in the tissue of biotransformation. Most cells, particularly in the liver, have protective biochemical systems to prevent damage to vital cell processes from locally produced toxic metabolites.

In phase 1 metabolism, biotransformation may result in the formation of compounds with a variety of properties depending on whether toxicity has been increased or decreased.

### INCREASED TOXICITY

Parathion, an organophosphate pesticide, is relatively non-toxic to man, but in insects is rapidly metabolized (activated) by desulphuration to paraoxon, a potent cholinesterase inhibitor. There is some evidence for variability in man of parathion activation by P450 and of activity of the enzyme, paraoxonase, which further metabolizes the paraoxon.

### DECREASED TOXICITY

Phenobarbitone is detoxified by hydroxylation of the aromatic ring to form parahydroxyphenobarbitone. Amphetamines are similarly detoxified by aromatic hydroxylation to parahydroxymphetamines and by deamination to a benzyl methyl ketone. Both of these metabolites are less active than the parent compound.

Specific chemical reactions can occur in phase 1 metabolism.

Although biochemical activation may present some human hazard, it may have a useful application in the development of new pesticides or prodrugs that are converted into active products only following metabolic transformation in a target species.

### DECREASED TOXICITY

Phenobarbitone is detoxified by hydroxylation of the aromatic ring to form parahydroxyphenobarbitone. Amphetamines are similarly detoxified by aromatic hydroxylation to parahydroxyamphetamines and by deamination to a benzyl methyl ketone. Both of these metabolites are less active than the parent compound.

Specific chemical reactions can occur in phase 1 metabolism.
Epoxidation

Epoxidation is the insertion of an oxygen atom between two carbon atoms. It is an important mechanism for the initial metabolism of aromatic compounds and cytochrome P450 is involved. This reaction can increase the toxicity of the parent compound, but many epoxides are unstable and undergo further reactions, such as hydroxylation. Unstable epoxides are often toxic because they bind to proteins and other macromolecules. For example, vinyl chloride is converted to an intermediate, chloroethylene oxide, which spontaneously transforms to chloracetaldehyde. The two metabolites are mutagens and considered to act as proximate carcinogens.

Since both of these intermediates can bind directly with cellular macromolecules, such as DNA and proteins, it would be expected that local hepatic biotransformation of vinyl chloride is associated with liver damage. Many epidemiological studies have confirmed the association of chronic vinyl chloride exposure with the development of a hepatic angiosarcoma, an otherwise rare primary liver cancer. Carcinogenicity appeared to follow chronic exposure to relatively low levels of vinyl chloride (50–100 ppm or less). Chronic exposure to higher levels of exposure (500–1000 ppm) was more commonly associated with serious hepatotoxicity, the hepatocytes dying before malignant transformation could occur. Vinyl chloride-induced angiosarcoma of the liver can have a latency of between 15 and 40 years. As a result of stringent workplace controls limiting exposure to below 1 ppm, vinyl chloride-associated diseases are now rarely seen (see Chapter 39, Gases and Chapter 88, Hepatotoxic effects of workplace exposures).

Another example of epoxide formation is the conversion of the pesticide aldrin to dieldrin, a stable epoxide.

Hydroxylation

Hydroxylation is the attachment of a hydroxyl group to hydrocarbon chains or rings and may follow epoxidation. An example is the metabolism of benzene epoxide, an intermediate in the biotransformation of benzene, to phenol. Benzene is initially metabolized by oxidation, primarily in the liver, with phenol as the major metabolite.

Other metabolites that can be formed by hydroxylation of the aromatic ring include hydroquinone, catechol and 1,2,4-trihydroxybenzene. These hydroxylated metabolites can be further oxidized to quinones and semiquinones. Urinary excretion of muconic acid, a short chain dicarboxylic acid, suggests that the benzene ring may be opened by biotransformation.

The principal target organ for benzene toxicity is bone marrow. Marrow cells contain peroxidases and mixed function oxidases capable of metabolizing benzene. The metabolites produced may bind covalently to cell macromolecules causing disruption of cell growth and replication. The specific target of benzene is probably the DNA in the pluripotential stem cells and lymphocytic cells. Cytogenetic abnormalities of bone marrow cells and circulating lymphocytes have been observed in workers exposed to benzene. Myelodysplasia may be seen in the bone marrow of individuals with chronic exposure to benzene. Benzene-induced leukaemia has a latency period of 5–15 years and in many cases is preceded by an aplastic anaemia (see Chapter 90, Haematopoietic effects of workplace exposures).

Hydroxylation may involve the addition of one or more epoxide groups and both reactions are responsible for making several xenobiotic compounds more toxic, such as the production of the carcinogenic 7,8-diol-9,10-epoxide of benzo[a]pyrene. Benzo[a]pyrene is classified, therefore, as a procarcinogen since metabolic activation is required to convert it to a carcinogenic species.

Oxidation

Oxidation of nitrogen, sulphur or phosphorus is another important metabolic reaction in biotransformation that may increase toxicity. The oxidation of nitrogen in 2-acetylaminoflourene produces the carcinogen N-hydroxy-2-acetylaminofluorene.

With parathion, the oxidative desulphuration of phosphorus produces paraoxon which is more effective than
the parent compound as an inhibitor of acetylcholinesterase (see Increased toxicity, p. 133).

**Dealkylation**

Dealkylation is the removal of an alkyl group (such as a methyl group) and its replacement by a hydrogen atom. The reactions are carried out by mixed function oxidases. Examples include O-dealkylation of methoxychlor insecticides, N-dealkylation of the insecticide carbaryl and S-dealkylation of dimethyl mercaptan.

**Reduction**

Reduction of some of the major functional groups in xenobiotics is carried out by reductases. Examples include the reduction of nitro groups by nitroreductases, which are found mainly in the liver, but to a lesser extent in other organs, such as the lung and kidney. They may occur also in intestinal bacteria and reduction of xenobiotics may take place locally in the intestinal tract (e.g. dinitrotoluene).

**Hydrolysis**

Hydrolysis is the addition of water to a molecule prior to its division into two chemical species. Two types of compounds that undergo hydrolysis are esters (such as organophosphates) and amines, many of which are pesticides. Hydrolases occur predominantly in the liver, but also in the gastrointestinal tract, nervous tissue, blood, kidney and muscle. Aromatic esters are hydrolysed by the action of aryl esterases and alkyl esters by carboxylesterases (an example being the metabolism of synthetic pyrethroids). Esterases were originally subdivided into A, B or C esterases on the basis of their interaction with organophosphates.22

Depending on their degree of water solubility, the products of metabolic transformation are either excreted directly or undergo further metabolism by conjugation (phase 2 reaction).

In phase 2 reactions, the functional groups on a molecule (e.g. carboxyl, amino, hydroxyl and sulphhydryl groups) are conjugated with endogenous compounds, such as glutathione, glucuronic acid, amino acids (e.g. glycine) or sugars, to form water-soluble, polar derivatives that can be more readily excreted and are less toxic. A reduction in lipid solubility decreases the ability to diffuse back across membranes.

Conjugation with glucuronic acid is the most important and most common mechanism. The enzyme UDP-glucuronyltransferase catalyses the transfer of glucuronic acid from uridine diphosphate glucuronic acid. Glucuronide conjugation products are classified by the site of binding: a hydroxyl functional group forms an ether glucuronide, a carboxyl acid group an ester glucuronide. Glucuronides may be attached directly to nitrogen as the linking atom (e.g. aniline glucuronide) or through an intermediate oxygen atom, such as occurs in the conjugation product in N-hydroxyacetylaminoglucuronide. In contrast to the usual decrease in toxicity that results from glucuronide conjugation, this is a more potent carcinogen than the parent compound, N-hydroxyacetylaminofluorene.

Glutathione, a tripeptide of glutamic acid, cysteine and glycine, is another endogenous compound used in phase 2 reactions. The thiol groups (SH) in glutathione form covalent bonds with xenobiotic compounds and glutathione conjugates may be excreted directly, or after further metabolism to mercapturic acids (compounds with N-acetyl cysteine attached). The enzyme glutathione transferase is generally required for the conjugation process and is found throughout the body.

Sulphate conjugates are completely ionized and, therefore, highly efficient in eliminating xenobiotics in the urine. The major species that form sulphate conjugates are alcohols, phenols and amines. Phenols are conjugated with either glucuronic acid or sulphate to form phenol glucuronide and phenol sulphate. Sulphation is a saturable pathway and so may have limited capacity for detoxification.

Other reactions can occur. Acetylation involves acetylation such as in the final step in the production of mercapturic acid conjugates. Amino acids, such as glycine, form peptide conjugates. Some compounds, such as salicylic acid, can be metabolized by several different mechanisms, as well as glucuronide conjugation. Cyanide is detoxified by conjugation with sulphur to form thio-cyanate (which can be monitored in blood or urine).

Most compounds undergo both metabolic transformation and conjugation, but occasionally only one of these reactions. Biotransformation may produce a metabolite that is sufficiently water soluble to be easily excreted, so that conjugation is not necessary. If the compound already possesses groups which will easily conjugate then phase 1 metabolism may not be required.

**OTHER MECHANISMS**

Some xenobiotics are detoxified by linkage to a large molecule, such as a protein. This produces a complex that is less toxic and which can be stored in the body. Metallothionein, a low molecular weight cysteine-rich protein, binds to heavy metals such as cadmium, zinc and copper and is found in high concentrations in the liver and kidneys.

**Other sites of xenobiotic biotransformation**

The liver is not always the most important site of metabolism. Reactions can occur in extrahepatic sites as a result of the activity of both microsomal and non-microsomal enzymes. For example, microsomal UDP-glucurononyltransferase is found in skin and the gastrointestinal tract. Many non-microsomal enzymes occur in plasma, the gastrointestinal tract, lungs and kidneys. Alcohol dehydrogenase in the liver, kidney and lungs oxidizes an alcohol to its aldehyde and a number of amino-oxidases and esterases are found in plasma. Bacterial flora in the gut may also have a role in xenobiotic metabolism (see above under Reduction) and first-pass metabolism by this route of exposure.
If these metabolic reactions did not occur then xenobiotics of high lipid solubility would remain and accumulate in the body with the resultant risk of toxicity. A more detailed review of the principles of biochemical toxicology can be found in standard texts.23

**Pulmonary biotransformation**

Over 40 histologically different cell types have been identified in the lungs but the susceptibility of a lung cell to toxic compounds or metabolites depends partly upon the specific biochemical activity of that cell.24 The lungs can be the target organ for toxicity and, in some cases, there is a selective toxicity to a particular type of lung cell.25 The level of metabolic activity of a cell depends upon its degree of specialization and the nature of the enzymes and substrates.

The lung is capable of metabolizing many xenobiotics by both phase 1 and phase 2 reactions.26 The non-ciliated bronchiolar, or Clara, cell is the most metabolically active lung cell and has a high activity of mixed-function oxidases.27 The mycotoxin 4-ipomeanol has been widely studied in animals as a model substrate for investigating organ-specific toxicity, since it undergoes selective metabolism and activation in the lung. It appears that the Clara cell metabolizes ipomeanol to a reactive metabolite.28,29 Significant amounts of the cytochromes P4502B1 and P4504B1 are found in the Clara cell of the rabbit lung. In vitro these isoenzymes are effective at converting ipomeanol to its reactive metabolite. A specific Clara cell lesion is seen also following the administration of the hepatotoxin, 1-nitronaphthalene.

Carbon tetrachloride (CCl₄) is a recognized hepatotoxin-producing fatty degeneration and centrilobular necrosis of the liver (see Chapter 88, Hepatotoxic effects of workplace exposures). Biotransformation of carbon tetrachloride takes place in the liver and toxicity is believed to be linked to the production of a CCl₃ radical that causes lipid peroxidation and irreversible damage to membrane systems. Bioactivation of CCl₄ is a classical model for free radical-induced toxicity. The first metabolic step is the formation of the trichloromethyl-free radical (CCl₃⁻) by a cytochrome P450 enzyme. This free radical binds directly to microsomal lipids and other cellular macromolecules causing the breakdown of membrane structure, energy production and protein synthesis. The trichloromethyl-free radical may also undergo both anaerobic and aerobic reactions leading to the further production of toxic metabolites.

Although the liver is the target organ of toxicity for this chemical, damage to the metabolically active Clara cells, as well as types 1 and 2 alveolar epithelial and pulmonary endothelial cells, has been reported. Gould and Smuckler30 found focal atelectasis and haemorrhages with ultrastructural changes in type 2 cells which suggested damage to the pulmonary surfactant system. Carbon tetrachloride probably also has toxic effects on lung phospholipids as the main route of elimination of unchanged carbon tetrachloride is via the breath.

The profile of the isoenzymes of cytochrome P450-dependent monooxygenases in the lung cells is important for understanding of the toxicity of substances that undergo metabolic activation. The heterogeneity of cellular distribution and the high levels of enzyme activity in certain cells can explain specific cell toxicity for some compounds (such as ipomeanol for the Clara cell), but it is not so clear why other toxins (e.g. butylated hydroxytoluene and trialklyphosphorothioates) appear to be specifically toxic to the type 1 alveolar epithelial cells. Butylated hydroxytoluene appears to be species-specific in causing murine lung damage but, despite extensive human safety evaluation, the potential for butylated hydroxytoluene in food to cause toxic lung damage in man has not been determined. Similarly, the trialklyphosphorothioates, as impurities in many organophosphorous thionates manufactured for use as pesticides (e.g. malathion), may be environmental causes of cell-specific lung damage in man. The type 1 alveolar epithelial cells do not demonstrate significant cytochrome P450 activity and their potential for xenobiotic biotransformation is unknown. It is possible that there is metabolic activation in another cell type, or even organ, and transport of the toxic metabolite to the type 1 cell. There is some evidence to suggest that certain conjugates may dissociate at a remote site after conjugation and release the toxic compound. Type 1 cells are derived from type 2, which have demonstrable metabolic capability, but in vitro the total enzyme activities of a lung preparation cannot be accounted for by the sum of just the Clara and type 2 cells. The other enzyme systems that may be involved in the activation of toxins in the lung include pulmonary flavinoxygenases (Clara and alveolar type 2 cells) and pulmonary prostaglandin synthetase which is capable of activating chemicals by co-oxidation with prostaglandin precursors. This pathway, in particular, could be relevant to the pulmonary toxicity of α-naphthylthiourea (ANTU) and N-methylthiobenzamide. The latter compound has a similar toxicity profile to ANTU and has been shown to be metabolized by a pulmonary flavin adenine dinucleotide (FAD)-dependent monooxygenase. ANTU produces severe, non-haemorrhagic, pulmonary oedema with fibrin-rich pleural effusions in animals and has been used as a model for the study of the pathophysiology of pulmonary oedema. Pulmonary prostaglandin H-synthase-mediated co-oxygenation has been shown to activate procarcinogens, such as benz[a]pyrene and aflatoxin B1.

The role of glutathione (GSH) in pulmonary detoxification has been investigated for ipomeanol and naphthalene, both of which selectively damage Clara cells in mice. GSH and GSH-S transferase concentrations are lower in the lungs than in liver and the cellular distribution is unclear, although there appears to be more activity in the Clara cells than the type 2 cells. Consequently, the protective detoxification mechanisms of the lungs are less effective than those of the liver. Low glutathione transferase activity in the lung, compared with aryl hydroxylase activity, has been
associated with the increased risk of lung cancer in tobacco smokers.

The lung is a target organ for toxicity of many other compounds. Some of the mechanisms involved in systemic lung toxicity have been identified in animal toxicity models. Administration of paraquat to animals causes lung fibrosis, the herbicide entering types 1 and 2 lung cells by a selective active uptake process. Hydrazine, given intraperitoneally in mice, can produce lung tumours, and chlorphentermine, after chronic oral dosing, accumulates in the fatty tissue of the lung (and the adrenals) and causes a phospholipidosis. Polycyclic aromatic hydrocarbons may be activated in the lungs or metabolized elsewhere and transported to the lungs. There are significant species differences between animals and humans in susceptibility to the toxic effects of butylated hydroxytoluene (BHT), the trialkylphosphorothioates, ANTU, ipomeanol and paraquat.

**Dermal biotransformation**

The importance of dermal metabolism, during absorption through the skin in vivo, for disposition and local toxicity is now recognized. Esterase activity in skin is exploited in the delivery of ester prodrugs; lipophilic prodrugs (containing an alkyl group ester-linked to the pharmacophore) are able to penetrate the stratum corneum. Esterase activity in the viable epidermis cleaves the ester linkage and liberates the pharmacophore. Metabolic activity plays a key role in activation of procarcinogens such as benzo[a]pyrene in the skin of experimental animals and is believed to have a similar role in humans. Metabolic activation also appears to have a key role in haptenation during skin sensitization reactions. Dermal absorption and metabolism has been assessed in tissue homogenates and in intact skin in vitro, using flow through diffusion systems and more recently short-term organ culture. The viability of skin in these systems and the maintenance of metabolic capacity are important but still require complete verification for all enzyme systems, especially those requiring energy. Nevertheless, expression and enzymatic activity for a wide range of enzymes in cutaneous systems has been demonstrated in vitro as well as in vivo. The degree of skin metabolism depends on the physicochemical characteristics of the compound, the rate of absorption, as well as the capacity of any metabolizing enzymes. A suitable choice of model systems is important to reflect not only absorption characteristics in vivo, but also metabolic capacity. Metabolism may be relatively unimportant quantitatively in vivo, compared with metabolism by the liver, but may be highly significant when conversion to toxic metabolites causes local toxicity or where rapid detoxification follows absorption and enables the skin to act as a protective metabolic barrier against a toxic xenobiotic entering the system circulation. Furthermore, metabolic activity for the majority of cutaneous enzyme systems is highly localized in the basal layer of the epidermis and appendages. Consequently, specific activities for dermal biotransformation may be more significant than values from tissue homogenates suggest. The lower metabolic capacity of human skin compared with animals must be considered when extrapolating from animals to man in quantitative risk assessment.

**VARIATION IN SUSCEPTIBILITY TO XENOBIOTICS**

Disorders following occupational exposure to chemicals are well documented and some have been known for hundreds of years. In a population exposed to toxic xenobiotics in the workplace, or general environment, there is a broad range of responses between individuals. The causes of this variability, in the nature and degree of acute response or susceptibility to long-term health effects from intermittent or chronic low-dose exposure, remain largely unanswered. Research into the role of genetic polymorphisms, and the contribution of epigenetic factors, in predisposing individuals to disease is beginning to identify important differences within populations. Recent advances in genetics have identified the genetic basis of many human diseases and it is probable that similar genetic mechanisms will underlie some of the effects of occupational and environmental exposures to xenobiotics. Genetic polymorphisms for xenobiotic metabolism are likely to play an important role in an individual’s level of susceptibility.

The clinical consequences of slow acetylator phenotype have been well studied following drug exposure and this pathway may have a role in some occupational exposures (examples include exposure to isoniazid and hydralazine). It is also known that phenotypic variation in plasma esterases, especially cholinesterases, can contribute to the relative toxicity of some anticholinesterases by affecting both the specific toxicity of these compounds and influencing the efficiency of their metabolism and elimination. Thiomethyl transferase produces S-methylation and masks functional chemical groups, producing S-methylation and masks functional chemical groups, reducing water solubility and impairing further conjugation. Thiomethyl transferase is involved in the detoxification of substances, such as hydrogen sulphide and other free sulphhydryl groups, including the thioesters of glutathione conjugates (a final common pathway for many toxic xenobiotics). Hydrogen sulphide has a similar toxic mechanism, as a mitochondrial poison, to cyanide and can cause an acquired defect in mitochondrial function leading to disease similar to that found in Parkinson’s disease. Heavy metals, such as mercury, can form toxic derivatives with the enzyme thiomethyl transferase and increased activity, such as that reported in motor neurone disease, may predispose individuals to heavy metal poisoning.

An individual’s response to toxic xenobiotics is influenced by the rates of absorption, distribution, biotransformation and excretion, as well as the toxidynamics of the chemical. The body’s defences against toxic effects are complex...
and there are considerable interindividual (and interspecies) variations in both toxicokinetics and toxicodynamics. Many of these variations will depend on genetic polymorphisms for the specific enzymes (frequently cytochromes P450) involved in the toxic mechanisms.\(^1\)

Epigenetics is the study of the ‘all heritable and potentially reversible changes in genome function that do not alter the nucleotide sequence within the DNA’. \(^36\) Although our current understanding of the epigenome is constantly changing in response to environmental factors affecting absorption, distribution, metabolism and elimination or the mechanism of toxicity in humans to justify this assumption. Toxicokinetic data suggest that for some compounds the degree of workplace exposure is not directly related to individual risk. Similarly, greater understanding of the mechanisms involved in the development of toxic effects in humans and the frequent discrepancies from the results of animal toxicity studies, indicate a need for more information from human studies. In addition, as with the effects on drug toxicity of genetic differences in drug metabolism, so the role of genetic polymorphisms in susceptibility to the toxic effects of hazardous chemicals must be defined. The application of more extensive human data in toxicology to the assessment of health risks in the workplace should not necessarily increase the complexity of controls, but will increase their direct relevance. Experience in the workplace can then be applied to the more contentious issues of general environmental exposure.

The epigenome serves as an interface between the dynamic intra/extracellular environments and the inherited static genome. Epigenetic aberrations have similar consequences to some genetic polymorphisms and can result in variations in gene function. Recent data suggest that the epigenome is constantly changing in response to environmental signals.\(^36\) Although our current understanding of how epigenetic mechanisms impact on the toxic action of xenobiotics is limited, it is anticipated that epigenetic factors may need to be considered in the safety assessment of chemicals. It would seem reasonable to anticipate a role in an individual’s susceptibility to toxic chemicals. The notion of a dynamic epigenome implies that variations in gene function and phenotype are modulated not only by DNA sequence polymorphisms, but also by reversible, but nevertheless stable, epigenetic changes. The epigenetic pattern is cell type specific, which distinguishes it from genomic polymorphisms, and thus could create cell type specific phenotypic variations between individuals and explain some aspects of target organ specificity and idiosyncratic responses.

Epigenetics provides a mechanism through which transient exposures to an environmental or occupational hazard may have persistent lifelong phenotypic effects. It may have potential implications in toxicology, for example non-genotoxic agents that have an epigenotoxic effect. Variations in epigenetic states could vary the response to toxic agents amongst individuals. Interestingly, individual variation may be tissue specific, so interindividual epigenetic variations could result from genetic differences as well as from exposures to different chemicals at critical periods throughout life. The concept is complex, but does suggest additional factors affect an individual’s susceptibility to toxicity other than genetic variations.

**SUMMARY**

It has been assumed to date that measurement of air concentrations of hazardous chemicals in the workplace is sufficient to adequately assess the health risks to individual workers. For most of these chemicals there are very few data on the factors affecting absorption, distribution, metabolism and elimination or the mechanism of toxicity in humans to justify this assumption. Toxicokinetic data suggest that for some compounds the degree of workplace exposure is not directly related to individual risk. Similarly, greater understanding of the mechanisms involved in the development of toxic effects in humans and the frequent discrepancies from the results of animal toxicity studies, indicate a need for more information from human studies. In addition, as with the effects on drug toxicity of genetic differences in drug metabolism, so the role of genetic polymorphisms in susceptibility to the toxic effects of hazardous chemicals must be defined. The application of more extensive human data in toxicology to the assessment of health risks in the workplace should not necessarily increase the complexity of controls, but will increase their direct relevance. Experience in the workplace can then be applied to the more contentious issues of general environmental exposure.

**Key points**

- The toxicokinetic profile of a chemical is an important factor in the health risk assessment process.
- Knowledge of toxic mechanisms in man enables better understanding of potential health effects.
- Interindividual variation in response to toxic exposures may have a genetic component.

**ACKNOWLEDGEMENTS**

The author is grateful to Dr SW Wilkison for expert advice on the dermal absorption section.

Risks and hazards in occupational and environmental exposures

ROBERT L MAYNARD

INTRODUCTION

Occupational physicians and hygienists identify hazards, estimate risks and seek to reduce both. The most direct way to assess a health risk to physical and chemical hazards arising in the workplace is through exposure assessment: this is also an essential tool by which an occupational physician can attribute a health problem to an individual’s occupation. For further details, the reader is referred to Chapter 4, Occupational exposure to hazardous substances (p. 43). This companion chapter provides an introduction to the concepts of risk and hazard assessment.

A hazard may be identified as:

A phenomenon, an act, a toxic substance or a living organism that can, but does not always, pose a threat to health. For example lightning, jumping, hydrogen cyanide, a lion or a bacterium.

Risk may be defined:

Risk is the probability of an adverse effect associated with a hazard. For example, the risk of being struck by lightning or of contracting tuberculosis.

In estimating risk, it is assumed that exposure to the hazard occurs. This is important: risk may be reduced to zero if exposure to the hazard is made impossible. Removing the hazard completely achieves this, reducing exposure to the hazard can achieve this if the reduction is complete, but this is less satisfactory (and less certain) than removing the hazard itself.

HAZARD IDENTIFICATION

Many, perhaps all, occupations involve exposure to hazard. Office work involves exposure to hazard: poor ergonomic conditions, stress, danger associated with repetitive movements, such as typing, etc. Industrial work is likely to involve exposure to greater hazards: moving machinery, chemicals, high temperatures, etc. In many cases, identification of hazards involves little more than common sense: a circular saw is a rather obvious hazard, as is a hydraulic press or a conveyor belt. Chemicals pose hazards, but these are less easy to recognize. Occupational health studies and toxicological work form the bases for identifying hazardous chemicals. In the case of most chemicals, hazards can only be identified by in vivo – laboratory animal – toxicological studies; in the case of genotoxic carcinogens, in vitro mutagenicity studies may be sufficient. However, discovering that a chemical poses a hazard is very different from estimating the risk associated with exposure to that chemical. In vivo studies may allow exposure or dose–response relationships to be defined: extrapolating from such data to estimates of risks in man is difficult, almost always impossible. Because of this, toxicological data tend to be used for identifying levels of exposure likely to be associated with low risk. The application of safety factors (better described as uncertainty factors) to the results of in vivo toxicological studies has long been used.
for this purpose. The use of such factors should not be confused with risk estimation. If we assume that a no adverse effect level (NOAEL) can be defined or estimated in animals then dividing this by ten, to allow for unknown factors that may control for interspecies variations in sensitivity, may yield a level of exposure unlikely to have effects in man. However:

- There is no guarantee that exposure to such a level of exposure will not have effects in man and
- There is no guarantee that greater exposure will have effects in man.

The assertion that exposure to the calculated level of exposure (NOAEL/10) is unlikely to have effects, can only be based on experience with other chemicals, and experience may be misleading.

It will be obvious that hazard identification based on animal studies is less satisfactory than that based on studies in man. Human data showing adverse effects on health of occupational exposure to chemicals used to be more commonly available than at present. We should be glad to know that modern standards of occupational hygiene have reduced access to such data. For some chemicals, data can be obtained from population studies if the general public is exposed to the chemical in question. This has been the case with common air pollutants. It is a fact that such studies, often large and therefore statistically powerful, reveal effects at levels of exposure well below those shown to produce effects in animal studies, volunteer studies or smaller scale occupational studies. For example, the World Health Organization (2006) Air Quality Guidelines for nitrogen dioxide and sulphur dioxide include the following recommendations:

- NO2: Annual average concentration: 40 μg/m³
- SO2: 24-hour average concentration: 20 μg/m³

In occupational circles, these would be regarded as very low and challenging guidelines. The reader is advised to examine the World Health Organization report for the justifications behind these figures. One important conclusion from the epidemiological studies that form the basis of the guidelines is that expected thresholds of effect may not be demonstrable at a population level. This conclusion has been generally accepted in the air pollution field and has serious implications for risk assessment. These include a move away from identification of no adverse effect levels as a substitute for quantitative risk assessment (QRA).

**RISK ASSESSMENT**

At its simplest, risk assessment involves deciding on whether a given level of exposure to a chemical is or is not associated with some risk of adverse effects on health. Such an assessment is of limited value unless it proves easy, or at least not too difficult, to prevent exposure entirely. As soon as questions about costs and benefits are raised, as they often are, the need for quantitative estimation of risk becomes pressing. Such estimates can be made on the basis of:

1. Real data that allow risks at relevant levels of exposure to be assessed – as in the air pollution field.
2. The use of predictive models.

The use of predictive models has been the cause of much debate among toxicologists.

Let us take an example. Studies conducted in occupational settings show that exposure to measured concentrations of some compound (for given periods) produce adverse effects. We need to be able to predict effects on exposure to lower concentrations. Thus, some form of extrapolation is needed. To the purist, extrapolation ‘beyond the data’ is always a risky process and one likely to be beset with errors. Some assumptions regarding the shape of the exposure (dose)–response relationship at low levels of exposure need to be made. If the mechanism of effect of the chemical is well understood, it may be possible to construct an equation that relates exposure to effects. In practice, this is very difficult and fitting a line to the available data and then producing or extending that line beyond the data is the common approach. However, we are, at once, in difficulties. Is there a threshold of effect and, if so, what is it?

Consider exposure to ozone, which may occur to workers in the chemical industry and to the general population as a ubiquitous air pollutant. Exposure to 120 ppb (240 μg/m³) without exercise produces a small change in indices of lung function, such as FEV1. Exposure to 80 ppb (160 μg/m³), with intermittent vigorous exercise, for about six hours produces small changes in FEV1. If we assume that the body has natural defences against the adverse effects of ozone (airway surface antioxidants such as reduced glutathione, vitamins C and E, and uric acid), we might reasonably assume that for each individual there was some level of exposure that would not produce an effect on FEV1. This is, in fact, widely assumed. However, it is known that levels of antioxidants in the airways differ from person to person and in some hardly any exists – at least in the upper airways (nose) where measurements have been done. If, in lieu of anything better, we assume that the level of antioxidant defences varies amongst people in a way that conforms to a normal distribution curve then, at a population level, the notion that a threshold of effect exists disappears. There is nothing revolutionary or surprising about this. The Probit slope, once used so widely in toxicology, is based on such assumptions and the now rather less used LD50 is derived from such thinking. Of course, the problem with such thinking is that the mid range of such curves inevitably tends to be better defined than the extremes of the curve and the confidence limits about the curve tend to veer away from the curve at its extremities. Even in a large toxicological study in animals one would expect to have much more confidence in the reliability of an LD50 value than in an LD1.0 or LD99 value.
It will be appreciated that we have moved away from predicting effects on a truly mechanistic basis to predicting them on a statistical basis. Statistical models have been extensively used in quantitative risk assessment of risks associated with exposure to genotoxic carcinogens. Many such models exist. Some are entirely statistical and are based on assumptions regarding the distribution of sensitivity in the population (Probit and Logit models); others are based on assumptions regarding mechanisms of effect or, rather, characteristics of mechanisms of effect as assumed in ‘one hit’ or ‘multi-stage’ models. However, all these models are just models and their predictions of effects or risks at low levels of exposure cannot be verified. Cannot? Well – cannot as yet. It is assumed that if mechanisms of effect were perfectly understood, then a perfect model could be constructed; this is still very far away.

A very simple model has been used by the World Health Organization in predicting unit risks for carcinogens. Let us examine the derivation of the unit risk for benzene. A cohort of workers studied in the United States by the National Institute for Occupational Safety and Health (NIOSH) comprised 748 workers who had been exposed to benzene in the production of rubber film material for 15 years. The cohort was followed for 25 years. Seven workers died from leukaemia. The expected number of deaths, based on national figures, was 1.25 and thus the relative risk was calculated as 5.6. The average duration of exposure was found to be 8.5 years and the average level of exposure was 30–300 mg/m³. Peak exposures of up to 2170 mg/m³ were recorded. So much for the data: it will be noted that the actual exposure was only rather inaccurately known and that peaks of exposure far above the average may have occurred. This raises the question of overloading of defence mechanisms by occasional very high exposures: an unresolved problem.

Now for the assumptions. It was assumed that exposure had been to 300 mg/m³ for 8.5 years. This was taken as equivalent to a lifetime exposure of:

\[
300 \times \frac{8}{24} \times \frac{240}{365} \times \frac{8.5}{70} \text{ mg/m}^3
\]

i.e. 8 mg/m³ (8000 μg/m³).

The unit risk was calculated as the increase in risk associated with lifetime exposure to 1 μg/m³ of benzene.

Let \( P_b \) = background risk (in this case 0.007). Then putting RR as the relative risk associated with lifetime exposure to 8000μg/m³ as 5.6:

\[
\text{Unit risk} = \frac{P_b \times RR - P_b}{8000} = \frac{P_b (RR - 1)}{8000} = \frac{0.007 (5.6 - 1)}{8000} = 4 \times 10^{-6}
\]

The unit risk was more accurately defined as the ‘incremental unit risk’.

It will be seen that the model used here is the simplest possible: it is entirely linear. No assumptions regarding ‘one hit’ or ‘multi-stage’ characteristics of the mechanism by which benzene causes leukaemia are included. The authors of the World Health Organization report recognized the assumptions made:

- Response (measured as relative risk) is some function of cumulative exposure.
- There is no threshold of effect for genotoxic carcinogens.
- Linear extrapolation of the dose–response curve towards zero gives the upper bound conservative estimate of the true risk function if the unknown (true) dose–response curve has a sigmoidal shape.
- There is constancy of the relative risk in the specific study situation. It was noted that in a strict sense, constancy of the relative risk means that the background age/cause specific rate at any time is increased by a constant factor. The advantage of the average relative risk method is that this needs to be true only for the average.

One important drawback of the method was noted: background rates vary from country to country and thus the incremental unit risk will also vary from one country to another. This should be borne in mind if the World Health Organization unit risk estimates are applied in calculations of benefits to health expected to be produced by reducing exposure to carcinogens.

**AMBIENT LEVELS OF CARCINOGENS**

It was noted by the authors of the World Health Organization report that the method outlined above was easy to use – easier than more sophisticated methods of extrapolation from the results of occupational studies to possible effects of exposure to ambient concentrations of carcinogens. The authors also pointed out that the use of more sophisticated models led to similar results to those obtained with the average relative risk model, as described above. This is an important but controversial point. The UK Department of Health Committee on the Carcinogenicity of Chemicals in Food, Consumer Products and the Environment (COC) in 1991 published a report entitled ‘Guidelines for the evaluation of chemicals for carcinogenicity’, which included a discussion pointing out that the application of a range of models produced very different predictions of the risk (expressed as number of cases of cancer per lifetime) for a given exposure to a carcinogen. The wide range of results caused the committee to question this quantitative approach. It should be noted, again, that the accuracy of predictions produced by all such models cannot be verified. Examination of the results yielded by different models show that the mechanistic ‘one hit’ model produced the largest risk estimate, for a given dose, of all the models examined. This model might be used to produce a worst case estimate of risk to a specified level of exposure. In 2003, the Committee on Carcinogenicity of Chemicals in
Food, Consumer Products and the Environment agreed that if human data were available and if groups of similarly acting compounds (e.g. PAH compounds) were being considered, then the ‘one hit’ model might form the basis for a ranking of carcinogenic potency. This is not at all the same as predicting risks, but can be useful in setting priorities for regulatory action.

EXPLAINING RISK: COMMUNICATING WITH THE PUBLIC

If estimating risk is difficult, communicating ideas about risk to the public is very difficult and failure is common. The following brief account draws heavily on a UK Department of Health Report ‘Communicating about risks to public health: pointers to good practice’. People respond to information about risks, including risks to health, in a variety of ways, sometimes unpredictably. Understanding the bases of these variable responses has been seen as a useful starting point for improving risk communication. Whether this has been startlingly successful may be doubted but what more rational basis for risk communication can be proposed? We shall consider a number of points.

Lay perspectives

It is generally believed that scientists (and doctors) adopt a critical approach to evidence bearing on causality. The hypothesis-testing approach to research, as advocated by Karl Popper, identified falsification of bold hypotheses, as a reliable, perhaps the only reliable, means of making scientific progress. This philosophy was embraced by distinguished scientists and philosophers, but disputed by others. This has led to the perception that scientists are instinctive non-believers, or falsifiers, in the causality of associations: until, that is, the hypothesis of non-causality is disproven. Put simply in this example, scientific method leads to a tendency for scientists to choose to believe that proximity of residence to high power cables is not associated with cancer until this assertion is disproven. Thus, the statistical framework used (the null, or no effect, hypothesis) can make it appear that scientists are themselves more interested in avoiding false-positive findings (type 1 errors) rather than false-negatives (type 2 errors) in situations of uncertainty. This can lead to conflict with public opinion. Many argue as follows: it is known that exposure to high concentrations of air pollutants, such as sulphur dioxide, causes bronchoconstriction, bronchoconstriction is a characteristic of asthma, therefore exposure to high concentrations of air pollutants causes asthma. Two points arise at once:

1. Is bronchoconstriction only seen in asthma?
2. Does the use of the word ‘causes’ imply induction of symptoms and signs associated with asthma or the induction of a permanent asthmatic state?

Many doctors would reply No to (1). Point (2) is more difficult, but many would agree that an episode of irritant-induced bronchoconstriction need not necessarily imply induction of a permanent asthmatic state. This may be disputed and reactive airways disorder syndrome (RADS) (see Chapter 40, Reactive airways dysfunction syndrome and irritant-induced asthma, p. 310) provides an example of how transient exposure to pollutants can induce long-lasting airways dysfunction. The phrase ‘need not necessarily’ is the key to the above assertion. Such words are commonly used and might well be used in a case such as this by many professional scientists or doctors. To the layman, their use is likely to be seen as an example of sophistry. Indeed, by including these words the assertion has been rendered vague and probably immune to falsification or, for that matter, confirmation. It seems to say: in some cases this may be true but it does not follow that it is true in all cases, or better, it does not follow that it must be true in all cases. In terms of Popperian logic, the assertion would be regarded as unscientific. An honest opinion would be that we do not know whether exposure to irritant air pollutants can, sometimes, induce asthma. The reader will have noticed a flaw in all this: asthma is not defined, except in the sense that it is not the only condition characterized by bronchoconstriction. Can asthma be defined? The layman might well say, yes of course: the diagnosis is made every day, by doctors. The respiratory physician might agree that this is certainly true, but might add that a universally acceptable definition of asthma is still awaited despite many international conferences on this subject. The layman is, by now, likely to be annoyed or alarmed: what began as an observation and an apparently simple proposition seems to have drowned in a welter of philosophical argument and dispute about terminology. He could hardly be blamed for saying: well, until the experts make up their minds, might it not be safer to assume that exposure to irritant pollutants can cause asthma? At first glance this seems a reasonable proposal; only when its implications are considered might we ask for better proof. We shall return to this point when the precautionary principle is considered.

Causality

It is widely accepted that mere association is not proof of causality. Less well known is that causality can seldom be proven. Following Popper, we may feel that causality can only be disproven. Causality is closely bound up with the concept of risk. We may say, using the example given above, that exposure to benzene is causally related to the development of leukaemia. The risk of developing leukaemia, however, as a result of a specified exposure benzene is less than 100 per cent. Why is this? Presumably individuals differ in their capacity to resist the effects of benzene: perhaps their DNA repair processes differ in efficiency. If this is the case, then increasing the exposure should increase the risk – let us assume this is so. Thus, we might argue that if the
exposure was increased sufficiently all those exposed would
develop leukaemia. Risk of developing leukaemia associ-ated with a specified exposure to benzene is thus an expres-sion of interpersonal variation. This sort of risk seems
different from the risk associated with random events. Interpersonal variability has nothing to do with the like-lihood of winning a lottery or being struck by lightning or
throwing a double six at dice. Yet, are the risks really so dif-
ferent? Perhaps the binding of benzene (or some metabolic
derivative) to a critical point on the DNA molecule is just
an event controlled by what we describe, in lieu of a better
explanation, as chance. The more often you throw the dice,
the more likely it is that you will get a double six eventually
(although the likelihood on each throw is unchanging);
the more benzene molecules to which you are exposed,
the more likely you are to develop leukaemia. Unless the
association between exposure to benzene and leukaemia is
causal however, the risk of developing leukaemia as a result
of exposure to benzene must be zero. Deciding on causality
must, therefore, precede any discussion of risk.

Discussion of causality is bedevilled by one particular
 misconception. This is that the nine characteristics or fea-
tures of causal associations set out so clearly by Sir Austin
Bradford Hill are singly, or in total, tests of causality.
The features defined by Bradford Hill were:

1. Strength of association
2. Consistency (of observed associations)
3. Specificity
4. The relationship in time
5. The biological gradient
6. Biological plausibility
7. Coherence of the evidence
8. The experiment

We might contend that (8) and (9) are not features or char-
acteristics of causal associations but, rather, lines of evidence
or argument that might be advanced in support of the con-
tention that an association is causal. It is not possible to dis-
cuss all these features here. A few points, only, will be made:

• There is no a priori reason why a strong association
should be more likely to be causal than a weak associ-
ation. But, as Bradford Hill pointed out, if a strong asso-
ciation is actually caused by a confounding factor
closely associated with the proposed causal agent, then
that factor should be easily identifiable. It follows that
if the association is weak, but caused by some weak
confounding factor, then that factor may be difficult to
identify. This is Popperian: Bradford Hill is saying that
the putative causality of a strong association is more
easily falsified than that of a weak association.

• Specificity. Bradford Hill argued that a specific effect
was more likely to represent the operation of causal
association than a number of different effects. Put
simply, if a is found to be associated with b, then the
association is more likely to be causal than if a is found
to be associated with b, c, d and e, etc. I accept this point,
but propose a modification: if a is found to be only asso-
ciated with a single mechanism of effect, then though a
is found to be associated with b, c, d and e, etc., the asso-
ciation remains likely to be causal. In the air pollution
field, the generation of free radicals has linked exposure
to particulate air pollutants with a range of outcomes.
The specificity of mechanism seems, to me, to support
the case for causality.

• Biological plausibility. Bradford Hill argued, cogently,
that this characteristic should not be demanded. An
association may be demonstrated long before it can be
explained. This has sometimes proved a difficulty for
toxicologists who perceive that their efforts cannot
refute the findings of epidemiological studies: they can
only support them or fail to explain them. Of all the
characteristics of causal associations discussed above,
only temporal plausibility seems an inevitable require-
ment. The horse must be seen to precede the cart, but as
Bradford Hill acknowledged, this presupposes that the
cart can be confidently distinguished from the horse.
This is not always easy. It was pointed out above that
causality cannot, perhaps, be proven: the possibility of
an undetected confounding factor playing a part can
never be completely disregarded. Thus, discussion
focuses on the strength of belief in the hypothesis of
causality. This difficult area was not discussed by
Bradford Hill. In describing levels of certainty, descrip-
tive terms such as ‘probably’, ‘possibly’, ‘unlikely’ etc.,
are often added to the term ‘causal’. These do not lend
themselves to quantification, but it will be seen that
uncertainty here needs to be combined with the risk
estimate used to predict the likelihood of effects at an
individual or population level. Attempts to refine the
wording used to convey uncertainty regarding causality
have sometimes led to confusion.

The following series indicates a declining level of confi-
dence in causality:

• imprudent not to regard the association as causal;
• prudent to regard the association as causal;
• not imprudent to regard the association as causal;
• not prudent to regard the association as causal;
• imprudent to regard the association as causal.

The first of these formulations was used some time ago
in a report by the Committee on the Medical Effects of
Air Pollutants (COMEAP)11 and provoked criticism that
the committee was taking refuge in a double negative: so
much for subtlety! Of course, it might have been easier had
the committee’s level of confidence in causality been
scored from 1 to 5 or from 0 to 4. Why is this important?
The answer is because it bears on the application of the
precautionary principle as a device with which to manage
risk.
The precautionary principle

Few principles are less well understood than the precautionary principle. It is well described by Foster et al. The precautionary principle is designed to help the risk managers in the face of uncertainty. The government health and safety or environmental regulatory agencies are entrusted with developing policies (at a national, local or individual scale) to limit risks. They should not be confused with the scientists who attempt to define the risk in a given situation, whether they be epidemiologists or toxicologists. In essence, the precautionary principle urges the risk managers not to wait for the perfect proof before acting to reduce risk if, and this is important, inaction could lead to serious effects. What is seldom remembered is that the precautionary principle is qualified by the following points:

- **Proportionality**: measures taken should not be disproportionate to the desired level of protection and must not aim at zero risk.
- **Non-discrimination**: comparable situations should be treated similarly.
- **Consistency**: across problems and with cases where data are available.
- **Costs and benefits**: where possible these should be taken into account.
- **Examination of scientific developments**: provisional responses may be appropriate.

The cynical reader will not find it difficult to believe that these caveats were written within the European Commission. Yet they are important: without them the precautionary principle could become a charter for those pressing for action in every case of a postulated association between an alleged cause and a supposed effect.

One point of not entirely semantic confusion has been generated by equating the terms ‘cautious’ and ‘precautionary’. The scientist assessing causality and/or risk should exercise proper scientific caution in his work. Caution is implicit in the current paradigm of research: hypothesis based, evidence driven and taking note of such guidance as is provided by Bradford Hill’s work. ‘Precautionary’, on the other hand, applies to the work of the risk manager using the scientist’s properly cautious conclusions as a basis for developing policies. The scientist undertaking risk assessment need not concern himself with ‘precaution’.

**Why explaining risk is difficult**

Explaining anything is made easier when the recipient of the explanation trusts its provider. In the risk-communication field, trust may be lacking. It is useful to consider why this may be so:

- Experts no longer command automatic trust, irrespective of how genuine their expertise may be. The reasons for this generally accepted observation are not completely known, but scientific overconfidence, unfulfilled expectations (a cure for cancer, for example) and the entirely correct tendency for experts to modify their views as evidence changes, may all play a part. A reluctance on the part of some experts to show how they arrive at their conclusions also inspires doubt.
- Even less trusted than ‘the experts’ are the risk managers. Their task is a hard one in that risk management is far from an exact science and many of the factors taken into account defy precise, or at least quantitative, definition. It is certain that people want to know how a decision was taken: who contributed to it, who influenced it, who benefited from it, was it taken openly or ‘behind closed doors’?
- Peoples’ perceptions of risk vary with the specific risk being considered. This is sometimes described as loading of the actual risk by ‘fright factors’. Much work has been undertaken to identify such factors and the following list is probably incomplete (see, for example, Slovic et al.).

Perceptions leading to increased worry are listed below:

- involuntary or imposed risk;
- inequitably distributed risk;
- inescapable risk;
- unfamiliar risk;
- man-made as opposed to natural causes of risk;
- capacity to cause hidden or irreversible effects;
- risks that affect future generations;
- a form of death or illness that inspires dread, e.g. cancer;
- damage to identifiable, rather than anonymous victims;
- poorly understood by science;
- subject to contradictory statements from responsible sources or, even worse, from a single source.

These various factors combine to control the extent to which specific risks tend to be the cause of worry. We might write: worry = risk × fear (risk here being calculated or objective risk). Additionally, we might define acceptability of risk as:

\[
\text{Acceptability} = \frac{1}{\text{worry}} = \frac{1}{\text{risk} \times \text{fear}}
\]

The extent to which people worry about risks leads to misperceptions of the magnitude of specific risks. Overestimation of risks is common in examples such as risks from nuclear power, floods or tornados; underestimation is common with such risks as heart disease, obesity, accidents at home.

**Social amplification of risks**

The public’s reaction or response to information about risk can be difficult to predict: sometimes the information seems to sink without trace, on other occasions something
akin to panic occurs. This is discussed at some length in the Department of Health report. One factor controlling this is the response of the media to an announcement about a risk to health. Media responses are themselves, seemingly, controlled by factors: media triggers. The Department of Health report identified the following:

- blame;
- secrecy and cover ups;
- human interest;
- links with high profile issues or personalities;
- signal value;
- many people potentially at risk;
- strong visual aspects;
- links to sex or crime.

These factors reflect, no doubt, upon our natures as much as upon the media per se: it is likely that combinations of these factors attracted interest in Rome or Athens in classical times as they do now. Signal value is an interesting factor: this implies that the event or risk is taken as indicating that ‘the same thing’ could happen elsewhere. Put simply: if the experts have been wrong about ‘X’ what else could they be wrong about?

CONCLUSIONS

‘Risk’ is a difficult topic. The usual paradigm of hazard identification, risk assessment, risk management is well understood, although risk communication should be added as an essential component of risk management. Each step presents problems, but those associated with the earlier steps tend to be less difficult than those occurring later. The public perceives risk differently from professional scientists and regulators: if this is not understood, risk communication can be a disaster.

Key points

- Hazard should not be confused with risk. Hazard implies the potential to cause harm. Risk specifies the likelihood of harm occurring.
- Hazard identification is usually dependent on toxicological studies; estimation of risk more often involves epidemiological approaches.
- Methods for predicting risks associated with exposure to carcinogens have been developed. Such methods, although widely used, are not without problems and the accuracy of the predictions is difficult, or impossible, to confirm.
- Causality is an important concept in assessing evidence linking exposure to chemicals with potential effects. Causality is difficult, perhaps impossible, to prove.
- The precautionary principle is often misunderstood: it is not a carte blanche for action in the presence of doubt.

PROPERTIES OF METALS

The term ‘metal’ refers to those elements in the periodic table (of just over a hundred elements) that have specific characteristics. They are good conductors of heat and electricity; they are bright, shiny and malleable; and they produce a ringing sound when struck. Metals lose electrons to form cations, and the resulting electropositivity gives it an affinity to bind with sulphur, chlorine and other non-metals to form compounds. Alloys are formed from a homogenous mix of metals with other elements. Examples are brass (copper and zinc), bronze (copper and tin) and steel (iron and carbon). These often have physical properties that are different from their components. The term ‘superalloy’ has been used for alloys with excellent mechanical strength, and the ability to resist deformation at high temperature. Many superalloys are based on nickel or cobalt. Metalloids are elements such as antimony, arsenic, polonium and tellurium. They have properties in between those of metals and non-metals. Some metalloids with documented health effects on humans have been included in this chapter.

Gold, silver, copper, iron, tin, lead and mercury have been mined and used extensively before and during the times of the ancient Greek and Roman civilizations. Today, metals have considerable benefits for industry, for example in engineering, construction, electronics and for dental and pharmaceutical applications. However, they have also been well recognized as a cause of human health effects, and adverse effects on the environment. Measures to limit occupational exposure, while allowing safe use of metals and their compounds remains an ongoing challenge for industry.

TOXICITY VERSUS ESSENTIALITY

A number of the metals considered to be toxic in an occupational setting are essential for some metabolic processes in humans. Examples of essential metals are iron (for haem synthesis), copper (for enzymes such as ceruloplasmin and cytochrome-c oxidase), zinc (for development of skin, hair and nails), cobalt (in cyanocobalamin or vitamin B12), manganese (for transferases), and magnesium (cofactor for enzymes). These metals create a dilemma in terms of the extent to which overexposure and intake should be reduced to balance toxicity against deficiency. In theory, the U-shaped relationship between dose and effect can be used to determine the ideal range for exposure and intake levels which will prevent deficiency, as well as toxicity.

The toxicity of any metal depends upon a number of factors, including:

● those related to the nature of the metal, e.g. the chemical species, including its valency and particle size;
● exposure circumstances, the route of exposure, the mode of entry to the body, other concomitant exposures, use of protective equipment; and
● the reaction of the body to the metal, and the capability for clearance.

Absorption from the lungs is generally more effective than from the gut. About 40 per cent of an inhaled dose of a metallic aerosol may be retained in the lungs, whereas usually only 10 per cent or less of an ingested dose will be absorbed. Other than particle size and solubility, relatively few factors affect uptake from the lungs. Only particles that are of respirable size of around 4 μm or less penetrate to the
alveoli and thus become available for absorption from the lungs. The uptake of metals from the gastrointestinal tract varies inversely with age. This is especially relevant in younger workers and in parts of the world where child labour continues to exist. Interactions with other constituents of the diet can affect the rate of uptake from the gut. For example, the absorption of lead varies inversely with the amount of calcium and iron in the diet and it may also be influenced by the presence of fat, protein and vitamin D in the gut. The uptake of cadmium is affected by the zinc content of the diet and that of manganese by the iron content.

Recognition of ‘speciation’ is fundamental to the understanding of metal toxicology. Chemical species refers to chemically identical molecular entities, such as specific compounds of a metal or specific forms or isomers of a compound. The concept of speciation includes the organic and inorganic compounds, as well as the elemental metal, and is based on the expected differences in physical, chemical and toxicological properties of different metal species. Toxicity is related to physicochemical characteristics, such as solubility and valency. As a general rule, the water-soluble forms are associated with acute toxicity, and may be cleared more easily by the body compared to water-insoluble compounds which tend to be retained for longer periods in bones and tissues. However, those forms that are slightly soluble in the biological matrix, if they allow a slow release of toxic ions, are frequently associated with chronic diseases, such as fibrosis or malignancy. Several metals can exist in different valency states, with properties differing depending on the valency. The valency of a metal refers to the maximum number of hydrogen or chlorine (or univalent) atoms that may combine with one atom of the element. It has also been defined as the number of chemical bonds formed by the atoms of a specific element. Iron, for example, can exist as ferrous (valency 2) or ferric (valency 3) forms. Chromium has a range of valencies, including trivalent, hexavalent and other rarer valency forms. Trivalent chromium is considered essential, while several hexavalent chromium compounds are toxic and carcinogenic.

DIAGNOSIS OF METAL POISONING

For a diagnosis faced with a case of possible metal poisoning, the diagnosis of occupational metal poisoning is not always easy, for few cases present as clear clinical entities and, usually, an occupational cause will be part of a list of different possibilities. Exposure to a metal (or, indeed, any other substance) at work does not prove that it is the cause of the patient’s illness. The diagnosis often depends on the balance of probability. The higher or greater the extent and duration of occupational exposure, the more likely it is to be a cause of the illness. Epidemiological studies may provide evidence for the range of exposures that are relevant, but when an individual patient is being assessed, an additional difficulty is that there may be considerable individual variation in susceptibility. It is therefore necessary to obtain reliable information, as explained in Chapter 1, Donald Hunter and the history of occupational health:

Some metals, such as iron, copper, zinc, cobalt, manganese and magnesium, are essential for metabolic function, although overexposure causes harm (a U-shaped dose–response relationship). Metal toxicity is dependent on factors related to the agent (speciation, physical and chemical properties), the circumstances of exposure and the body’s reaction. A diagnosis of metal poisoning requires confirmation of the nature, extent and duration of exposure.

ACKNOWLEDGEMENTS

The editors would like to acknowledge those individuals who contributed material to the Metals chapters in the eighth and ninth editions of Hunter’s Diseases of Occupations, some of which may persist in updated form or otherwise here.

FURTHER READING

Aluminium (Al) is the most abundant metal and the third most abundant element in the earth’s crust, mainly in combination with oxygen, fluorine and silicon. It is not considered to be an essential trace element for humans.

Aluminium is a light metal, which is used more widely throughout industry than any other non-ferrous metal. Its major applications are in transportation, building and construction, packaging and electrical equipment. Aluminium and its compounds have numerous other applications, for example, in paints, fuel additives, explosives, fireworks and powder metallurgy (aluminium powder); in the manufacture of abrasives, refractories, ceramics, catalysts, paper, artificial gems, glass and heat-resistant fibres (aluminium oxides); in water purification (as alum, bentonite, zeolite); in (para)pharmaceutical products (antacids, astringents, antiperspirants, vaccines, dental products, as aluminium hydroxide and aluminium chlorohydrate) or as food additives (preservatives, fillers, colouring agents, emulsifiers, baking powders).1–3

In such settings, workers are exposed not only to aluminium, but also to caustic mist, hydrogen fluoride, particulate fluorides, perfluorocarbons, polycyclic aromatic hydrocarbons, sulphur dioxide, carbon dioxide and monoxide, and carbon dust. Exposure in secondary smelting is not well characterized; many pollutants have been identified including thermal degradation products of polyvinyl chloride, lubricants or petrol modifiers. Occupational exposures of concern appear to be inhalable dust, fluoride salts, lead, aluminium and manganese.4,5

Once formed, aluminium is alloyed with other materials (iron, silicon, zinc, copper, magnesium) to make an array of alloys with different properties which can be rolled, cast and extruded. Aluminium founding includes a number of different casting techniques (mainly sand and die casting), alloys, additives to melt, and binders in cores and moulds, all contributing to very heterogeneous exposures. In sand foundries, exposure to high levels of total dust and silica occur, as well as exposure to furfuryl alcohol and dimethylethylamine. High levels of mineral oil mist can be measured during die casting.5,6

Aluminium powder is generally produced by atomization in air or inert gas, which forms particles of different shapes (irregular, spherical) and sizes (from coarse to superfine). Aluminium powders can be treated with materials such as isostearic acid or other lubricants to minimize surface oxidation or coated with polystyrene to reduce or eliminate the fire hazard.1,2

Welding of aluminium creates submicron-sized particles, but depending on the process and materials used, the elemental composition of total and respirable fume/dust may differ considerably.
**KINETICS**

Gastrointestinal absorption of aluminium is low (<0.5 per cent), but it depends on the chemical species and solubility and the simultaneous presence of ligands in the gut. Ligands such as citric acid (or other carboxylic acids) enhance uptake, while phosphate and silicon-compounds reduce it.\(^7\)–\(^9\)

Occupational exposure to aluminium fumes, dusts and powder has resulted in increased serum and urinary levels of aluminium providing indirect evidence for inhalation absorption. The bioavailability is likely to be dependent on Al species and particle size of the inhaled material. Biokinetics investigations with \(^{26}\)Al oxide particles and occupational exposure studies suggest an inhalation absorption rate of about 1.5–2 per cent. It is suggested that inhaled nanoparticles could reach the brain through the nasal–olfactory system, bypassing the blood–brain barrier.\(^3\)–\(^7\),\(^9\)

In plasma, Al is transported in high molecular weight complexes, mainly bound to transferrin. Less than 10 per cent is associated with low molecular mass compounds (citrate). There is evidence that transferrin can mediate Al transport across the blood–brain barrier.\(^9\),\(^10\)

About 2 per cent of Al entering the blood is retained within the body for years, but the remainder is rapidly excreted, mainly in urine (>95 per cent),\(^7\) explaining the higher susceptibility of subjects with renal insufficiency to Al toxicity. Aluminium is distributed in the body in bone (60 per cent), lung (25 per cent), muscle (10 per cent), liver (3 per cent) and brain (1 per cent).\(^3\)

Reported urinary half-lives in occupationally exposed subjects range from days to months or even years depending on the duration and the type of exposure. A mono-exponential decay in both urine and plasma, with half-lives of 136 and 162 days, was calculated in a welder exposed to aluminium.\(^11\)

In prolonged exposure, clearance is characterized by multiple half-lives. Endogenous release of Al from compartments with slow elimination kinetics (i.e. bones) and the progressive resorption of sparingly soluble particles trapped in lungs could explain why elevated urinary Al excretion can be measured for years after cessation of exposure.\(^1\),\(^2\),\(^13\)

**TOXICITY**

**Respiratory manifestations**

A wide spectrum of respiratory symptoms and diseases, including interstitial fibrosis, pneumoconiosis, asthma, granulomatous disease, chronic obstructive disease, emphysema, desquamative interstitial pneumonia, and pulmonary alveolar proteinosis has been ascribed to occupational activities involving exposure to aluminium dust or fumes. Reports are often based on small numbers of cases, which limits their interpretation, and there is no consensus with regard to the causal role of aluminium in the occurrence of these effects.

Pulmonary fibrosis has been observed, in the past, in bauxite and potroom workers, as well as in workers engaged in the manufacture of alumina abrasive.\(^3\),\(^14\) It is very likely that simultaneous exposure to silica was the causative agent. Recent epidemiological studies provide little evidence of a serious adverse effect on the respiratory health associated with exposure to bauxite in an opencast mine or to alumina in refinery workers in present-day conditions.\(^15\),\(^16\)

Aluminium was given prophylactically to some Canadian gold and uranium miners between 1944 and 1979, in the mistaken belief that it prevented silicosis. Men were exposed to 20 000–34 000 ppm of ‘McIntyre powder’, consisting of 85 per cent aluminium oxide and 15 per cent aluminium for ten minutes before each shift. Follow up over 22 years has not revealed any cases of pulmonary fibrosis and the pattern and the prevalence of respiratory disease were similar to those in gold miners who had not been exposed to aluminium.\(^17\)

A number of cases of pulmonary fibrosis associated with occupational exposure to aluminium powder have, however, been reported.\(^3\),\(^18\)–\(^21\) As conflicting study results were published, it was speculated that factors such as particle size, density of the dust, and presence or absence of stearic acid (thought to be protective) or mineral oil (associated with fibrosis) were relevant to the development of pulmonary fibrosis.\(^11\),\(^14\),\(^22\)–\(^24\)

Krewski et al.\(^3\) identified an airborne aluminium powder concentration of 50 mg/m\(^3\) as a level at which adverse effects have been observed (end point: irritation). However, high-resolution computed tomography revealed lung fibrosis changes in aluminium powder workers exposed to lower levels. Biological monitoring in plasma and urine revealed higher internal exposure to Al in affected workers (33.5 \(\mu\)g/L plasma to 15.4 \(\mu\)g/L plasma) and (340.5 \(\mu\)g/g creatinine to 135.1 \(\mu\)g/g creatinine in urine).\(^24\),\(^25\)

A number of studies have demonstrated an association between aluminium smelting and the development of an asthma-like syndrome.\(^3\),\(^26\)–\(^31\) The reported incidence varied from 0.06 to 4 per cent of exposed workers per year. It is still unclear whether ‘potroom asthma’ is related to exposure to respiratory irritants, such as hydrogen fluoride, particular fluoride, chlorine, sulphur dioxide, inspirable dust exposures, carbon dust or a specific reaction to aluminium.\(^3\),\(^29\)–\(^33\) Inhalation challenges in an aluminium foundry worker\(^34\) and an aluminium welder\(^35\) provided evidence that aluminium can cause asthmatic reactions.

**Central nervous system**

The toxicity of aluminium to the central nervous system of human beings is supported by reported cases of iatrogenic aluminium intoxication. Very high plasma/serum
aluminium levels caused by haemodialysis, oral consumption of large amounts of Al-containing antacids/phosphate binders by individuals with impaired renal function, as well as irrigation of the urinary bladder with massive amounts of alum to stop haemorrhaging or reconstructive otoneurosurgery with Al-containing material have resulted in encephalopathy (dialysis dementia, a degenerative neurological syndrome, characterized by the gradual loss of speech, motor and cognitive functions).

Cross-sectional studies investigating the neurological effects of Al in occupationally exposed workers have provided controversial results. Some data support the hypothesis of a relationship between chronic aluminium exposure in welders and subclinical neurological effects (impairment on neurobehavioural tests) or an increased incidence of subjective neurological symptoms. However, there is still no firm conclusion as to whether occupational aluminium exposure can result in neuropsychological disorder. In an investigation on steel welders in shipyards, Riihimaki et al. reported a threshold for central nervous system adverse effects in the concentration range of 108–162 μg/L urine and 6.75–9.5 μg/L in serum. A longitudinal study over a period of four years in welders, in the train and truck construction industry, did not support a neurotoxic effect of aluminium at a level of 88–140 μg/L plasma in urine and 13–16 μg AL/L plasma (preshift samples) and a mean exposure of 15 years. No neurological effects related to the exposure to aluminium were found in smelters (Al-urine, median 4.0 μg/L; range, from detection limit up to 34 μg/L), aluminium welders (median, 22.0; range, 4–255) and a small group of flake powder production workers (median, 83.0; range, 12–282). Data from Letzel et al. indicate that chronic exposure to Al, in an Al powder plant, at median (range) level up to 110 μg/L (5–337), 87.6 μg/g creatinine (4.6–605), and 8.7 μg/L plasma (5.1–25) did not induce measurable cognitive deficits. According to a review by Krewski et al., evidence of an association between inhalation exposure and neurological effects is limited. However, a meta-analysis on neurobehavioural data obtained by epidemiological studies in occupational settings concluded that there is converging evidence from different studies that urinary Al concentrations below 135 μg/L urine have an impact on cognitive performances.

Despite numerous epidemiological studies investigating the possible relationship between Al levels in drinking water and Alzheimer’s disease, the association is highly controversial and although it cannot be excluded that it may play a role in the disease, the available data do not indicate that aluminium has a causal role.

**Medical surveillance**

Workers exposed to Al dusts or fumes should be submitted to periodic health checks, including clinical examination with special attention to the lungs and central nervous system. Depending on the clinical findings from such surveillance, pulmonary function testing, periodic chest radiographs and neuropsychological testing may be considered as additional investigations.

Al concentrations <5 μg/L serum and <30 μg/L urine are generally expected in the general population. Analysis of serum concentration is performed for follow up of aluminium status in dialysis patients. Routine biological monitoring in occupationally exposed workers is recommended by some authors. Samples collected immediately after a work shift are strongly related to the current exposure, whereas samples taken later after exposure (e.g. Monday morning after a weekend free from exposure) are more likely to reflect the body burden of aluminium. The Deutsche Forschungsgemeinshaft adopted 200 μg/L urine (end of shift sample) as a biological tolerance value based on a MAK value of 6 mg/m³ for welding fumes (Al 2.34 mg/m³). The biomonitoring action limit recommended by the Finnish Institute of Occupational Health is 160 μg/L urine (Monday morning sample). However, data are scant and it is not known how well serum and urine concentrations of aluminium reflect the concentrations in the target tissues among workers exposed to different species of aluminium. Moreover, because Al is ubiquitous, great care should be taken to avoid contamination at all stages of sampling and analysis.
Aluminium (Al) is ubiquitous, but it has no known physiological function in humans.

Accumulation of Al caused by dialysis with Al-contaminated dialysate often with concurrent intake of Al-containing drugs has resulted in encephalopathy and osteomalacia.

A wide spectrum of respiratory effects (e.g. interstitial fibrosis, pneumoconiosis, asthma) has been ascribed to occupational activities involving exposure to Al dust or fumes; there is no consensus with regard to the causal role of Al.

Subclinical neurological effects (impairment on neurobehavioural tests) have been reported in Al-exposed workers, however this has not been consistently observed across studies. There is no evidence for bone toxicity in Al workers.

The possible association with Alzheimer’s disease is highly controversial.

References

Antimony was previously one of a group of important occupational toxins, but is now largely of historical interest in the workplace setting. While this is true in most developed countries, where good workplace control has eliminated antimony as a major cause of disease, this is not necessarily the case in newly developing countries.

Antimony is a brittle, silver-white metalloid, usually obtained from the sulphide ore stibnite, which is mined in many counties worldwide. It is mixed into alloys and used in solder, sheet and pipe metal, motor bearings, castings, semiconductors and pewter, and is a byproduct of smelting lead and other metals. Antimony oxide is added to textiles, plastics, rubber, adhesives, pigments and paper to prevent them from catching fire. It is also used as a flame retardant for plastics, paints, textiles, paper, rubber and adhesives, in the form of the trioxide.

Antimony and its compounds have been found to cause several health effects in miners and other exposed workers, although these are less common now in the United Kingdom and other developed countries. Such effects included irritation of mucous membranes, dermatitis (antimony spots), nose bleeds, gastrointestinal symptoms, bronchitis and a simple pneumoconiosis, characterized by fine nodular opacities close to the hilum with little effect on lung function. Antimony can also form another compound, stibine (SbH₃), which is known to cause a profound haemolytic anaemia, similar to that caused by arsine.

The International Agency for Research on Cancer (IARC) has concluded that antimony trioxide is possibly carcinogenic to humans (group 2B) on the basis of sufficient evidence in experimental animals and inadequate evidence of carcinogenicity in humans. One problem with epidemiological studies of antimony-exposed workers is that the workers are often exposed to several other metals, such as arsenic, a known cause of cancer. The American Conference of Governmental Industrial Hygienists (ACGIH) has set a threshold limit value (TLV) of 0.5 mg/m³ and considers antimony to be a suspected human carcinogen.

Key points
- Antimony can cause respiratory effects such as irritation and a form of simple pneumoconiosis.
- Other effects include a type of dermatitis and gastrointestinal symptoms.
- In the form of stibine, antimony can cause a profound haemolytic anaemia.

Arsenic

MALCOLM R SIM

Arsenic is one of a group of previously important occupational toxins, but which is now largely of historical interest in the workplace setting. While this is true in most developed countries, where good workplace control has eliminated this group as a major cause of disease, this is not necessarily the case in newly developing countries. In addition, inorganic arsenic has become more important as a cause of disease in the environmental health setting, as its importance in the workplace has waned.

Arsenic is a metal which has been known since antiquity, but it differs from other ancient metals in that it was not extracted and used in its elemental form, but is used in compounds such as sulphides. It occurs as an impurity in the ores of other metals, such as copper, lead and zinc, and has been found in considerable quantities in some bronzes from archaeological sites. Arsenic can be found in industry in its inorganic or organic forms, but the inorganic forms have been the most important in terms of worker exposure and toxicity, especially the trivalent forms.

Most current inorganic arsenic exposure in the workplace occurs through the application of pesticides and herbicides, metal smelting, timber treatment and in the chemical and pesticide manufacturing industries. Another traditional use is in pigments such as Paris green (cupric acetoarsenite) and Scheele's green (cupric arsenite). In the middle of the nineteenth century, the use of these pigments was so common that chronic arsenical poisoning from their dusts was widespread.

Chronic, rather than acute, poisoning is the more common form of arsenic poisoning in the occupational setting and can affect many systems of the body, causing hyperpigmentation and hyperkeratosis in the skin, a sensorimotor peripheral neuropathy, megaloblastic anaemia, hepatotoxicity and liver cirrhosis. Many of these effects are caused by arsenic reacting with the thiol groups of proteins and enzymes and inhibiting their catalytic activity. While these non-malignant effects of inorganic arsenic exposure are becoming less common in developed countries, there is still concern over their impact in low to medium income countries. There is no effective treatment for chronic arsenic poisoning, but removal from exposure can help to at least partially reverse some of these effects.

While the health impact of inorganic arsenic in the workplace setting is waning in many countries, arsenic has become a major cause of ill health throughout the world in many communities through contamination of drinking water. While such effects were first documented in Taiwan, in more recent times the country with the highest degree of exposure over a substantial proportion of its population is Bangladesh, where exposure occurs through drinking contaminated water from the millions of tube wells widely used in rural areas of the country. Elevated levels of arsenic in drinking water have also been documented in communities in many other countries across most continents, including India, Chile, Mongolia, Mexico and countries in Eastern Europe. Arsenic in drinking water in Bangladesh has led to widespread health effects, such as arsenical keratosis and alterations in skin pigmentation in the exposed population, and considerable public health concern has been raised for action to deal with this problem. The contamination in Bangladesh groundwater has been thought to be naturally occurring, but recent evidence suggests that this may be contributed to by man-made ponds.

Arsenic has a half-life in blood of approximately 60 hours and about 75 per cent of absorbed inorganic arsenic is excreted as methylated forms, which are less toxic than inorganic arsenic and so this in vivo methylation represents a true detoxification process. With normal renal function, the biological half-life of arsenic in the urine after exposure to inorganic arsenic is between one and two days. Therefore, urinary arsenic monitoring, preferably with a 24-hour sample and corrected for creatinine, is the most
appropriate method for monitoring inorganic arsenic absorption in workers. Monitoring arsenic in serum, hair or nails is considered to be a less reliable method.

Arsenic has been considered by the International Agency for Research on Cancer (IARC) and has been classified as a definite (group 1) human carcinogen as there is sufficient scientific evidence to cause cancer of the lung, skin and bladder, with the mechanism thought to be via oxidative DNA damage. Although cancer is currently the primary end point of interest and is usually used as the basis for setting occupational and environmental exposure limits, associations have been found between inorganic arsenic exposure and other important human diseases, such as diabetes and adverse reproductive outcomes.

The American Conference of Governmental Industrial Hygienists (ACGIH) has set the threshold limit value (TLV) for inorganic arsenic at 0.01 mg/m³ and has set the biological exposure index (BEI) for inorganic arsenic and its methylated metabolites at 35 μg/L. For the latter, it is recommended that the urine sample be collected at the end of the working week.

Key points

- The main malignant effects from occupational exposure to arsenic are cancers of the lung, skin and bladder.
- Non-malignant health effects from workplace exposure are less common in developed countries, but are still a concern in low and medium income countries.
- Inorganic arsenic in drinking water is a major cause of hyperkeratosis and changes in pigmentation of the skin, and other ill effects in Bangladesh and other countries.

Beryllium

LEE S NEWMAN AND HOLLY M CHRISTENSEN

Chemical and physical properties 162
Compounds and alloys 162
Production and use 162
Exposure and health effects 163

CHEMICAL AND PHYSICAL PROPERTIES

Beryllium has chemical and physical properties that make it desirable for high technology applications, but which unfortunately lead to pernicious use of this highly toxic metal. The fourth lightest element (atomic weight, 9.012), beryllium is corrosion resistant, non-sparking, non-magnetic, has a low density (1.85 g/cm$^3$), is heat resistant (melting point, 1278°C), and has high tensile strength and thermal conductivity. Beryllium differs chemically from other alkaline-earth metals, forming covalently bonded compounds rather than ionic.$^1$

COMPounds AND ALLOYS

Beryllium is found in industry in many different forms. Beryl and bertrandite ore are processed into beryllium hydroxide, which is used to produce beryllium metal, alloy and oxide. Chemical forms of beryllium include beryllium salts, sulphate, fluoride and chloride. Beryllium is most commonly alloyed with copper, aluminium and nickel.$^2$

PRODUCTION AND USE

The United States is the leading producer of beryllium metals, alloys and oxide. The applications for beryllium and its alloys are widespread, including use in aerospace, the automotive industries, dental alloys, electronics, computers, nuclear weapons and telecommunications. Bertrandite is extracted via open-pit mining. The ore is leached with sulphuric acid to form beryllium sulphate, which is converted to basic beryllium carbonate by reaction with aqueous ammonium carbonate. Subsequent heating yields beryllium hydroxide, which is the basis for metal, alloy and oxide production.

Beryllium oxide is prepared by calcining beryllium hydroxide and has applications in the automotive, electronic and computer industries. As a ceramic, it is an excellent heat conductor and can be used as an electric insulator in automotive ignition systems, lasers, electronic circuits for computers, heat sinks and microwave oven components. Pure beryllium metal is used primarily in aerospace, nuclear and defence applications because of its stiffness, light weight and temperature stability. The metal is an integral part of nuclear reactor technology because it is an excellent neutron reflector and moderator. Beryllium is used in nuclear weapon triggering devices because it emits a large number of neutrons when bombarded with alpha radiation.

The most common alloy, beryllium-copper (up to 4 per cent beryllium), is obtained by fusing beryllium oxide with copper and has many desirable properties including strength, high electrical conductivity, high fatigue strength, wide temperature tolerance, high elasticity and corrosion resistance. Beryllium–copper alloys are useful in parts subject to abnormal wear or subject to extreme vibration, such as bearings, cams and gears. It is used in corrosion-resistant springs, electrical contacts, switches, relays and connectors in automobiles, computers and radar, satellite, and telecommunications equipment. Beryllium-aluminium alloy ($<1$–60 per cent beryllium) is used in high technology applications, such as aircraft, scientific devices on
spacecraft, defence avionics packaging, high resolution medical and industrial x-ray equipment. Beryllium-nickel alloy (0.275–7 per cent beryllium) has high tensile strength and has age-hardening characteristics. It is used for diamond drill-bit matrices, watch balance wheels and airplane brakes.3

EXPOSURE AND HEALTH EFFECTS

Beryllium exposure assessment is focused on controlling exposure and preventing beryllium-related health effects in the workplace (see also Chapter 83, Berylliosis). Exposure to beryllium dust and fumes can cause an immune hypersensitivity reaction, dermatitis and lung diseases, including acute berylliosis, chronic beryllium disease and lung cancer. Most hazardous exposures to beryllium come from dust or fume generated by disturbing the surface of a beryllium product through machining and polishing processes. Health effects can result from exposures to beryllium metal dust, powdered and fired forms of beryllia ceramic, beryllium hydroxide, beryllium fume, and mists and dusts of soluble beryllium salts.

The dose and duration of beryllium exposure that causes adverse health effects is the subject of ongoing research. There is strong evidence, for example, that sensitization and chronic beryllium disease can occur at levels as low as 0.02 μg/m3 lifetime weighted exposure.4,5 Current governmental permissible exposure limits may not be sufficiently protective. Certain beryllium industrial processes and job tasks increase the risk of developing an immune response to beryllium and disease.6–13 Even seemingly trivial and bystander exposures have caused beryllium sensitization and chronic beryllium disease.7,8,12–22

Because of these health effects, beryllium has been monitored in industry since the 1940s. In the United States, for example, the US Atomic Energy Commission (AEC) adopted the first beryllium permissible exposure limit (PEL). This limit was the basis for the US Occupational Safety and Health Administration (OSHA) permissible exposure limit for beryllium adopted in 1971. The limit is an eight-hour time-weighted average of 2 μg/m3, a ceiling level of 5 μg/m3 and a maximum peak concentration of 25 μg/m3 for no more than 30 minutes per eight-hour workshift. The PEL is currently under review, upon recognition that cases of chronic beryllium disease (CBD) continue to occur at exposure levels 50–100 times lower than the PEL.

In the workplace, beryllium is measured using various sampling methods including area and stationary sampling, and personal breathing zone sampling. The latter is considered the preferred method. Whether particle size sampling should be performed is open to debate. It is known that the majority of beryllium particulate generated by most machining operations creates a high percentage of respirable-sized particles.

The major emission source of beryllium in the environment is from the combustion of coal and fuel oils and industrial processing of beryllium. The average concentration of beryllium in the general atmosphere in the United States is 0.03 ng/m3. The median atmospheric concentration of beryllium in cities is 0.2 ng/m3.3 The ambient air standard in the United States was set at 0.01 μg/m3 by the AEC in 1949.23

In the late 1940s, cases of CBD were diagnosed in residents living in the neighborhood of a beryllium plant, in Lorain, Ohio. In an evaluation of beryllium in the community, almost all the cases resided within 0.25–0.75 miles (1.2 km) of the plant and had ambient exposures of 0.004–0.02 μg/m3. Disease rates were comparable to rates found among beryllium plant workers. These studies helped form the basis for setting the beryllium community air standard at 0.01 μg/m3 as a 30-day average.24 Later, 21 community cases were reported in Reading, Pennsylvania, within 5.3 miles from a beryllium facility.25 Eight additional cases in that same community were published recently by Maier and colleagues among individuals who never worked in the plant.14

BIOMARKERS

Biomarkers for beryllium include exposure, disease susceptibility, effect and disease progression. The most useful biomarkers for disease are found in the blood and lung.26

The most widely used beryllium biomarker is the blood beryllium lymphocyte proliferation test (BeLPT), which is commonly used to determine beryllium sensitivity. High in sensitivity, specificity and both negative and positive predictive value, beryllium-reactive blood lymphocytes proliferate when presented with beryllium antigen. The BeLPT is widely used in industry as part of workplace medical screening and surveillance. To a much lesser extent, the BeLPT can be considered a biomarker of exposure. If the test is abnormal, it is indicative of past exposure to beryllium since it is a prerequisite for this immune response. However, a negative test does not rule out past exposure. Serum neopterin levels in the blood have been found to be higher in patients with CBD compared to those who are sensitized, suggesting that it may discriminate between sensitization and disease.32,33 The most promising new test of immune response to beryllium is the beryllium ELISPOT assay which measures beryllium-stimulated T-cell production of the cytokine gamma interferon. Class II MHC HLA-DP and -DR gene variants are blood biomarkers of CBD susceptibility, but are not recommended for screening workers because of their low positive predictive value and ethical considerations. Although a high percentage of beryllium-sensitized and CBD patients carry these genes, the genes are also common in the general population.3,23 Blood biomarkers of disease progression include markers of inflammation, such as cytokines.
Bronchoalveolar lavage (BAL) fluid obtained from the lung during bronchoscopy is used to distinguish between beryllium sensitization and CBD. The lung cells of CBD patients proliferate in response to beryllium indicating lung-specific sensitization, measured by the BeLPT using lung cells instead of blood. BAL white blood cell count and lymphocytosis in CBD patients correlate with pulmonary gas exchange and reflect disease severity.

HEALTH EFFECTS

Beryllium and its alloys have a high toxic potential, predominantly targeting the lung, lymph nodes and skin, either by direct toxicity and/or its impact on the immune system. Skin lesions, including granuloma formation and ulceration, occur following direct injection of beryllium into the skin. Cutaneous contact with beryllium salts can induce contact dermatitis.

The primary route of exposure in beryllium-related respiratory diseases is through inhalation of fumes and respirable dusts of beryllium salts, metal or oxides, or beryllium alloys. Exposure to high concentrations of beryllium, usually in the 25 μg/m³ range or greater, can result in acute inflammation of the upper and lower respiratory tract and airways, tracheitis, bronchiolitis, pulmonary oedema and chemical pneumonitis. Dermal exposure is thought to contribute to sensitization risk.

Once inhaled, beryllium particles obey general principles of particle disposition in the lung. The chemical properties of the inhaled beryllium particle may also influence its toxicity. The solubility and the form of beryllium inhaled influence the development of an immune response and chronic disease. Workers exposed to beryllium may develop an immune-mediated, antigen-driven immune response to beryllium without the pathologic or clinical features of CBD. These individuals are asymptomatic and have normal pulmonary function, exercise tolerance, chest radiographs, BAL and lung biopsies. The majority of those beryllium sensitized eventually develop CBD. CBD can develop many years after exposure has ceased and typically has an indolent course and insidious onset of symptoms, including fatigue, non-productive cough, shortness of breath and chest pain. Also common is anorexia, weight loss, fevers, night sweats and arthralgia.

The International Agency for Research on Cancer classifies beryllium as a class I human carcinogen. A preponderance of data support beryllium as a human carcinogen, especially in individuals with beryllium-related lung disease.

PREVENTION AND TREATMENT

Primary prevention, including removal from exposure, is superior to medical treatment of CBD. Unfortunately, there is no known cure for CBD. The goals of treatment are to inhibit inflammation and slow disease progression using oral glucocorticoids as the first-line therapy. Those with more severe disease may require additional supportive measures and use of other immunosuppressive pharmaceuticals.

Key points

- Broader use of beryllium in modern industry has created an increasing public health problem globally, affecting 1–15 per cent of exposed workers.
- Chronic and acute forms of berylliosis continue to occur as a result of immunologic recognition of beryllium antigen.
- Beryllium sensitization and chronic beryllium disease can be detected in workplace surveillance programmes and can be distinguished from other granulomatous disorders using the beryllium lymphocyte proliferation test.
- Chronic beryllium disease is a latent disorder preferentially affecting the lungs and immune system, as well as other organs.
- Exposure to beryllium at levels below current permissible exposure limits results in disease, necessitating strict attention to ventilation, use of personal protective equipment, administrative controls, exposure monitoring and substitution of beryllium with safer materials whenever possible.

Cadmium (Cd) is one of the ‘newer’ metals, having been isolated by Strohmeyer in 1817. It occurs in nature mainly with zinc. It is recovered as a byproduct during the smelting of zinc and some lead ores. Primary cadmium metal production has continued to decrease from its highest levels in 1997, which roughly corresponds to the peak in worldwide NiCd battery production. Reductions in primary cadmium metal production have occurred mainly in Europe where many of the zinc/cadmium producers have shut down their cadmium refineries and now dispose of the cadmium-containing material from their zinc smelting process as hazardous waste. Asia and the Americas, on the other hand, have increased their cadmium primary production capacity from previous years, especially in Korea.1

Cadmium and cadmium compounds are utilized in five major product areas which include NiCd batteries (about 80 per cent of its use), pigments, stabilizers, coatings, and minor uses which include specialized alloys and electronic compounds. The major classes of products where cadmium is present as an impurity are non-ferrous metals (zinc, lead and copper), iron and steel, fossil fuels (coal, oil, gas, peat and wood), cement and phosphate fertilizers.1

In occupational settings, workers may be exposed to Cd through the inhalation of oxide fumes generated during heating or welding of Cd-containing materials, or inhalation of particles of metal, oxide and pigment dust.

The major non-occupational route of cadmium intake for non-smokers is ingestion through food or water. This is largely due to the presence of trace amounts of cadmium in foodstuffs of natural origin or to the use of phosphate fertilizers or sludge on agricultural soils. Smoking typically doubles the daily absorption of Cd by inhalation of cadmium oxide fumes.

**METABOLISM**

Cadmium is poorly absorbed from the gut (<5 per cent); its bioavailability is, however, dependent on the composition of the diet (low Ca, Fe, Zn and protein contents tend to increase Cd absorption) and the source of Cd (soil and seafood Cd are less absorbed than ionic Cd; rice-associated Cd appears to be more absorbed than that of other sources). In individuals with depleted iron stores, bioavailability could increase up to 5–10 per cent (mainly in women). Absorption rate after inhalation ranges from 10 to 50 per cent, depending on the particle size and solubility.2

In blood, about 70–90 per cent of Cd is bound in the red cells; in plasma, Cd is predominantly bound to proteins of high molecular weight (albumin or larger). In tissues, cadmium is largely bound to metallothionein which is a zinc storage protein containing between 30 and 35 per cent of cysteine. The high proportion of sulphur-containing amino acids enables it to bind heavy metals, each molecule being able to bind seven divalent cations, usually zinc or copper, but also cadmium, mercury and a number of other metals. Its synthesis is induced by the presence of zinc, cadmium, copper and mercury.

Cadmium has a long biological half-life (about 10–20 years) and with continued exposure, it accumulates with age. The body burden in smokers is higher than in non-smokers.
After long-term low-level exposure, about half of the body burden of cadmium is localized in the kidneys and liver, a third of the total being in the kidneys mainly in the renal cortex. At higher levels of exposure, a greater proportion of the body burden is found in the liver. The ratio between the cadmium concentration in the kidney and that in the liver decreases with the intensity of exposure. Cadmium is excreted in the urine, largely as a cadmium–metallothionein complex, but the rate of excretion is low (hence the long biological half-life) unless there is concomitant kidney damage. Small amounts of cadmium may also appear in the bile, saliva, hair and nails.²⁻⁴

**TOXICITY**

**Respiratory manifestations**

Acute effects may be noted after the inhalation of cadmium oxide fumes which are generated from welding or brazing on cadmium or its alloys. Because of its low boiling point (765°C) by comparison to other metals such as zinc, Cd fumes are generated in potentially toxic concentrations in Cd alloy production and welding, during oxyacetylene cutting of Cd-coated steel and rivets and in the smelting, melting and refining of metals that contain Cd. There is generally a lag period of up to ten hours after the inhalation of the fumes before any untoward effects become apparent. The patient then notices retrosternal pain, dyspnoea and cough. With heavy exposure, pulmonary oedema may develop after one or two days. The first stage is very similar to ‘metal fume fever’ (see Chapter 44, Welding), but it is essential not to confuse both conditions, since the lung effects from Cd exposure can include delayed pulmonary oedema and possibly death. Subjects who survive acute cadmium poisoning may recover without damage, although some authors have reported delayed development of lung impairment.²

Long-term occupational exposure has been reported in earlier studies to cause emphysema and dyspnoea. Other studies, however, have not shown a cadmium-related impaired respiratory function.²⁻⁵ Lung function tests, which have sometimes been reported to be abnormal in cadmium workers, do not seem to show any dose-response relationship and are certainly not as sensitive indicators of cadmium damage as the excretion of tubular proteins (see under Kidney manifestations).²

Anosmia was also noted to be a common finding in early reports. More recent investigations observed olfactory disorders in workers exposed to cadmium levels much lower than those reported in the past. A statistically significant correlation was found between olfactory dysfunction and cadmium concentrations in the blood and urine, but not between olfactory dysfunction and the duration of exposure. It was postulated that the action of the metal was due to an elective tropism for the olfactory epithelium and not to a non-specific irritant effect on the nasal cavity. These effects occurred in the absence of renal toxicity. Primary olfactory neurons may therefore represent early targets for cadmium toxic action. It seems most likely that cigarette smoking, which is a considerable source of cadmium, can intensify this dysfunction.²⁻⁹

**Kidney manifestations**

The kidney is generally considered to be the principal target organ affected by chronic exposure to Cd. An early sign of cadmium poisoning is tubular proteinuria. The increased excretion of low molecular weight (LMW) proteins (such as retinol binding protein (RBP), β₂-microglobulin (β₂-MG), α₁-microglobulin (α₁-MG) (or protein HC) or a urinary enzyme leakage such as N-acetyl-β-D-glucosaminidase (NAG)) is particularly characteristic of this tubular toxicity. The proteinuria may be accompanied by other evidence of tubular damage, such as calciuria, aminoaciduria, glycosuria and phosphaturia. Hypercalciuria might be responsible for the increased incidence of renal stones reported in some cadmium-exposed workers.²⁻⁴⁻¹⁰⁻¹²

Less commonly, an increased urinary excretion of high molecular weight (HMW) proteins (albumin, immunoglobulin G or transferrin) can occur indicating an effect of Cd on the glomerulus which can develop with or without tubular LMW proteinuria.²

Many other parameters have been investigated and suggested as early biomarkers of Cd nephrotoxicity (e.g. enzymes (intestinal alkaline phosphatase, alanine aminopeptidase, lactate dehydrogenase, glutathione-S-transferase), other proteins (Tamm–Horsfall glycoprotein, cystatin C, Clara cell protein, kidney injury molecule-1), extracellular matrix components (laminin, fibronectin, proteoglycans), tubular antigens or serum antibodies, eicosanoids, thromboxane B₂, kallikrein activity, sialic acid, glycosaminoglycans, cytokines). Changes in renal biomarkers of unknown health significance and predictive value can occur at very low levels; the health significance of most of these biomarkers and their predictive value for the development of end-stage renal failure are largely unknown.

Cadmium-induced LMW proteinuria is presently the only renal effect of Cd with documented health risk significance. The critical concentration of cadmium in the renal cortex associated with increased incidence of LMW proteinuria is estimated to be about 200 ppm, equivalent to a urinary Cd excretion of about 10 μg Cd/g creatinine. When the concentration of Cd in urine exceeds 10 μg/g creatinine, the risk of developing tubular proteinuria is well established. This risk increases almost linearly with the urinary Cd concentration from an expected prevalence of tubular proteinuria around 10 per cent for CdU (cadmium in urine) values slightly above 10 μg/g creatinine to more than 20 per cent when CdU values exceed 20 μg/g creatinine.¹³ This threshold has been considered as clinically
relevant because several studies have indicated that ongoing overexposure with CdU > 10 μg/g creatinine may lead to irreversible renal damage, an exacerbation of the age-related decline in the glomerular filtration rate and a decrease in the filtration reserve capacity. Cd-induced microproteinuria is often considered as irreversible, except at the incipient stage of the intoxication where a partial or complete reversibility has been found in some studies. In some studies on exposed workers, microproteinuria was reversible when reduction or cessation of exposure occurred, while tubular damage was still mild (β2-MG < 1500 μg/g creatinine) and CdU had never exceeded 20 μg Cd/g creatinine.

Although the concept of a critical concentration refers to the total amount of cadmium in the renal cortex, it is only the small amount of the metal not bound to metallothionein that is capable of causing nephrotoxicity. It has been suggested that the concentration of free cadmium which will produce β2-microglobulinuria is 2 ppm or 1 per cent of the critical concentration of the total cadmium concentration in the kidney. There is some evidence that factors, such as the capacity to synthesize metallothionein and ageing, may decrease the critical concentration of cadmium which is associated with the development of tubular damage. Workers that have higher plasma metallothionein antibody levels might more readily develop cadmium-induced renal dysfunction. 

**Bone manifestations**

High cadmium exposure is known to cause bone damage. 'Itai-itai disease' was the name given to an outbreak of osteomalacia found in postmenopausal multiparous women in Japan. The women in whom the condition was first noted lived in an area where crops had become contaminated with cadmium from water that had drained through an old zinc mine and had been used for irrigation. The women had pains in the back and legs (itai-itai literally means 'ouch-ouch') and some developed pathological fractures. Vitamin D and other nutritional deficiencies are thought to be cofactors in the aetiology of itai-itai disease. The metabolic changes in cadmium-induced osteomalacia have been described by Stanbury and Mawer.

Environmental exposure to cadmium has been associated with an increased loss of bone mineral density in both sexes, leading to osteoporosis and increased risk of fractures, especially in the elderly and in females. Data on workers are scant, although there is some evidence supporting the existence of an association between cadmium at low exposure level and alterations in the vitamin D metabolic pathway or bone mineral density. However, more supporting evidence on this relationship is required.

Whether disturbances in the calcium balance and the effects on the skeleton are mediated directly on bone or are secondary to kidney damage is still unclear. Several mechanisms have been postulated. A direct effect of cadmium on bone metabolism (with impairment of bone formation and/or increased bone resorption) and loss of bone calcium is a first possibility. The second putative mechanism includes several factors resulting from kidney damage. Increased calciuria, caused by cadmium-induced tubular damage is a possibility. Moreover, kidney damage may cause other changes capable of disturbing bone metabolism: loss of phosphate, reduced hydroxylation of 25-OH-vitamin D, and acidosis. The increase in parathyroid hormone secretion secondary to kidney damage may further aggravate bone disease.

**Other manifestations**

Cadmium exposure has been linked to lung and prostate cancer in humans. In 1993, a Working Group of the International Agency for Research on Cancer concluded that there was sufficient evidence in humans for the carcinogenicity of cadmium and cadmium compounds on the lung. More recent studies have indicated the importance of confounding exposures, such as arsenic, and do not support the hypothesis that cadmium compounds are human lung carcinogens. The association between cadmium exposure and prostate cancer was not confirmed in more recent reviews. A recent meta-analysis indicated that exposure to cadmium appears to be associated with renal cancer, but this conclusion is tempered by the inability of studies to assess cumulative cadmium exposure from all sources including smoking and diet.

Cadmium does not appear to be directly genotoxic. Indirect effects of cadmium are mediated by the generation of reactive oxygen species (ROS). Cadmium also modulates gene expression and signal transduction and reduces activities of proteins involved in antioxidant defences. Several studies have shown that it interferes with DNA repair.

It has been suggested that cadmium in the environment may be involved in the aetiology of hypertension. In experimental animals, exposure to cadmium modifies a number of mechanisms that regulate cardiovascular function, but there are some important differences between species. In epidemiological studies, cadmium workers do not have an increased prevalence of hypertension. The role of cadmium in the aetiology of hypertension in those who are exposed to it only in the general environment is uncertain.

Neurobehavioural disturbances have been dose-dependently associated with CdU in cadmium-exposed workers. The possibility of a promoting role by increased cadmium body burden in the development of peripheral neuropathy in the elderly has been raised. At present, this remains speculative.

Yellowing of the teeth has been associated with long-term ingestion and/or inhalation of cadmium. However, studies reporting these effects are subject to a number of uncertainties, including the measurements of cadmium exposure, the magnitude of confounding by other toxicants and the evaluation of the effect.
Although cadmium can accumulate in the liver, inhalation of Cd fumes does not appear to have significant effects on the liver. Liver damage is not a prominent feature of chronic cadmium poisoning.

HEALTH SURVEILLANCE OF CADMIUM WORKERS

Biological monitoring of cadmium workers is necessary to prevent excessive uptake leading to renal damage. The interrelationships between cadmium exposure and cadmium concentration in blood and urine are complex and reflect the accumulation of cadmium in liver and kidney over considerable periods of time. The maximum value of CdB (blood cadmium), which is about twice as high in smokers than non-smokers, is generally below 3 µg/L in European subjects not occupationally exposed to cadmium. In workers, after the start of exposure Cd concentration in blood increases linearly then levels off when an equilibrium is reached. Blood Cd is a useful indicator of recent exposure. After long-term high Cd exposure, an increasing proportion of blood Cd will be related to body burden. After cessation of exposure, CdB may reflect the body burden and the decrease of CdB displays an initial fast component with a half-life of three to four months and a slow component with a half-life of about ten years.

In subjects with no occupational or environmental exposure, concentrations of Cd in urine are normally below 1–2 µg/g creatinine. The urinary excretion of Cd is influenced by smoking habits, but not to the same extent as blood Cd levels. At low exposure levels (general environmental exposure), the amount of Cd absorbed may be insufficient to saturate all the body binding sites (e.g. induced metallothionein). Urinary excretion increases in proportion to the amount of Cd stored in the body and not proportionally to the exposure levels. In such circumstances, there is a significant correlation between urinary Cd and Cd in kidney. In high exposure conditions, the Cd binding sites become progressively saturated and any further absorption of cadmium cannot be retained in the kidney: it is rapidly excreted in the urine. In these situations, the urinary Cd concentration would be a better reflection of current exposure levels. The relative influence of the body burden and recent exposure on CdU depends on the exposure intensity. If exposure continues and kidney damage occurs, urinary Cd excretion is increased even more. Eventually, the amount of Cd that can be released from the kidney decreases progressively and the urinary Cd concentration follows the same trend. In newly exposed subjects, a latent period may thus be observed before Cd in urine correlates with exposure.

In workers, the critical CdU level (based on LMW microproteinuria) is around 10 µg/g creatinine. However, for several reasons, including the long biological half-life of Cd, the possible interaction with other causes of renal dysfunction (e.g. diabetes) and the fact that no treatment to remove Cd from its storage sites is presently available, it seems prudent to recommend that occupational exposure to Cd does not result in CdU levels exceeding 5 µg Cd/g creatinine or possibly even as stringent as 2 µg Cd/g creatinine. The assessment of renal function relies on the measurement of the excretion of both LMW and HMW proteins. Increased excretion of LMW proteins indicates tubular damage and failure of reabsorption, whereas excretion of HMW proteins, such as albumin, reflects glomerular damage. Measurement of urinary β2-MG has been widely used as an indicator of tubular function. This protein is, however, degraded rapidly in the bladder when urinary pH is less than 5.5. RBP is stable at all urinary pH values and is therefore a more suitable indicator for tubular function (see Chapter 5, Biological monitoring). Protein HC and NAG are other biomarkers of Cd-induced subclinical tubular dysfunction. The levels of plasma metallothionein antibody have been suggested as a biomarker of susceptibility to renal dysfunction in occupational cadmium exposure.

The following guidelines for interpreting CdU, β2-MG and RBP measurements in workers exposed to Cd have been recommended:

- CdU between 2 and 5 µg/g creatinine: sign of an increased body burden. Exceptionally, such levels can also be found in heavy smokers. At this stage, periodic screening for tubular dysfunction is usually not recommended.
- CdU between 5 and 10 µg/g creatinine: risk of developing tubular proteinuria remains unlikely, except perhaps in particularly vulnerable subjects or in subjects who have been exposed in the past and progressively lose their body burden of Cd. Screening for tubular proteinuria is recommended in subjects who persistently show an urinary Cd above 5 µg/g creatinine.
- CdU exceeding 10 µg/g creatinine: risk of developing tubular proteinuria well established.

A persistent increase of urinary LMW proteins over intervals of months or years may be a sign of irreversible degenerative changes likely to compromise renal function. Several stages can be identified from incipient tubular damage to overt nephropathy with decreased renal function (adapted from Ref. 13):

- <300 µg/g creatinine: normal;
- 300–1000 µg/g creatinine: incipient cadmium tubular damage with a possibility of reversibility after removal from exposure. No change in GFR (glomerular filtration rate);
- 1000–10 000 µg/g creatinine: irreversible tubular proteinuria which may lead to accelerated decline in GFR with age.
- >10 000 µg/g creatinine: overt cadmium nephropathy usually associated with decreased GFR.
There is presently insufficient evidence to support periodic surveillance for bone effects.

It is possible to measure cadmium concentrations in liver and kidney in vivo using neutron activation analysis. This technique is non-invasive, produces negligible amounts of radiation and uses transportable equipment. However, it is presently a research tool, and not recommended for periodic assessment of exposed individuals.51,52

Key points

- Cadmium (Cd) has no beneficial function in humans and is toxic at low dose.
- Cd accumulates in the body, in particular in the liver and kidneys, and has a very long biological half-life. Smokers have a higher body burden than non-smokers.
- Acute cadmium oxide inhalation exposure occurs rarely, but may result in metal fume fever and pulmonary oedema, a much more severe condition.
- Long-term exposure to Cd affects primarily the kidney, especially the proximal tubules resulting in a Fanconi-like syndrome, and the skeletal system leading to bone demineralization.
- Regulatory bodies have concluded that there is sufficient evidence to classify Cd as a human carcinogen. However, the possible confounding by concomitant exposure to arsenic has been evoked.

Chromium

TOM SORAHAN

Introduction 173
Metabolism and action 173
The carcinogenicity of chrome compounds 174

INTRODUCTION

Chromium is a hard, silver white metal which is used for chrome plating and in the manufacture of special steels, such as stainless steel and ferrochrome. A number of its compounds are important as mordants in dyeing silk, wool and other textiles, as tanning agents and as pigments. Those chromium compounds which are commercially important occur in two valency states: trivalent (including chromic oxide and chromic sulphate) and hexavalent (including chromium trioxide, chromic acid and the dichromates of a number of metals). The trivalent compounds are generally considered to be virtually non-toxic, whereas the hexavalent salts are irritant, corrosive and, in some instances, carcinogenic.

METABOLISM AND ACTION

Chromium is an essential element; it is required for normal carbohydrate metabolism and it potentiates the action of insulin. Its hexavalent salts can be absorbed from the lungs, the gut and, to a certain extent, through the intact skin. Trivalent chromium, however, is very poorly absorbed. Chromium is rapidly excreted in the urine with a half-life of between 15 and 41 hours.

All chrome compounds are sensitizers and may cause contact dermatitis; some may be a cause of occupational asthma. Chrome ulcers (chrome holes) are circular, well-demarcated lesions which look as if they have been punched out of the skin (Figure 18.1). They are only slightly painful and tend to heal spontaneously, but may be troublesome if secondarily infected. They can, however, be treated adequately with a 10 per cent solution of calcium EDTA. Long-term exposure to chromium compounds may cause perforation of the cartilaginous nasal septum (Figure 18.2) and occasionally lead to chronic rhinitis and chronic bronchitis. It may also induce conjunctivitis, keratitis and ulcerations on the eyelids.

Figure 18.1 Chrome ulcers in various stages of activity on the hand of a fitter who worked in a chromium plating shop maintaining the plating tanks. Courtesy of Professor RI McCallum.
The inhalation of large concentrations of hexavalent chromium compounds may cause coughing, wheezing, inspiratory pain, fever and loss of weight. Prolonged skin contact may lead to local irritation and, if skin damage is extensive, enough of the compound may be absorbed to cause renal damage and death.

THE CARCINOGENICITY OF CHROME COMPOUNDS

The most serious consequence of exposure to chromium compounds is the risk of developing lung cancer (see Chapter 85, Occupational cancer: epidemiology, biological mechanisms and biomarkers). The carcinogenicity of hexavalent chromium compounds is well established and markedly elevated lung cancer rates have been found in workers engaged in primary chromate production, in the chrome pigment production industry, and in chrome plating. The direct evidence relating to stainless steel welders and workers in the ferrochromium industries is inconclusive. The human evidence relating to trivalent chromium is also inconclusive.

In short-term tests, hexavalent chromium produces mutations in bacterial systems without prior activation and, in vitro, the mutagenic potential of soluble and slightly soluble compounds does not differ. Trivalent chromium has a limited mutagenic effect, although it has been shown to be 20 times more potent in decreasing the fidelity of DNA synthesis in vitro than the hexavalent form.

It may be that, in fact, the trivalent form of the metal is the proximate carcinogen having been produced by intracellular reduction of the hexavalent form. The apparent inactivity in vivo is thought to result from poor absorption. Bound to certain ligands, trivalent chromium is able to cross cell membranes. The carcinogenic effect may not be due to the trivalent form at all, however, but to some reactive intermediate formed during the reduction of hexavalent chromium, perhaps a pentavalent compound.

Lung cancer was prescribed in 1986 under the Social Security Act for occupations involving the use or handling of or exposure to the dust of zinc chromate, calcium chromate or strontium chromate (see Chapter 8, Compensation schemes).

MONITORING OF WORKERS EXPOSED TO CHROMIUM

Special attention should be given to the skin and nose of chrome workers. It may also be prudent to conduct periodic tests of lung function if cases of asthma are suspected.

The chromium concentration in the urine at the end of a work shift is an index of recent exposure to soluble hexavalent chromium compound. Levels in unexposed people are below 12 nmol/L in blood and 0.2–3 mmol/mol creatinine in urine.

Key points

- Chromium is an essential element.
- Heavy chrome exposure can cause chrome ulcers.
- Hexavalent chromium compounds are potent human lung carcinogens.

Cobalt

INTRODUCTION

Cobalt (Co) is a silvery grey, magnetic metal mainly recovered as a byproduct from copper and silver mining. The main mining centres are in Central Africa, Canada, Russia, Australia and Central America. Cobalt is a transition element occurring in four valences \((0, +2, +3\) and \(+4\)), the divalent oxidation state being the most common. It is an essential element and central to the action of vitamin \(B_{12}\).

Cobalt has a wide application in many sectors: metalurgy (super alloys, high speed and high strength steels, prosthetics, spring alloys), magnetic alloys, chemicals (batteries, tyres, paint dryers, soaps, pigments, catalysts in the petroleum and the textile industry, adhesives, electroplating, agriculture and medicine), cemented carbides, electronics, ceramics and enamels (colours in pottery, enamels, glass and china).\(^1\)

The metal form of cobalt is used in the manufacture of superalloys which are alloys developed for applications where elevated temperatures and high mechanical stress are encountered, principally used in jet engines. It is also used in magnetic alloys and alloys that are required for purposes requiring hardness, wear resistance and corrosion resistance. Recently, cobalt oxide has been used in the active ingredient of lithium ion rechargeable batteries. In nickel-cadmium and nickel metal hydride batteries, several cobalt compounds are used as additives, for either the positive or negative electrode. Radioactive cobalt \(^{60}\text{Co}\) is used as a source of high energy gamma radiation in radiotherapy and industrial radiography.\(^1\)

The main use of cobalt is in hard metals. Exposure to cemented carbides and cobalt-diamond tools should be distinguished from the other types of exposure to cobalt. Hard metals are materials in which metallic carbides are bound together or cemented by a soft and ductile metal binder, usually cobalt or nickel.\(^2\) Hard metals usually consist of more than 80 per cent tungsten carbide (WC) particles and less than 10 per cent cobalt metal, although the cobalt content can be more (up to 25 per cent) depending on the application. These powders are compacted and heated at high temperature in a process called sintering, hence the term ‘sintered carbides’ or ‘cemented carbides’. Other constituents – chromium, titanium, tantalum, vanadium, niobium, etc. – may be added. Hard metals have a hardness almost that of diamond and are used to make machine parts that require high heat resistance, or to make tools used for drilling, cutting, machining or grinding. Exposure to hard metal dust takes place at all stages of the production of hard metals, but the highest levels of exposure have been reported to occur during the weighing, grinding and finishing phases.\(^2\) The continuous recycling of coolants, used with hard metals, has been shown to result in increased concentrations of dissolved cobalt in the metal-working liquid and hence a greater potential for exposure to (ionic) cobalt in aerosols from these fluids.\(^2\) Although they do not contain WC, cobalt-containing diamond tools are often considered in the same category. They are also produced by powder metallurgy, whereby microdiamonds are impregnated in a matrix of compacted, extrafine cobalt powder and the proportion of cobalt in such tools is higher (up to 90 per cent) than in hard metals. Diamond polishers have been reported to inhale metallic Co, iron and silica.

The absorption from the gut varies considerably from 5 to 45 per cent, and about 30 per cent of an inhaled dose of cobalt oxide is absorbed. The solubilization and bioavailability of cobalt in the extracellular milieu was shown to increase in the presence of WC.\(^3\) Cobalt does not accumulate in any specific organ, except in the lungs when inhaled in the form of insoluble particles. In blood, cobalt ions bind strongly to proteins, mainly albumin. It is mainly (80 per cent) excreted in the urine, the remainder in the faeces.\(^5\)
Respiratory disorders that have been related to occupational exposure to cobalt involve the upper respiratory tract (inflammation of the nasopharynx), the bronchial tree (bronchial asthma) and the parenchyma with the development of an interstitial lung disease, the so-called ‘hard metal lung disease’ (HMLD) which may cover several clinical pictures from hypersensitivity pneumonitis or desquamative alveolitis to interstitial lung fibrosis (see Chapter 82, Metal dusts and fumes).

In its most typical clinical presentation, interstitial lung disease consists of a giant-cell interstitial pneumonia (GIP), characterized by the presence of ‘cannibalistic’ multinucleated giant cells in air spaces and bronchoalveolar lavage. The process by which these giant cells are produced and the role of Co, if any, in this process are still unknown. Typical symptoms are wheezing, shortness of breath and chest tightness, and lung function tests show restrictive effects (reduced FVC) with a reduction in the diffusion capacity. The chest radiograph may be normal or show a nodular, reticulonodular or reticular pattern. High resolution computed tomography (HRCT) findings have been described in a small number of patients. Reported abnormalities include patchy lobular ground-glass opacities, reticulation, centrilobular nodularity, honeycombing, bronchiectasis, and large peripheral cystic spaces in the mid and upper lung zones.

The alveolitis usually improves spontaneously when the subject is no longer exposed to cobalt, but if exposure continues, irreversible pulmonary fibrosis may develop gradually and may lead to cor pulmonale and death.

The disease has only been diagnosed in workers in the hard metal and diamond polishing industries and also in dental technicians, where exposure is mixed, being not only to cobalt metal, but also to different carbides, diamond or other particles. Experimental findings, both in vitro and in vivo, indicate that the biological reactivity of the mixture of cobalt powder with different carbides is much higher than that of pure cobalt powder. There is no evidence for the occurrence of typical HLMD in workers exposed to cobalt alone. An epidemiological study in a large cobalt refining plant did not find evidence of parenchymal disease among workers highly exposed to pure cobalt. Based on a 13-year surveillance programme (from 1988 to 2001) of these workers, FEV₁ was found to decrease over time, but only in association with smoking. It was calculated that an exposure resulting in urinary cobalt levels of 10, 20 or 40 µg/g creatinine (which is roughly equivalent to a time-weighted average exposure at 10, 20 or 40 µg/m³) would cause, for a 30-year-old smoking worker, an additional decrement of 64, 84 or 103 mL of FEV₁ after ten years of work at this plant. Another investigation on current and former workers who had worked more than ten years in a cobalt plant found no chronic respiratory diseases, except asthma. Simultaneous exposure to cobalt and other substances is probably necessary to cause HMLD. It is conceivable that the individual susceptibility to develop HMLD is related to an innate or acquired inability to deal with oxidant injury. The existence of genetic susceptibility to HMLD has been suggested because of the very low prevalence of the disease (less than 1 per cent) and the lack of correlation with the intensity or duration of exposure.

There is ample evidence that cobalt causes bronchial asthma. Cobalt asthma is associated in some, but not all cases, with circulating cobalt-specific IgE and generalized bronchial hyperresponsiveness; a type 1 allergic reaction is therefore suspected. Occupational asthma has been recorded in all industry sectors with exposure to cobalt, either alone or in association with other constituents. There is strong evidence that all cobalt species that are significantly soluble in biological media can cause asthma. Cross-respiratory sensitization between nickel and cobalt compounds has been reported.

In 1990, the International Agency for Research on Cancer (IARC) concluded that cobalt and cobalt compounds were possibly carcinogenic to humans (group 2B), with inadequate evidence of carcinogenicity in humans, and sufficient evidence for the carcinogenicity of cobalt metal powder in experimental animals (see Chapter 85, Occupational cancer: epidemiology, biological mechanisms and biomarkers). Further evidence in respect of carcinogenicity of cobalt compounds came in 1996 when the National Toxicology Program in the United States reported that a two-year inhalation bioassay with cobalt sulphate in rats had shown an increased lung cancer incidence. In 1998, the European Union classified cobalt metal and all metal compounds as category 2 carcinogens, i.e. ‘may cause cancer in experimental animals’. Since the 1990 IARC evaluation, several epidemiological studies addressed cancer risks among workers exposed to dusts containing cobalt with or without tungsten carbide in hard metal production facilities. Those conducted in France provided evidence of an increased lung cancer risk related to exposure to hard-metal dust containing cobalt and tungsten carbide, taking into account potential confounding by smoking and other occupational carcinogens. Hence, in 2003, cobalt metal with tungsten carbide was re-evaluated as probably carcinogenic to humans (group 2A) on the basis of limited evidence in humans for increased risk of lung cancer and sufficient evidence in experimental animals for the carcinogenicity of cobalt sulphate and of cobalt metal powder. The evidence of carcinogenicity for exposure to cobalt in the absence of tungsten carbide was considered inadequate, so that with sufficient evidence in experimental animals for the carcinogenicity of cobalt sulphate and of cobalt metal powder, the overall evaluation of cobalt metal without tungsten carbide was possibly carcinogenic to humans (group 2B). Cobalt sulphate and other soluble cobalt (II) salts were evaluated as possibly carcinogenic to humans (group 2B). There is insufficient information for cobalt oxides and other compounds.

Co(II) ions are genotoxic in vitro and in vivo, Co metal is genotoxic in vitro. Hard metal dust is proven to be genotoxic in vitro and in vivo. The production of reactive oxygen species and/or DNA repair inhibition are
mechanisms possibly involved. Contrary to what is generally assumed for most metals, the biological activity of cobalt metal is not exclusively mediated by the ionic form dissolved in biological media.

Cobalt and cobalt compounds have skin-sensitizing properties which may lead to occupational contact dermatitis, particularly of the hands. Concurrent reaction to cobalt, nickel and chromate may occur.

At one time, cobalt salts were added to beer as a foam stabilizer and a number of outbreaks of congestive cardiomyopathy were linked to that use. Those affected suffered from an abrupt onset of left ventricular failure with pericardial effusion and polycythaemia. It was generally considered that the aetiology was multifactorial since the amount of cobalt consumed, even by the most heavy drinkers, was far less than that given therapeutically for anaemia. The fact that the condition was seen almost exclusively in heavy drinkers suggested that there was a synergistic action between the cobalt in the beer, the direct effects of alcohol on the myocardium and an inadequate intake of proteins and vitamins. Isolated cardiomyopathy cases have been reported among workers exposed to cobalt or hard metals. Cumulative exposure to cobalt in cobalt production workers was found to be associated with echocardiographic changes indicating altered left ventricular relaxation and early ventricular filling, but not associated with clinically significant cardiac dysfunction. A possible mechanism for the findings could be the accumulation of cobalt in the myocardium, the result being an increase in myocardial stiffness and the inhibition of cellular respiration due to inhibition of mitochondrial dehydrogenase.

Cobalt has an effect on thyroid function. It inhibits tyrosine iodinase which prevents the synthesis of thyroxine. This, in turn, leads to an oversecretion of thyroid-stimulating hormone and to thyroid hyperplasia.

Cobalt also mimics hypoxia and induces the production of erythropoietin, leading to polycythaemia.

**MEDICAL SURVEILLANCE**

Workers exposed to pure cobalt powder or to cobalt-containing dusts should be submitted to periodic health checks, including clinical examination with special attention to the lungs and skin. Pulmonary function testing and periodic chest radiographs may be considered in the surveillance programme. The retention time of cobalt in the human body is short. Excretion is biphasic, a rapid phase of elimination lasts approximately two days after which a second phase of prolonged and low-level elimination follows. Where exposure is to soluble cobalt compounds (e.g. salts), to the metal or to hard metal dust, measurement of cobalt in the urine at the end of the working week will give an indication of the extent of recent exposure. However, when exposure is to cobalt oxides, the urinary concentration of cobalt does not correlate well with recent exposure.

For unexposed people, the level of urinary cobalt is generally <1 μg/L. Elevated levels have been reported in cobalt metal, oxide and salt production workers, hard metal workers, battery plant workers, pottery painters, as well as in dental technicians. Metal-on-metal hip and knee arthroplasties can cause increased blood and urine levels.

In Germany, exposure equivalents for carcinogenic materials (Expositionsschwellenwerte für krebserzeugende Arbeitsstoffe (EKWs)) are derived for substances in carcinogen categories 1 to 3. These substances are not given biological tolerance values (BAT) because it is considered that, at present, it is not possible to specify safe levels of such substances in biological materials. However, the relationship between the concentration of the substance in the workplace air and that of the substance (or metabolite) in biological materials is investigated for the occupational medical detection and quantification of the individual exposure to the substance. For cobalt, the EKA values are 15, 30, 60 and 300 μg/L urinary cobalt (sampling time not fixed) for 0.025, 0.05, 0.10 and 0.50 mg/m³ cobalt in air. The biological exposure indices (BEI) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) for cobalt are 15 μg/L urine and 1 μg/L blood (end of shift at end of work-week samples), corresponding to an atmospheric exposure level of 0.02 mg/m³ (TLV-TWA, inhalable fraction).

Exhaled breath condensate (EBC), a fluid formed by cooling exhaled air, is postulated to be a suitable matrix to assess target tissue dose and the effects of inhaled cobalt and tungsten. It was speculated that Co-EBC reflects not only exposure, but also the amount of the element retained in the lung and eliminated with exhaled air after its interaction with – and possibly damage to – resident cells. However, this technique is still at an exploratory stage and generally not available for routine surveillance of cobalt-exposed workers.

---

**Key points**

- Cobalt is an essential element necessary for the formation of vitamin B₁₂.
- Following inhalation exposure to Co, the main target organ is the respiratory tract. Fibrosing alveolitis (hard metal disease) has been reported in hard metal workers and in diamond polishers, but not in workers exposed to other cobalt species. Exposure to cobalt alone can cause asthma and allergic contact dermatitis.
- Cobalt metal with tungsten carbide (hard metal) is considered as probably carcinogenic to humans, cobalt without tungsten carbide, cobalt sulphate and other soluble salts as possibly carcinogenic to humans.
- Other target organs include the thyroid, the haematopoietic system and the myocardium.

Copper

PETER AGGETT

PROPERTIES AND USES

Copper was one of the first metals to have been used by man and its use in bronze, a mixture of nine parts copper with one part tin, has defined a stage of human civilization. This started, possibly 10 millennia ago, but certainly the alloy was being used in the Aegean littoral about 7000 years ago. Copper is the third most widely used metal after iron and aluminium.1–3

Copper’s malleability, ductility, thermal conductivity and resistance to corrosion underpinned its early usage as the native metal, as bronze and as other alloys such as those with zinc (brass) and nickel. Subsequently, its electrical conductivity and biostatic effects extended its domestic, commercial and industrial exploitation.

Thus, copper is used in the following applications: in coinage, either as copper coins or as a coating or alloy with nickel cupronickel or zinc; piping and plumbing systems; as a roofing material (exposed copper becomes green as the metal forms the pale green carbonate, verdigris); guttering, doors and similar architectural features; bronze statuary; cooking utensils; electroplating; kitchen and domestic fittings; work surfaces; stills; furniture and domestic fittings; door fittings, electrical wiring and electronic applications; photography; wood preservatives, often as the arsenate; as an anti-fouling agent on boat hulls; pigments, for example, in paints and glass; fireworks; munitions; and as in the manufacture of rayon, textiles, paper and tyres.

The metal is used as a self-disinfecting and bacteriostatic surface. Copper sulphate is used in topical sterilizing agents and as a water treatment, and it has been used as a fungicide and algacide, for example in Bordeaux mixture which is a mixture of copper sulphate 0.05–2 per cent with soda lime (i.e. a mixture of calcium hydroxide with sodium or potassium hydroxide). A similar compound of copper sulphate is an accepted pesticide in organic farming. Additionally, copper is used as a food supplement in animal husbandry, not simply as a nutrient, but also as an intestinal microbiocidal to alter the intestinal microflora. This may improve the energy efficiency of growth in the livestock, usually pigs, and may also lead to atypical concentrations of copper in pig carcass livers. In some areas where local soil characteristics limit the uptake of copper by plants, copper salts may be included in fertilizers.1–3

Metallic copper occurs naturally, but most copper is obtained from sulphide minerals of copper: chalcopyrite, bornite, covellite and chalcocite. Other mineral sources are the carbonates azurite and malachite, and the chloride and oxide, cuprite. The principal sources are pit mines in Chile and the Sonora Desert, but there are many other mines throughout the world, particularly in Africa. Global copper supplies are thought to be at risk of running out in the next 50 years, so increased recovery of copper from existing artefacts may become a source of occupational exposure.

ESSENTIALITY AND METABOLISM

Copper is an essential nutrient.1 It has two biologically relevant oxidation (valency) states: Cu (I) and Cu (II) which are exploited in redox enzyme activities. Cuproenzymes include oxidases and electron transport systems, such as cytochrome-c-oxidase. Thus, copper underpins the synthesis of adrenaline and noradrenaline, neurotransmitters, encephalins and neuropeptides; substrate metabolism and mitochondrial respiration; antioxidant activity via superoxide dismutase; cross-linking of collagen for the formation of connective tissue and the organic matrix of bone; the absorption and distribution of iron, and haemoglobin synthesis; efficient muscle contractibility; and the formation of melanin.
Copper is absorbed by a carrier-mediated process and by passive diffusion in the proximal small intestine. Absorbed copper is carried in the portal circulation bound to albumin, amino acids and a specific carrier, transcuprein, to the liver where it is taken up by the hepatocytes and is incorporated into apo-cuerauloplasmin to form caeruloplasmin. The liver contains at least four pools of copper, one is the cuproenzymes, another is caeruloplasmin which is the major means for systemic distribution of copper, the third pool is a depot of copper bound to a cysteine-rich protein, metallothionein, and which is probably a reserve of the element, and the fourth pool is that of copper principally accrued from recirculated caeruloplasmin from which copper is transferred to a pool destined for biliary excretion. The regulation and exchange of copper between these pools within the liver is unknown.

Copper is distributed peripherally mostly bound to caeruloplasmin (70–80 per cent) from which copper is taken up by endocytosis. The role of caeruloplasmin is not absolutely clear. It is a copper donator, but in individuals with acaeruloplasminaemia copper metabolism is unaffected, so the residual 20–30 per cent of circulating copper which is bound to albumin, transcuprein and amino acids is also available to peripheral tissues, and can compensate the absence of caeruloplasmin.

The major route of copper excretion is in the bile, in which it is associated with low molecular-weight copper-binding components, as well as macromolecular binding species. Reabsorption of biliary copper is negligible, but the reason for this is unclear. At high intakes of copper, intestinal uptake and transfer is downregulated by reduced expression of enterocytic copper carriers, and by the induction of metallothionein which binds copper and blocks its transfer to the body. Urinary losses of copper are small.1

EXPOSURE AND HEALTH EFFECTS

Mining and extraction of copper causes exposure to copper particulates, as does processing and working on the metal. Copper powder is pink-red, but it turns green on exposure to moist air; prolonged exposure to this may cause an asymptomatic superficial discolouration of the exposed skin, hair and the tongue, and of the teeth. Occasionally, copper dust induces a contact dermatitis. Copper in copper carbonate and oxide minerals can be released by gastric acid from ingested dust and particles, and might increase systemic exposure. Copper in copper sulphide and other complexes is not released by gastric acid and is thought not to pose such a risk. Some workers exposed to high atmospheric levels of copper, estimated to provide 200 mg/day (the recommended dietary intake is around 2.0 mg/day) have developed elevated serum copper levels and hepatomegaly.2,3

However, such exposure is seldom limited to copper alone, and simultaneous exposure to arsenic, nickel, silica, lead, cadmium, zinc and iron needs to be considered in the assessment of occupational exposure. Workers using Bordeaux mixture have developed diffuse pulmonary linear and nodular interstitial fibrosis and granulomatous disease of the lungs and liver.

Exposure to fumes causes metal fume fever and may occur during smelting, brassing, welding, and working on preserved woods; and from the burning of coal and waste incineration. Exposure standards to atmospheric copper dust have been set at 2.5–3.5 mg copper/L which is just below the threshold for the onset of gastrointestinal effects of nausea, abdominal pain and vomiting which are associated with drinking water containing 4–5 mg copper/L. This threshold does not, of course, represent actual exposure levels, and in some areas higher concentrations are tolerated. The regulatory upper limit for copper in drinking water has been set at 3 mg copper/L.1,4

Suicidal drinking of copper solutions involving doses of 20–70 g of copper is associated with the above gastrointestinal features which progress to haematemesis, diarrhoea, headache, dizziness, and, some hours later, more severe systemic features, such as tachycardia, respiratory difficulty, intravascular haemolysis, haematuria, gastrointestinal haemorrhagic necrosis, hepatocellular necrosis and liver failure, hypovolaemic shock, and acute tubular necrosis and kidney failure, coma and death. The stools and vomit may be green.

In young children, similar copper overload syndromes have been described: Indian childhood cirrhosis (ICC) and idiopathic copper toxicosis (ICT). The former arises from drinking milk that has been heated or stored in brass vessels first described in India, classically buffalo milk, and the latter from high copper content in water supplies, for example local well water, in North America and Europe. Both are associated with progressive hepatic inflammation, steatosis, fatty infiltration, necrosis, fibrosis, cirrhosis and liver failure. These appear to be ecogenetic conditions in that affected individuals have a genetic susceptibility to a high exposure to copper.1 It is not known if such populations, or other individuals who are heterozygous for the copper overload syndrome, Wilson disease, are at increased risk when exposed to copper occupationally.

The diagnosis of these conditions depends on history. There are no reliable markers of copper excess. Serum copper or caeruloplasmin concentrations are tightly controlled and are more responsive to elevations during infection and stress than they are to increased body burdens which are predominantly in the liver. Thus, liver biopsy is needed for a definitive diagnosis of systemic overload.

Acute ingestion of copper can be managed by early gastric lavage if possible. In this situation, serum copper values may be of prognostic value. Concentrations below 3 mg/L (50 µmol/L) suggest moderate toxicity, and levels above 8 mg/L (125 µmol/L) indicate severe poisoning. Treatment with standard systemic metabolic support and with the chelator D-penicillamine (25 mg/kg body weight daily) will reduce the copper load, in both acute and chronic copper overload. Other treatments include unithiol and N-acetyl cysteine.3,5
Key points

- Systemic copper toxicity can arise via inhalation and ingestion of particulates and salts in solution.
- Industrial exposure often involves potentially toxic co-exposure to other metals.
- Inhalation of copper fumes and salts causes metal fume fever and pulmonary fibrosis.
- Acute oral toxicosis includes necrosis of the gastrointestinal tract, liver and kidneys with resultant organ failure.
- Chronic systemic copper toxicosis is associated with progressive hepatic fibrosis and failure.
- Treatment includes D-penicillamine, Unithiol, and N-acetyl cysteine.

Gold

INTRODUCTION

Gold has been found in countries throughout the world and, though present as a trace element in many ore bodies, the important sources are South Africa, Australia, North America and South America. Due to its high value, there is considerable recycling and refining of this precious metal.

Many hazards are associated with the mining of gold, including silicosis, barotraumas, noise-induced hearing loss, hand and arm vibration and heat exhaustion, as well as those due to public health issues in underdeveloped countries which may include losses of mercury in the recovery process. Refining of gold may be accompanied by exposure to toxic contaminants, e.g. mercury, cadmium, selenium and lead, depending on the source of the metal ore and processes used. Chlorine may be used, for example in the Miller process by which base metals and silver are removed from molten gold as metal chlorides, some of which are corrosive. If platinum is present, highly allergenic chloroplatinates may accumulate in the condensates from this process. Electrefining uses a solution of gold chloride or gold cyanide. Lead oxides are used in fire assay and in cupellation for concentration of gold. Gold is very dense and, even with small volumes, there are considerable manual handling challenges particularly in handling molten metal and heavy moulds.

PROPERTIES AND USES

Gold, a precious metal and therefore resistant to corrosion, has a high lustre and the depth of the gold colour depends on other metals in the alloys which provide strength and hardness. It is malleable, ductile and electroconductive.

For thousands of years, gold has been valued and used for jewellery and as a monetary unit and for investment. It is applied as decorative finishes on fine ceramic and glassware and on conductive surfaces in electronics. As it is biologically inert, the metal is used for medical and dental prostheses, although gold compounds, such as aurothiomolate, may be used therapeutically for rheumatoid arthritis.

OCCUPATIONAL TOXICOLOGY

Metallic gold is biologically inactive, but gold compounds may be toxic, e.g. gold cyanide used for plating solutions, and cases of dermatitis have been attributed to this, as well as gold sodium thiosulphate. Cyanide salts are used in the extraction of gold and other metals, and fatalities from cyanide poisoning have been reported in these extraction processes (see also Chapter 39, Gases). Aurothiomolate is nephrotoxic and therefore when used for therapy requires close monitoring of the patients.

Splashes of gold chloride during the electrefining process result in a temporary purple discolouration of the underlying skin which is shed by normal desquamation.

EXPOSURE LIMITS

There is no exposure limit for gold.

MEDICAL SURVEILLANCE

There is no indication for medical surveillance of workers exposed only to gold metal or fume. However, the recovery
and refining processes and the manufacture of gold products may be associated with other exposures, e.g. chlorine, lead, mercury, cadmium, and medical surveillance may be appropriate for these.

ENVIRONMENTAL RISKS

Gold being a noble metal and resistant to corrosion does not have an adverse environmental effect.

**Key point**

- Risks associated with gold are those of the extractive process and contamination of the refining and fabrication processes by other contaminants, such as mercury and lead.

Iron

Iron is the fourth most abundant element, comprising about 5 per cent of the Earth's crust and it is the most widely used metal; 90–95 per cent of metal production is devoted to iron for use, usually alloyed with carbon and silicon as steel, in construction, engineering, vehicle and shipping manufacture. Correspondingly, about 90 per cent of mining activity is applied to the extraction of iron, most commonly from hematite and magnetite which are iron oxides. The metal is then released by the reduction of the ores in blast furnaces at 2000°C, impurities are removed by the addition of limestone (calcium carbonate).

Essentiality and metabolism

Iron is a biologically essential element. Organisms have evolved means of exploiting its two oxidation (valency) states, ferrous (FeII) and ferric (FeIII) iron, and controlling the potential damage that ionic iron species could do to tissues. Adult humans contain 2.5–4.0 mg of iron, males having larger depots than females. Most iron is used in haemoglobin in red cells and in myoglobin in muscles which distribute and store oxygen, respectively. In these compounds, iron is incorporated in haem which in turn is encased in globin, the juxtaposition of which enables it to bind oxygen and carbon dioxide reversibly, according to prevailing gas tensions and pH conditions.

Haem is in other enzymes such as cytochromes a, b, c, cytochrome c oxidase, the cytochrome P450 system, peroxidizes including iodoperoxidases, catalase and sulphite oxidase. Iron-sulphur compounds are in aconitase, aldehyde and xanthine dehydrogenases, NADH and succinate dehydrogenases, and tyrosine, tryptophan and phenylalanine hydroxylases, as well as prolyl hydroxylase. Collectively, these demonstrate the element’s involvement with the citric acid cycle, oxidative phosphorylation, mixed function oxidase systems, neurotransmitter synthesis, pyridine metabolism, collagen synthesis and thyroid function, and antioxidant activity. Even so, only about 1 per cent of systemic iron is present in enzymes, the largest pools are haemoglobin (60–70 per cent) and myoglobin (10 per cent). Variable amounts (0.5–1.5 mg) are in depots in the liver and in the reticuloendothelial system, in which iron is bound to ferritin, or to haemosiderin which is degraded ferritin.

Iron has a low margin of safety and, given its environmental ubiquity and its potential systemic toxicity, systems have evolved mechanisms to limit the amount of iron they take up, and to minimize the possibility of free iron causing systemic tissue damage. Thus, in humans, the intestinal uptake and transfer of the element is regulated according to the systemic need for iron, which is to compensate adventitious losses in shed skin and epithelia, hair and menstruation, with the additional need in young people of meeting their requirements for growth. Consequently, the intestine is set to absorb a relatively small amount of dietary iron. This regulation is effected by down-regulation of iron uptake into the enterocytes, and by reducing the transfer of iron out of the intestinal mucosa into the portal circulation. Iron that is taken up into the gut mucosa, but which is not transferred systemically is retained bound as ferritin and is lost when the enterocytes are desquamated. These processes are controlled principally by feedback from the liver mediated by a low molecular weight protein, hepcidin. The inherited iron overload syndromes, the haemochromatoses, of which there are
probably six, two of dominant inheritance and four with autosomal recessive inheritance, all involve defects in this regulatory control and feedback.\(^1^,4\)

In the circulation, iron is distributed by transferrin; this takes up iron from specific carriers at the enterocytic basolateral membrane and distributes it to the hepatocytes. Iron in the Kupffer cells of the liver arises from the breakdown of erythrocytic haemoglobin by the reticuloendothelial system. The systemic pool of iron and its turnover is also tightly regulated, and there is no means of specifically excreting iron. The only way that the body loses iron is through the adventitious losses mentioned above.

Intracellular iron is mainly bound in ferritin. In situations of iron overload, ferritin is degraded to haemosiderin which can be further degraded within the lysosomes. Iron in ferritin can be released when it is needed, but once ferritin has been degraded to haemosiderin, it is only released during lysosomal breakdown of the protein. This can result in ‘free’ iron in the liver and tissues, which in turn can cause oxidative damage to membrane lipids, proteins, nucleic acids and other components. The resultant inflammation and fatty degeneration may progress to necrosis and fibrosis, leading to liver cirrhosis, and similar functional and architectural damage in the heart, adrenals and endocrine organs. Classically, this degree of overload occurs only in people with one of the haemochromatoses, or in patients who have secondary iron overload from repeated transfusions for the management of defective haemoglobin synthesis or haemolytic anaemias.\(^2^,4\)

**EXPOSURE AND HEALTH EFFECTS**

There is no good evidence that occupational iron toxicosis occurs. However, the estimated carrier frequency for the major form of haemochromatoses is 0.1 and there is interest in the possibility that heterozygous individuals, particularly males, may be at an increased risk of excessive systemic accumulation of iron. However, although such individuals may have serum ferritin concentrations at the upper end of the reference ranges, there is no evidence that they have iron overload, nor an increased risk from occupational exposure to iron.\(^1\)

African iron overload, previously called Bantu siderosis,\(^2\) is an ecogenetic disorder caused by a combination of a genetic defect affecting iron metabolism and increased exposure to iron. The former is a suspected propensity to accumulate iron caused by a defect distinct from those causing the haemochromatosis, and the source of iron is classically the consumption of beer that has been stored in ungalvanised steel containers. However, exposure may also come from iron cooking pots. In contrast to haemochromatosis, in African iron overload, the excess iron is in both the hepatocytes and Kupffer cells, as is seen in transfusion overload, and both heterozygotes and homozygotes appear to be affected.\(^2\) It is not known if occupational exposure to iron is a risk factor for African iron overload.

Chronic exposure to large doses of iron interferes with the intestinal uptake and absorption of zinc and copper. It is speculated that this interaction may cause systemic defects in the utilization of these elements causing deficiency features, such as growth retardation and anaemia. However, these considerations apply principally to children rather than the workforce.\(^5\)

Most cases of acute iron toxicity occur accidentally and also predominantly in children.\(^6\) There are no systematic dose–response data for acute toxicity. Doses in the order of 20 mg elemental iron/kg body weight are said to precipitate intestinal features, whereas systemic manifestations occur at a threshold around 40–60 mg/kg, and exposures in the order of 100 mg/kg body weight are usually lethal. Features include initial nausea, vomiting and loose stools resulting from corrosive damage and haemorrhagic necrosis of the gastrointestinal mucosa. Four to six hours later, the loss of the gastrointestinal barrier may result in fluid loss leading to early hypovolaemic shock and increased systemic uptake of iron. The increased iron load causes multiorgan damage, particularly affecting the liver. This may take 12–48 hours to develop. The shock worsens, and metabolic acidosis, coagulopathies and cardiovascular collapse may progress to death. After recovery, intestinal scarring may lead to strictures and mechanical obstruction.

Treatment\(^6,7\) is with induced vomiting or gastric lavage. These are useful if they can be done within two hours of ingestion. Further management involves supportive measures for shock, acidosis and chelators such as desferoxamine (15–30 mg/kg) with which there is most experience for acute poisoning. Secondary iron overload may also be managed with desferoxamine or with deferiprone.\(^8\)

**Key points**

- Iron salts can cause metal fume fever, otherwise occupational toxicity is uncommon.
- A common cause of toxicity is the ingestion of iron salts used as nutritional supplements.
- Acute high exposures cause severe gastrointestinal necrosis with haemorrhage, hypovolaemic shock and systemic organ failure.
- Chronic exposure to excess iron might induce zinc and copper deficiencies.
- Treatment is with desferoxamine or deferiprone.

**REFERENCES**

Lead is a bluish-grey metal with the symbol Pb, atomic number 82 and atomic weight 207.2. Due to the high specific gravity (sg 11.34), ease of casting and fabrication, low melting point (327.4°C), resistance to corrosion and opacity to x-rays, it has had a wide range of uses, such as soldering, printing type, ammunition, brass, piping and shielding against x-rays.1,2 Inorganic lead has been used in paint pigments, glass and ceramics. Among organic lead compounds, tetraethyl lead was used extensively as an anti-knocking agent in gasoline. Because of the health problems caused by lead, its use in, for example, solder, printing type and water pipes, has been replaced by other materials. Use of tetraethyl lead in petrol for cars has ceased in high economy countries.

In advanced economy countries, lead poisoning no longer occupies the predominant position it once held, and few physicians will see a case during their working lifetime. By contrast, in developing countries, lead poisoning is still commonplace, and on a worldwide scale it remains the most common of the occupational poisonings. However, it is essential that physicians who encounter lead workers have an understanding of the clinical effects of lead and can detect symptoms of poisoning at an early stage, as faulty work practices with lead can in some instances be extremely hazardous to health. Concerns over exposure to low levels of lead fume or dust in small workshops are justified and regular blood lead monitoring is usually required, as elevated blood lead levels are easily attained in the absence of sufficient awareness of the hazard lead working can present.
women who dipped the wares into lead glazes had a stillbirth rate which might approach 60 per cent. Lead poisoning also afflicted great numbers of the general population who were exposed to contaminated water supplies and to adulterated food.

Because of its widespread occurrence, physicians in the nineteenth century became expert on lead poisoning, perhaps none more so than Tanquerel des Planches whose ‘Traite des maladies de plomb ou saturnines’ in 1839 was a synthesis of his experience with more than 120 patients with lead poisoning whom he had treated in Paris. One of the features of lead poisoning that Tanquerel described was the blue line on the gums which was described in the Lancet the following year by Burton and which has since been known (in English-speaking countries at least) as the burtonian line; clearly, Burton had not read the Traite!

Concern about occupational lead poisoning in the second half of the nineteenth century contributed to the establishment of the Medical Inspectorate of Factories. Thomas Legge devoted much energy to reducing the toll from this disease, which he accomplished with considerable success.

In more recent years, much has been written about lead poisoning, but perhaps the most influential work has been that of Robert Kehoe who first put forward the notion that, if the blood lead concentration was kept below 80 mg/dL, the probability of a worker contracting lead poisoning was remote. Although this concept has been challenged in recent years, with the possibility that ‘subclinical’ forms of lead poisoning might occur, experience has tended to support Kehoe’s point of view and it is only in recent years that the maximum blood lead concentration considered safe for male lead workers has been lowered from 80 mg/dL.

**PRESENT-DAY EXPOSURES**

Worldwide, about 2.5 million tonnes of lead are produced each year, almost half of which is consumed in the United States. Workers engaged in primary or secondary lead smelting may have heavy exposures and they may also be exposed at the same time to other metals, such as arsenic or cadmium. Primary lead smelting is the process by which lead is extracted from its ore, usually lead sulphide (galena). High temperatures are used and, although large amounts of respirable lead oxide fume are evolved, the processes are usually well enclosed and ventilated. Secondary smelting involves the melting of scrap lead to reclaim the metal. This is usually carried out at temperatures below 500°C, with little evolution of lead oxide fume provided that temperature control is effective. The ‘dross’ (oxidized lead) that is skimmed off the surface of the molten metal may, however, give rise to considerable quantities of lead-bearing dust which may be inhaled or ingested by workers. Lead in any of its forms may be processed by secondary smelting and breaking down lead storage batteries is a main source.

There is still a demand for lead in the building industry. Significant quantities of lead were used in the manufacture of motor vehicles, although the practice has now been mostly phased out. Repairing car radiators involved rebuilding them using lead, but the trade has almost ceased with the introduction of radiators made from plastic, although it lives on in the restoration of radiators in antique vehicles and aeroplanes.

Airborne lead dust, sufficient to cause poisoning, may be produced during the manufacture of lead batteries, paints and colours, lead compounds, rubber products and glass, and during the dry disking, grinding and cutting by power tools of lead. Exposure may also arise from ‘sanding down’ (rubbing down) and from the application of lead paints and glazes, unless they are low solubility lead compounds. Stained glass workers and roofers who renovate ancient buildings and churches may be exposed to large amounts of fine, oxidized lead dust when removing weathered lead. Archaeologists and paleopathologists can also have inadvertent exposure to the dust when handling old lead coffins. Poisoning from the inhalation of lead oxide fume may occur in the demolition industry where lead-painted metalwork is cut up with gas-powered burning torches. Figure 23.1 shows the use of local extraction and personal protective wear to protect against lead dust and fume.

Firearms instructors and members of rifle clubs have also been found to have increased lead absorption resulting from exposure to lead dust from bullets and lead azide fume from the explosive charge. Some enthusiasts have been known to make their own bullets on the kitchen stove.

Lead compounds, such as dibasic lead phthalate, lead chlorosilicate and basic lead carbonates, are frequently incorporated into polyvinyl chloride (PVC) plastics when thermal stability and high tensile strength are needed. Some exposure to lead may occur during the manufacture of these plastics, although there is no risk from the finished materials.

Organic lead compounds have been added to petrol as anti-knock agents for over half a century. The most important additives are tetraethyl and tetramethyl lead; the former is extremely toxic, but the latter is less so. Exposure may result from the handling of these compounds in refineries or during the cleaning out of tanks that have contained leaded petrol. Because of the strict control measures in industrialized countries, lead poisoning among workers who put the additives into petrol is exceptionally rare. Poisoning has also been reported when leaded petrol has been inadvertently used as a solvent in the manufacture of cheap shoes or as a degreasing agent. A few cases of organic lead poisoning have also occurred in those who habitually sniff petrol.

The International Agency for Research on Cancer (IARC) has determined that inorganic lead compounds are probably carcinogenic to humans (group 2A), and that organic lead compounds are not classifiable as to their carcinogenicity to humans (group 3).³
THE UPTAKE OF LEAD

Lead can be absorbed through any route (respiratory, gastrointestinal and dermal), but the major route for elemental and inorganic lead is the respiratory and gastrointestinal tracts, whereas organic lead, such as tetraethyl lead, may be absorbed through the skin as well. Lead particles deposited in the upper airways are cleared by mucociliary movements and passed into the gastrointestinal tract where absorption takes place, whereas those in the lower respiratory tract are absorbed directly. Lead deposited deep in the lungs may be completely absorbed.1 About 6–19 per cent of lead in the gut is absorbed, but it may be higher in children or in fasting adults.2

The rate of absorption from both gut and lungs depends upon the solubility of the lead compound in body fluids; lead chromate is highly insoluble, whereas lead oxide is highly soluble and for this reason the toxicity of the chromate is considerably less than the oxide.

At one time, it was customary to give lead workers a pint of milk a day in order to protect them against the toxic effects of the metal. This well-meant gesture would have had little protective effect, however, for the presence of calcium in the gut cannot influence the uptake of lead from the lung and, moreover, the large amounts of lactose in the milk might have had the effect of actually increasing the uptake from the gut. Nevertheless, it was commonly observed that the general health of lead workers improved when they were given milk to drink – almost certainly a comment on their poor diet.

Inhalation is still the major route of entry for those with occupational lead exposure, but the risk from ingestion tends sometimes to be overlooked. Ingestion is often the principal route of entry, particularly where good standards of personal hygiene are not followed. Lead workers who are allowed to eat or drink in their workplace without first carefully washing their hands are unnecessarily increasing the risk they run, as are those who smoke at work. Inorganic lead compounds are not significantly absorbed through the skin, but organic ones may be.

DISTRIBUTION OF LEAD IN THE BODY

Once absorbed, lead is distributed in the body independently of the route of absorption. Most of the lead in blood is in erythrocytes. Approximately 94 per cent of the total body burden of lead is in the bones in adults.2 Pregnancy, lactation, menopause and osteoporosis may increase bone resorption and may increase blood lead levels. Organic lead compounds are dealkylated by P450 enzymes in the liver and converted to inorganic lead. The main routes of excretion of lead are urine and faeces. Renal clearance is positively related to blood lead levels at least in the range of 25 to 80 µg/dL. The elimination half-lives of inorganic lead are approximately 30 days in blood and 27 years in bone.2

Lead circulates in the blood bound to haemoglobin molecules, and substantially less than 5 per cent of the total blood lead is in the plasma; clinicians should therefore request blood lead and not serum lead analyses in a suspected case of lead poisoning. Lead has a long biological half-life and the total body burden increases with time. For the sake of simplicity, the total body burden can be considered to consist of three pools: a rapidly exchangeable pool in the blood and soft tissues, an intermediate pool in the soft tissues, and the skeletal pool. The skeletal pool may be further subdivided into an intermediate exchangeable pool in the marrow and the trabecular bone, and a very slowly
exchangeable pool in the compact bone and dentine. By far
the greatest part of the total body burden is in the skeletal
tissues.

The rapidly exchangeable pool in the blood is toxicologi-
ically the most important, although it represents only
about 2 per cent of the total body burden and has a biolog-
ical half-life of about 30 days. The blood lead concen-
tration is the most commonly used index of lead exposure,
but it should be remembered that it reflects only recent
exposure and is not necessarily related in any way to the
total body burden.

Lead is excreted through the kidney and the urinary lead
concentration was used for many years to estimate expo-
sure until reliable methods of blood lead analysis became
available. Furthermore, there is a considerable circadian
variation in excretion but, although urinary lead analyses
no longer have a role in the monitoring of inorganic lead
exposure, they are the most useful form of monitoring
exposure to organic lead. A small amount of lead is excreted
into the bile to appear in the faeces, but most of the lead in
faeces is that which was ingested but not absorbed.

Small amounts of lead are also eliminated in other body
fluids, e.g. sweat, saliva and breast milk, but they are not
important routes of excretion compared with urine.

Tetraethyl lead is dealkylated in the liver to the triethyl
form which then spontaneously dealkylates to the diethyl
form. Diethyl lead is excreted into the bile and is further
dealkylated in the gut to ionic lead. Diethyl lead is the only
metabolite of the tetraethyl form that appears in the urine.

**BIOCHEMICAL EFFECTS OF LEAD**

Lead has two important biochemical properties that largely
determine its toxic manifestations. First, it has a very high
affinity for sulphhydril (-SH) groups and thus is able to
inhibit the activity of enzymes which depend upon -SH
groups for their proper functioning. Two enzymes that
are inhibited by lead are of particular interest. They
are delta-aminolaevulinic acid dehydratase (ALAD) and
ferrochelatase, and both are concerned with haem synthe-
sis (Figure 23.2).
Second, the metabolism of lead mimics that of calcium in many respects and it is able competitively to inhibit the action of calcium at some important sites, such as the synapse, and during mitochondrial respiration. It is this feature of its metabolism that determines its bone-seeking properties.

**INORGANIC LEAD POISONING**

Lead gradually accumulates until critical body burdens are reached, when symptoms may appear suddenly and progress rapidly, although subclinical manifestations (e.g. depression of ALAD activity, reduced motor nerve conduction velocity) will have been demonstrable earlier. The outline of haem synthesis is shown in Figure 23.2, beginning with the reaction of glycine and succinyl coenzyme A to form delta-aminolevulinic acid (ALA). Two molecules of ALA move from the mitochondrium into the cell where they condense to form porphobilinogen (PBG) through the action of ALAD; from PBG are formed a series of porphyrinogens and porphyrins. The molecule then moves back into the mitochondrium where final rearrangement of the side chains produces protoporphyrin IX. The incorporation of ferrous iron into protoporphyrin IX, through the action of ferrochelatase, leads to the formation of haem. Normal functioning of this synthetic pathway is essential for the production of both haemoglobin and the oxidative enzymes in all body tissues.

Depression of ALAD and of ferrochelatase, results in increased amounts of ALA in the urine and increased amounts of protoporphyrin in the circulating red cells. Because of the ferrochelatase suppression, protoporphyrin forms a metal chelate with zinc instead of with iron, giving increased amounts of zinc protoporphyrin (ZPP). Other stages of the synthetic pathway are also affected and large amounts of coproporphyrin III are excreted in the urine.

The rate-limiting enzyme in this series is ALA synthase, so decreased formation of haem has the effect of increasing the amount of ALA formed. This process produces what is essentially a lead-induced porphyria. Depression of haem synthesis in many tissues (not only the erythropoietic) leads to progressive impairment of their ability to synthesize oxidative enzymes. There may also be competitive inhibition by ALA of transmission by gamma-aminobutyric acid (GABA), a putative brain neurotransmitter. The similarity in their chemical structures is shown below:

\[
\begin{align*}
\text{NH}_2\text{CH}_2\text{COCH}_2\text{CH}_2\text{COOH} & \quad 5\text{-aminolevulinic acid (ALA)} \\
\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{COOH} & \quad \text{gamma-aminobutyric acid (GABA)}
\end{align*}
\]

This pattern of effects is unique to lead poisoning and may be a useful adjunct in arriving at the diagnosis. The effects on ALAD occur at very low blood lead levels (less than 20 μg/dL; 1 mmol/L) and somewhere around 85 per cent of the activity of this enzyme may be suppressed before an increase in ALA in the blood is observed. Frank anaemia is usually a late phenomenon in lead poisoning. The mild anaemia of lead poisoning is mainly due to the impairment of haem synthesis, but there is also some evidence that red cell life span is somewhat shortened. This may be due to an increase in the mechanical or osmotic fragility of the red cells which, in turn, may be related to a loss of potassium caused by the inhibition of Na-K-ATPase.

**Symptoms and signs of overexposure to inorganic lead**

Classically, the patient with lead poisoning presents with a history of abdominal pain, colic and constipation. However, in high economy countries, not many patients now reach that stage. More likely, they will complain of the premonitory symptoms of undue fatigue, lassitude, generalized aches and pains in the muscles and joints with, perhaps, some abdominal discomfort. A few patients have diarrhoea; some may have a bad taste in the mouth. Because these symptoms are non-specific, the diagnosis of lead poisoning is not immediately considered, but a careful occupational history will be an important pointer. The diagnosis is a clinical one and the term ‘lead poisoning’ should not be used for asymptomatic workers who simply have abnormal biological tests. In the absence of clinical symptoms and signs, the term ‘excessive lead absorption’ may be more appropriate.

**Cardiovascular system**

In the British Regional Heart Study, a very weak but statistically significant positive association was found between blood lead and both systolic and diastolic blood pressure. The data also indicated that an estimated mean increase of 1.45 mmHg in systolic blood pressure occurs for every doubling of blood lead concentration. In a recent systematic review, Navas-Acien et al. concluded that the evidence is sufficient to infer a causal relationship of lead exposure with hypertension and that the evidence is suggestive, but not sufficient, to infer a causal relationship of lead exposure with clinical cardiovascular outcomes (e.g. coronary heart disease).

**Kidneys**

Lead is nephrotoxic, and when occupational exposures were considerably greater, renal damage was common (see Chapter 86, Nephrotoxic effects of workplace exposures). The early effects of lead poisoning on the kidneys are directed against the cells of the proximal tubule, but with continued exposure, severe and progressive renal insufficiency may
develop with interstitial fibrosis and secondary hypertension. Lead workers formerly had an increased mortality from cerebrovascular disease, but recent studies suggest that this is no longer the case. In adults with lead poisoning, renal effects are not likely to loom large in the clinical picture, but in children, renal tubular dysfunction, leading to a Fanconi-like syndrome, with aminoaciduria, glycosuria and hyperphosphaturia is much more common.

Toxic effects are uncertain over the range of blood lead level 20–50 μg/dL, but when the blood lead level exceeds 50 μg/dL, clear functional or pathological changes, including proteinuria, excretion of enzymes (e.g. N-acetyl-beta-D-glucosaminidase) in urine, and a lowered glomerular filtration rate may be observed. It was suggested that a low burden of lead (blood levels <5 μg/dL) may act as a cofactor with more established renal risk factors to increase the risk for chronic kidney disease and the rate of progression.9

**Nervous system**

Lead can affect the central, peripheral and autonomic nervous system. Mild changes in the central nervous system are characterized by progressive fatigue and lethargy. This is often first noted by family members and may become so severe as to disturb the patient’s work and social life. It is not unusual to hear the spouse complain that the patient has ‘changed’; he or she may lose interest in domestic and social activities and may come home from work, sit down and immediately fall asleep.

Severe encephalopathy with impaired consciousness, confusion and bizarre neurological signs is rare in adults in the developed countries, but is a common mode of presentation of lead poisoning in children. Occasionally, patients with inorganic lead poisoning may have psychiatric symptoms and the condition resembles a mixed affective organic state. It would be very unusual if these were presenting symptoms following occupational exposure, but the possibility that exposure to lead may exacerbate pre-existing psychiatric symptoms should be borne in mind.

In typical poisoning in adults with lead (metallic or inorganic), the major symptoms and signs are abdominal pain, anaemia and muscle weakness (peripheral neuropathy). Abdominal pains are often associated with abnormalities of intestinal movements (constipation and/or diarrhoea, and its repetition), which may reflect autonomic dysfunction. The pain is not necessarily so severe as to be referred to as ‘colic’. Neuropathy is predominantly motor, tending to be in the muscles most often used, often asymmetric, while sensory involvement is rare. In adults, the weakness is more common in the upper extremities than in the lower extremities. Extensors of fingers may be first impaired and then wrist extensors causing ‘wrist drop’ (Figure 23.3), but it is rarely encountered in developed countries today. Muscle weakness and atrophy may not be limited to the fingers and wrist: thenar and interosseous muscles may also be involved. Even upper arm and proximal muscles may show weakness. Weakness in lower extremities, which is more commonly seen in children, may be present as ‘foot drop’.10

Overt impairment of the brain (encephalopathy) occurs in one- to three-year-old children who have compulsive ingestion (pica) of lead-containing materials, such as wall chips in old, run-down houses. Adults who consume a large amount of ‘moonshine’ (whisky made in lead-lined stills) and some Ayurvedic medicines may develop lead encephalopathy.12 Rarely, occupational exposure to inorganic lead causes apparent encephalopathy.13 Most of the patients have anaemia. The severity of symptoms range from confusion, disorientation to repeated seizures, coma and death.11 Lateralizing neurologic signs (focal seizures, hemiparesis, positive Babinski sign on one side) were seen in 35 per cent of patients reported by Whitfield et al.11 Most seizures were refractory to standard anti-convulsants, but many of them responded dramatically to intravenous administration of CaNa2EDTA. Changes observed on magnetic resonance imaging (MRI) in one patient, also resolved after treatment with British anti-lewisite (BAL).11

Exposures to organic lead (tetraethyl lead) may occur occupationally and intentionally (sniffing leaded petrol).14 Encephalopathy may appear several hours to weeks after the exposure, with headaches, excessive salivation, vomiting, irritability, insomnia, delusions and hallucinations. Tremor and ataxia are often seen. Death may follow coma. However, in occupational intoxication with tetraethyl lead, once recovery starts, it often takes place rapidly and may be complete within two months.15

With much less severe exposures to lead, subclinical encephalopathy may be detected by a neuropsychological test in children. For instance, Canfield et al. reported that blood lead concentrations less than 10 μg/dL are inversely associated with intelligence quotient determined at the ages of three and five years.16 It has not been clarified whether such an association exists in adults. Nevertheless, low to moderate exposure in adults had been associated with symptoms of malaise, fatigue, irritability, lethargy, headache and decreased libido, as well as decreased neurobehavioural test scores.17 Analysing data from 21 environmental and
occupational studies from 1996 to 2006, Shih et al. concluded that there is moderate evidence for an association between psychiatric symptoms and lead dose, but only at high levels of current occupational lead exposure or with cumulative dose in environmentally exposed adults. Further work is needed to confirm if chronic lead exposure is related to a syndrome of mild cognitive impairment.18

Reproductive system

Lead may lower the fertility of men having blood lead levels higher than 30–40 μg/dL.2 Sperm abnormalities may appear when the blood lead level is higher than 40 μg/dL.2

Endocrine system

At blood lead levels higher than 40–60 μg/dL, serum thyroxine may be lowered and thyroid-stimulating hormone (TSH) may not be appropriately released.2 Delayed puberty (manifesting as delayed appearance of pubic hair and breast development) has been found in girls with higher blood lead levels.19

Musculoskeletal system

Arthralgia has been recognized as a manifestation of acute lead poisoning for well over 100 years, but is usually a non-specific symptom. Lead also interferes with normal urate metabolism and may precipitate attacks of gout sometimes associated with nephropathy.20 The condition affects those who consume large quantities of home-distilled spirits, which may contain significant quantities of lead derived from solder within the still – hence ‘saturnine gout’.

INVESTIGATION OF LEAD POISONING

There are few clinical signs to aid the diagnosis of lead poisoning. The patient may be pale and there may be some muscle weakness if there is a peripheral neuropathy; wrist drop is one of the classic signs of lead poisoning, but is now rare (Figure 23.3). A burtonian or blue line may be present on the dental margin of the gums. It is caused by bacterial deposition of lead sulphide, is associated with poor dental hygiene and is absent from the edentulous. It indicates lead exposure, not lead poisoning. There may be general tenderness of muscles and joints, and on palpation of the abdomen. The pallor of lead poisoning is not caused by anaemia, but by cutaneous vasoconstriction.

Laboratory investigations are important in the diagnosis of lead poisoning. About a century ago, the appearance of basophilic granules in the red blood cells was recognized as a concomitant, almost as a sign, of lead poisoning. By the 1920s, before the advent of microchemistry, the stippled cell count was used to monitor the exposure of lead workers. That has now been replaced by the biochemical measures described below. Stippled cells are not unique, as was at one time thought, but may be found, for example, in severe secondary anaemia, malignant disease and malaria. The importance of stippled cells today is that the haematologist may spot them in the blood film of a patient ‘under investigation’ and alert the clinician to consider the possibility of lead poisoning. In lead poisoning, iron entering the erythrocyte precursors is not fully utilized and accumulates. This non-haem iron, together with ferruginous micelles, fragments of damaged mitochondria, and some RNA is believed to comprise the basophilic granules (see Chapter 90, Haemopoietic effects of workplace exposures: anaemias, leukaemias and lymphomas).

A band of increased density may be seen on radiographs at the growing ends of the long bones and the phalanges in children with lead poisoning, but not in adults. This increased density is caused by an alteration in the architecture of the bone and not by deposition of lead. This may be comparable to ‘growth arrest lines’. In severe cases, there may be changes in the shape of the bone, which revert gradually to normal once the child is removed from exposure and recovers.

TREATMENT

The basis of the treatment of lead intoxication is immediate removal from any source of exposure to lead. If symptoms are mild, further treatment is unnecessary and the blood lead level will gradually fall towards normal and should be monitored periodically. The process may take up to several months, so blood testing every few days is unnecessary and the clinician should not be anxious provided the patient’s condition is improving. If the condition is more severe, treatment with chelating agents should be considered, but should be based on occurrence of severe symptoms and not on biochemical or haematological measurements. In some countries, chelation is carried out simply because the blood lead level is high: there is no evidence that this confers any long-term benefit and there is always the risk of an adverse reaction to the drug.

The agents most commonly used for chelation are penicillamine and sodium calcium edetate. Penicillamine is given orally, 1 g/day for adults in divided doses for five days. If after a few days the blood lead level rises again and the symptoms recur, the course of treatment might have to be repeated. Sodium calcium edetate is used at 50–75 mg/kg per day in two divided doses as a slow intravenous infusion for five days.21 This will relieve colic within a few hours. With both drugs, the full blood count should be tested at the beginning and end of each treatment period. Because of their nephrotoxicity, the urine should be tested for proteinuria and haematuria, although renal disturbance
ORGANIC LEAD POISONING

Poisoning with tetraethyl lead causes a toxic organic psychosis and so the picture is dominated by psychiatric symptoms which may appear suddenly. There is nothing in the clinical picture that is pathognomonic of organic lead poisoning and the diagnosis is made by establishing exposure. Occupational cases are uncommon and, as noted previously, usually occur in those who have been cleaning out tanks in which leaded petrol has been stored or who have been using leaded petrol inappropriately as a solvent or degreasing agent – tetraethyl lead is well absorbed through the skin. Occasionally, cases are seen arising from the abuse of solvents containing organic lead compounds.

Tetraethyl lead decomposes slowly in air, rapidly in bright sunlight, to yield needle-like crystals of tri-, di- and monoethyl lead compounds with a garlic-like odour. In their dry state, they may be dispersed mechanically in air to be inhaled or deposited on the skin. Their inhalation induces vigorous, often paroxysmal sneezing, irritation of the upper respiratory tract and, in sufficient dosage, mild organo-lead poisoning. In contact with warm, moist skin or unprotected ocular membranes, they induce itching, burning and transient redness.

The symptoms found in inorganic lead poisoning do not occur in organic lead poisoning, although patients may have some abdominal discomfort and anorexia. It is, however, important to remember that both forms of lead poisoning may occur together, particularly in workers involved in the demolition or refurbishment of leaded-fuel storage tanks, which may be lead painted. The blood lead is usually not raised above 50 μg/dL (2.5 mmol/L) and sometimes not elevated at all, and ZPP and porphyrin levels are usually within normal limits. A raised urinary lead is the most important confirmatory laboratory test.

Poisoning is not seen at concentrations below 150 μg/dL (0.7 mmol/L), but may occur at concentrations above 350 μg/dL (1.8 mmol/L). The use of chelating agents in the treatment of organic lead poisoning is of little value and symptomatic therapy, such as with diazepam, is required. Adequate sedation (which may need to be prolonged) and nutritional support are important and, because sedation is symptomatic, it should be used only as long as is necessary to control symptoms. Complete recovery is usual, but the illness may be prolonged and characterized by periodic and sudden psychotic relapses. The main features of a clinical case are shown in Figure 23.4.

EVALUATING LEAD EXPOSURE

In the United Kingdom and the United States, most lead workers and establishments working with lead come under specific regulations and there are criteria laid down for deciding whether lead exposure is going to be significant enough to warrant this legal requirement. In the UK, the Control of Lead at Work Regulations and accompanying Approved Code of Practice provides detailed stipulations on working with lead, including medical surveillance. Physicians monitoring the workers under these regulations have to be appointed by the Health and Safety Executive.23 In the UK and other countries, the general physician seeing a patient who has been working with lead should obtain further advice from the statutory health and safety body of their country, or from an occupational physician, when they suspect that the exposure may be causing ill health.

Among the methods to evaluate lead exposure in workers, lead levels in whole blood are the most widely used because of their relative ease and accuracy. The blood lead concentration in the normal UK population is less than 10 μg/dL (0.5 mmol/L). Occupationaly exposed workers can have levels much higher than this, but acute poisoning seldom occurs if the blood lead level is below 80 μg/dL (4 mmol/L), as described above. Data on the correlation between the clinical effects of lead and blood lead concentrations have been summarized in publications such as the International Programme on Chemical Safety (IPCS) Environmental Health Criteria on inorganic lead.22 Abdominal colic and renal effects are unlikely to arise if blood leads are below 100 μg/dL, and the risk of developing significant anaemia is small below 50 μg/dL. As far as severe neurological effects are concerned, life-threatening encephalopathy is unlikely to occur at blood levels below 100–120 μg/dL in adults (80–100 μg/dL in children). There are no firm quantitative data for the development of the classical sign of peripheral neuropathy.
Suspension levels

Lead workers may need to be removed from continuing exposure to lead if the blood levels rise too high. In the UK, there is a statutory requirement for doing this in asymptomatic men with blood lead levels greater than 60 μg/dL (3 mmol/L) and women of reproductive capacity with blood lead levels above 30 μg/dL (1.5 mmol/L), and for young people (under 18 years) with blood lead levels above 50 μg/dL (2.5 mmol/L). All such cases are reportable by the employer to the Health and Safety Executive and poisoning by lead or compound of lead is also a prescribed disease (see Chapter 5, Biological monitoring).

A woman of reproductive age who has a medical or physical condition that would make it impossible for her to conceive (e.g. she is sterilized, or had a hysterectomy, or is post-menopausal), would be suspended at 60 μg/dL (3.0 mmol/L). The reason for this higher level is that 30 μg/dL is set to protect the developing fetus, which does not apply in this situation.

The blood lead should be urgently repeated to confirm the level and the suspended worker can continue working (away from lead exposure) until the level falls, usually over a period of two weeks or more. There is a concession to workers who may have been in the lead industry for many years and who have built up a large body burden of lead (not a likely eventuality in the UK nowadays) which could take a long time to fall below the suspension level of 60 μg/dL. They may be asymptomatic, with normal levels of ZPP. Further official guidance should be sought on their management.

Action levels

Action levels are also laid down which warn the employer that the blood lead concentration is reaching the suspension level and action needs to be taken to control exposure with the aim of reducing the worker’s blood lead below the action level. The action levels are for women of reproductive capacity 25 μg/dL (1.25 mmol/L), young people (aged 16 and 17) 40 μg/dL (2.0 mmol/L), and for any other employee 50 μg/dL (2.5 mmol/L).

The frequency of blood testing for lead depends upon the levels found and is stipulated in the information provided with the regulations on medical surveillance.

A high blood lead is not synonymous with lead poisoning, so additional tests may be useful. The ZPP level in the normal population is usually less than 2.0 mg/g Hb. It begins to rise when blood lead concentrations reach the range 35–45 μg/dL (1.75–2.25 mmol/L) in males or 25–35 μg/dL (1.25–1.75 mmol/L) in females. Levels rise rapidly at blood lead concentrations higher than 50 μg/dL (2.5 mmol/L). In lead poisoning, the ZPP level will be above 20 mg/g Hb, often at least one order of magnitude greater. The only other common condition that causes a rise in ZPP is iron deficiency anaemia. It is important, however, to remember that the ZPP does not immediately increase following lead exposure as it depends upon the formation of new red cells, and lag periods of up to two months have been reported. For recent exposures, it is better to measure urinary ALA concentrations. Normal values for subjects not exposed to lead are less than 5 mg ALA/g creatinine (4 mg/mmol creatinine) and the increase consequent upon
lead exposure reflects that of ZPP. The lag period is only two weeks and levels in people suffering from lead poisoning will be above 20 mg ALA/g creatinine (16 mg/mmol creatinine). If the exposure period is less than two weeks, it may be possible to have the blood ALAD activity measured: the normal level is greater than 6 European units.

At blood lead concentrations lower than those which cause frank neuropathy, motor nerve conduction velocity, especially of the slower fibres, is reduced. There is no evidence of a dose–effect relationship. Changes in performance in psychometric tests have been reported in lead workers with blood lead levels below 70 μg/dL (3.5 mmol/L). There is almost no consistency in the pattern of changes observed and, although some improvement in test scores is reported following a reduction in exposure, the changes are of little long-term significance and the subjects are not themselves aware of any deterioration in their performance. These changes in the peripheral and central nervous systems are, however, of little value in the diagnosis of acute lead poisoning.

A recent advance is in making a distinction between recent and longer-term cumulative doses. Blood lead represents the former, and a biological marker of cumulative dose is the bone lead level which can be measured by K-shell x-ray fluorescence. The bone (e.g. tibia) is irradiated by x-ray to provoke emission of photons of lower energy (fluorescence) and the fluorescence characteristic of lead is determined. Since most lead is finally accumulated in bones, bone lead is a good index of exposures over a long period and it can be determined non-invasively. Utilizing this and magnetic resonance spectrometry (MRS), another non-invasive method applicable to the brain, Weisskopf et al. assessed metabolites in the hippocampus and suggested that glial changes may be a sensitive indicator of cumulative exposure to lead in adults.

At present, however, x-ray fluorescence is available only in a limited number of institutions. Repeated measures of blood lead over time of exposure can be used to derive time-integrated indices, i.e. integrated blood lead (IBL) or cumulative blood lead index (CBLI). These are mathematically the area under the curve of a graph of blood lead versus time. Such indices have been demonstrated to be well correlated with tibia lead levels.

Kosnett et al. consider that there is a growing body of evidence that establishes the potential for hypertension, effects on renal function, cognitive dysfunction and adverse female reproductive outcomes in adult workers with blood lead concentrations regularly below 40 μg/dL. These and other authors are concerned that while the effects of lead at low levels are reversible, repeated occupational exposure (as measured by tibia lead levels) is cumulative in the body and can lead to chronic health effects. Accepting that regulations and their action or suspension levels are an integral part of modern-day controls on exposure, it would nevertheless be prudent for the physician to recommend all employers and lead workers to adopt work practices and control measures that aim to keep the blood lead concentration below 30 μg/dL.

**Key points**

- Clinical lead poisoning has become increasingly rare in inorganic lead workers in advanced economy countries, but it remains common in other parts of the world. Regular environmental and blood lead monitoring is needed to prevent excess lead absorption by inhalation and ingestion.
- Blood lead action levels and suspension levels are laid down in Lead Regulations in the UK and doctors have to be specially appointed to undertake the monitoring of lead workers. Appointed doctors have powers to suspend workers in accordance with the Lead Regulations.
- Organic lead exposure, e.g. tetraethyl lead, is much less common in industry and clinical poisoning is marked by a toxic organic psychosis and encephalopathy. The symptoms found in inorganic lead poisoning do not occur in organic lead poisoning and sometimes the blood lead is not raised at all.
- In classical inorganic or metallic lead poisoning, the major symptoms and signs are abdominal pain, colic, constipation, anaemia and wrist drop (peripheral neuropathy). More commonly, workers will present with fatigue, lassitude and generalized aches and pains.
- Because of the lack of knowledge on the health effects of lead at lower levels of exposure, it would be prudent to ensure that the blood lead level in individual workers is kept below 30 μg/dL.

Exposure and health effects 199
References 200

PROPERTIES AND USES

Magnesium comprises 2 per cent of the earth’s crust and as such is the eighth most abundant element. It is an alkaline earth metal and its salts are highly soluble in water. Its major industrial uses are in alloys with aluminium, to produce light and strong materials employed in manufacturing automobiles, missiles, aircraft and ships, and in containers of all sizes down to cans. It is used in refining steel and titanium, and in the extraction of uranium. Its reactivity with oxygen in air is exploited in flares and fireworks and magnesite (magnesium carbonate) is used as furnace linings for the production of metal, glass and cement. Magnesium salts, such as magnesium hydroxide, are used as an antacid (milk of magnesia), and the sulphate has historical popular usage in topical applications to wounds and pustules, and as a laxative (Epsom salts).

There are many potential magnesium ores, such as magnesite, dolomite, calcite, talc, serpentine and olivine. Dolomite and magnesite are mined extensively throughout the world. Magnesium is also commercially produced as magnesium chloride by electrolysis of seawater.

ESSENTIALITY AND METABOLISM

Magnesium is a biologically essential nutrient and is the second most abundant intracellular cation, after calcium. Its affinity for phosphate ligands lends it to the stabilization of biological molecules, such as nucleic acids and nucleotides, particularly adenosine triphosphate. The magnesium–ATP complexes and similar nucleotide complexes are cofactors for a wide variety of enzyme activities involving energy transfer, phosphorylation, and the active transport of compounds and cations (e.g. sodium, potassium, calcium, copper, iron and zinc) across membranes.

Magnesium is ubiquitous in the body: 40 per cent of systemic magnesium is in soft tissue and 60 per cent is in the skeleton. At customary intakes (200–600 mg daily), magnesium is absorbed by specific carrier-mediated pathway across the enterocytes, and by a paracellular route driven by solvent drag. About 50 per cent of the daily intake is absorbed, and this is in essence unregulated, though it might increase in response to vitamin D. The element is distributed in the circulation principally (70–80 per cent) unbound, of which about half is ionized; the remainder is bound to proteins, particularly albumin. There is a rapid exchange of the cation between pools. The mechanisms and regulation of the systemic distribution and uptake of magnesium are becoming better understood. Overall, homeostasis is achieved by renal adaptation; with increasing body burdens of magnesium renal clearance of the element is increased and when systemic needs increase, renal excretion is reduced. Magnesium is reabsorbed in the thick part of the ascending loop of Henle, and this is influenced by calcitonin, thyroxin, glucocorticoids, glucagon and angiotensin. On typical dietary intakes, 95 per cent of the filtered load of magnesium is reabsorbed.

EXPOSURE AND HEALTH EFFECTS

There is very little evidence of occupational systemic magnesium toxicity occurring in otherwise healthy individuals. Excessive intakes, usually of medicines and unlicensed products, may cause adverse effects in individuals with renal dysfunction, and even in healthy individuals excessive...
ingestion of magnesium laxatives and antacids may cause diarrhoea, which is probably an osmotic effect of the metal cation and of the accompanying sulphate or chloride anions. With larger exposure, other features appear, including nausea, vomiting, abdominal pain, parasthesia, muscle weakness, reduced blood pressure, bradycardia and paralytic ileus. Biochemical features include hypermagnesaemia, metabolic alkalosis and hypokalaemia. The neuromuscular phenomena, and intestinal ileus arise from disturbances of calcium metabolism and they respond to a controlled intravenous infusion of calcium.3

Inhalation of magnesium oxide fumes from burning magnesium may cause metal fume fever; classically with fever, chills, nausea or vomiting and muscle pain 12 hours after exposure, lasting up to 48 hours.1

Key points

- Magnesium salts can cause metal fume fever.
- Magnesium toxicity is unusual in healthy individuals, but the risk is increased in those with impaired renal function.
- Magnesium salts cause gastrointestinal symptoms predominated by diarrhoea.
- Systemic features of magnesium excess include neuromuscular symptoms, alkalosis and hypokalaemia which arise from altered calcium-dependent functions.
- Treatment is by calcium infusion.

Manganese

GRANT McMILLAN AND FINLAY D DICK

INTRODUCTION

Manganese is relatively non-toxic to the adult human, but exposures can cause serious disease of the respiratory and central nervous systems.

SOURCES

Manganese (Mn), a ubiquitous naturally occurring element found in rocks, soil, water and food, is the twelfth most abundant element in the Earth’s crust, about 0.1 per cent of it. It is the fourth most widely used metal in the world in terms of tonnage, yet does not occur naturally as the free metal. Some 46 million tons of manganese ore are extracted annually (2008) from shallow underground mines or open pits – some of colossal size. Ninety per cent is used in steel production. Commercially important ores include those containing pyrolusite (MnO₂), the main manganese ore, and the much less commonly found rose-red to pink rhodochrosite (MnCO₃). The principal producers of manganese ore are South Africa (23 per cent), China (23 per cent), Australia (18 per cent), Gabon (13 per cent), Brazil (11 per cent), India (8 per cent) and Ukraine (4 per cent).

CHARACTERISTICS

After mining, the ore must be milled and further processed before it can be used commercially. The metal is whitish-grey in colour, very hard but ordinarily too brittle to be of structural value itself yet, paradoxically, has proved over centuries to be an irreplaceable alloying material imparting strength and hardness to iron and steel.

PRINCIPAL USES AND SOURCES OF OCCUPATIONAL EXPOSURES

Mining and preliminary treatment of ore

Manganese ore must be mined, milled, separated from other minerals, dried, sometimes crushed or ground again, often packed and mixed with other minerals before it can be refined for commercial use. Considerable amounts of airborne dust are liable to be produced during all these processes, with the attendant risk of exposure unless effective dust suppression and other protective measures are taken.
Refining manganese and making iron and steel

The ore must be refined. Pure manganese used for the production of non-ferrous alloys is produced by hydrometallurgical and electrolytic processes. Blast or electric furnaces are used to process the much greater quantities of ore required in the manufacture of basic iron and in steelmaking. In the former, it is added directly to the furnace charge. For steelmaking, alloys such as ferromanganese (50–80 per cent Mn), silicomanganese (60–70 per cent Mn) and spiegeleisen (10–35 per cent Mn) are made containing industry-specified amounts of manganese, iron ore, carbon and silica oxide. The furnaces are tapped into pots and moulds. After cooling, the alloy ingots may be cut for easier handling and/or are often crushed or milled for transport. This allows better control of formulation during steel manufacture when specified quantities of such alloys are added to the furnace charge to impart the properties (including hardness and wear resistance, stiffness and strength) which equip them for particular fabrication or manufacturing tasks. No substitute for manganese has been found to provide these essential qualities of steel.

Occupational exposures to manganese oxide compounds may occur at each and any of these stages in manufacture. The composition and structure of the aerosol particles in the emissions are complex and vary from process to process. The compositional complexity of these particles is such that toxicological investigations of the kinetics of pure compounds may not easily be associated with the work situation exposures.

Fabrication and manufacture

As welding to join steel components is such a widely used process and manganese compounds are always present in fume arising from it, it is probably now the greatest source of industrial exposure to manganese in terms of the number of people who work with or close to the process. Most steel welding consumables which are melted to form the alloy contain less than 6 per cent manganese, but those used on joining high manganese steels – such as those used on railway crossing points or in the process of hardfacing bulldozer blades) – contain much higher concentrations. (used for toughening surfaces such as the ‘biting edge’ of metal cleaning, bleaching and tanning; and as a preservative for fruit and flowers.

- **Manganese dioxide**: dry cell batteries, porcelain and glass-bonding materials, amethyst glass production, incendiaries, fireworks, matches, the starting material for other manganese compounds.
- **Manganese sulphate**: fertilizer, ceramics, glazes, varnishes, fungicide, livestock nutritional supplement.
- **Potassium permanganate**: produced by the electrolytic oxidation of MnO₂ in potassium hydroxide (KOH) is used as a disinfectant, anti-algal agent, water purifier; in metal cleaning, bleaching and tanning; and as a preservative for fruit and flowers.
- **Manganese ethylene-bis-dithiocarbamate** (MANEB): which is widely applied to edible crops as a fungicide against many foliage diseases and is therefore a potential source of manganese in soil and in food crops.
- **Methylcyclopentadienyl manganese tricarbonyl** (MMT) is used to improve combustion in boilers and motors and may be used as a substitute for lead as an anti-knock agent in petrol/gasoline.
- **Manganese dipyrdocarbdl phosphatd** and other manganese compounds have been recommended to replace gadolinium complexes as tissue-specific contrast agents.

### METABOLIC ACTIVITY

Manganese is an essential trace element for humans. It acts across a broad spectrum of activities within or as a cofactor for enzymes, such as superoxide dismutase and xanthine oxidase.

### EXPOSURE

Exposure to manganese may be dietary, background environmental and occupational.

Diet is the prime source of manganese for those not occupationally exposed. Examples of common sources are grains, nuts, milk products, meat, poultry, fish, eggs, fruits, leafy green vegetables and tea. Water is usually not a principal source. Dietary deficiency disease has not been reported.

Some manganese compounds, for example MnCl₂ and MnSO₄, are soluble in water and therefore exposure to manganese may result from the ingestion of drinking water which has been contaminated by natural sources or buried waste, e.g. batteries. This may be of particular importance to children’s intellectual function.

All humans have background exposure to manganese as it occurs in almost all types of soil. Erosion is the most important natural source of manganese in the air. Anthropogenic sources include the combustion of fossil fuels and emission of manganese from industrial processes. Above average background exposures are most likely to occur in those who work or live near a mine, ore mill, smelter, factory or other site where significant amounts of...
Manganese are released into the air. Almost all manganese-related disease is related to occupational exposures.

**ABSORPTION, TRANSPORT, DISTRIBUTION AND HOMEOSTASIS**

Manganese compounds may be absorbed into the body through the gastrointestinal tract and the lung, can cross the intact blood–brain barrier and penetrate the placenta. The route of exposure can influence the distribution, metabolism and potential for toxicity of manganese-containing compounds. The respiratory inhalation route is usually much more important than the oral route for risk assessment in the brain and elsewhere, whereas iron overload has been shown to increase susceptibility to manganese loading in the brain and elsewhere, whereas iron overloading is associated with decreased uptake. This may have an as yet unexplored practical effect on the risks of toxicity associated with some occupational exposure to manganese-containing compounds, e.g. some steel welders have been shown to be iron overloaded.

Absorbed manganese is rapidly eliminated from blood, initially mainly to the liver which seeks to maintain homeostatic control between absorption and requirement and where excesses are stored in the first instance. It is then widely distributed in the body. Some 98 per cent of excess amounts of manganese are excreted in the bile for disposal in faeces with the remainder being excreted in urine. Homeostatic mechanisms can be overwhelmed by excess exposure and absorption through the lungs and/or gastrointestinal tract and/or by liver dysfunction. This may result in accumulation of manganese in the brain (see below Acute effects on health).

**MUTAGENICITY, TERATOGENICITY AND CARCINOGENICITY**

Expert review indicates that relatively high doses of manganese affect DNA replication and repair in bacteria, and cause mutations in microorganisms and mammalian cells, although the Ames test does not appear to be particularly responsive to manganese. In mammalian cells, manganese causes DNA damage and chromosome aberrations.

Manganese deficiency can affect fertility adversely and be teratogenic – but this is unlikely to be a practical problem in humans as deficiency is rare. Large amounts of manganese salts also affect fertility in mammals, can penetrate the placenta and are toxic to the embryo and fetus. It has been stated that pregnant women should not be exposed to manganese at the workplace.

Information on cancer due to organic and inorganic compounds of manganese exposure is scanty, but the results available do not demonstrate that manganese is carcinogenic.

**ACUTE EFFECTS ON HEALTH**

Acute injury or illness due to manganese exposure appears to be rare. Exposure to freshly formed oxides of manganese may cause metal fume fever (which is described in Chapter 44, Welding, fumes and inhalational fevers). Inhalation of particulate manganese compounds has been linked causally to the development of pneumonitis, an association first reported in a group of British workers manufacturing potassium permanganate. A statistical association was observed between deaths from pneumonia and manganese exposure in Norwegian ferroalloy plants. Iron deficiency, resulting in skin lesions, has been observed in manganese mine workers and attributed to the cumulative effects of high levels of manganese in the drinking water in addition to dust, in the workplace.

Solutions of potassium permanganate >1:5000 are corrosive and mistaken ingestion carries the risk of local and possibly life-threatening burns of the upper gastrointestinal tract. Manganese may be absorbed through damaged skin, for example following burning with a hot acid solution containing 6 per cent manganese. Manganese has also been implicated in the development of allergic contact dermatitis in a worker handling aluminium alloy which contained manganese.

The acute onset of clinical neurological or psychotic symptoms was described over 40 years ago in a small number of mine labourers exposed to high concentrations of dust from drilling rock containing manganese compounds.

**CHRONIC EFFECTS ON HEALTH**

Long-lasting observed effects of overexposure to manganese include asthma and impaired lung function and the development of the serious mood and movement disorder termed ‘manganism’. It has been hypothesized that manganese exposure, especially during employment as a welder, might also cause or accelerate the development of Parkinson’s disease (PD). This and wider aspects of occupational manganism are considered in detail later in this section.
A rare manifestation of manganese poisoning known as Morvan’s fibrillary chorea has been postulated in a case report from Germany, but there is no definite proof. One group has reported that there may be toxic effects on the cardiovascular system.

**MANGANISM**

The clinical manifestations of manganism are well documented, largely due to the work of Huang and colleagues who have followed up a number of workers affected by manganese intoxication over many years. It is a slowly progressive, disabling, neurological complex of signs and symptoms characterized by neuropsychiatric and extrapyramidal dysfunction attributed to deposition of manganese in the brain, selectively within the basal ganglia. There is evidence of individual hypersusceptibility (see under Workplace exposure limits, p. 208).

Clinical manganism was first described in 1837 by John Couper, Regius Professor of Materia Medica in the University of Glasgow in Scotland. The victims were workers employed to grind ‘black oxide of manganese’ in that city’s St Rollox Chemical Works, the largest industrial chemicals complex in the world at that time. It was used as a catalyst in the production of chlorine in a new process to manufacture bleaching powder much less expensively than elsewhere. This material was required in vast quantities in the manufacture of linen and paper, two of Scotland’s main industries at that time. The savings which resulted gave Scotland a great commercial advantage and greatly enhanced its trade and wealth. Couper remarks, ‘the surface of their bodies is, of course, constantly covered with the manganese; the air which they breathe is loaded with it in the form of fine powder, and they are exposed, from neglect of cleanliness, to swallow portions of it along with their food’.

Little more was written about manganism until 1901 when Von Jaksch described similar symptoms, including very marked uncontrollable laughter, in three men who worked together in a factory making potassium permanganate – where they were employed as grinders of manganese dioxide by stamping on it wearing wooden shoes amidst much dust – and attributed their illness to their work. Elsewhere, the illness of four men who had been exposed for several months to air filled with fine dust as they ground ‘brownstone’ (manganese dioxide) was reported. They had mask-like faces, fell if they tried to walk backwards, ‘on stepping downstairs were compelled, after losing control of several steps, to take two or three plunging steps forward’, and many other clinical features of classical manganism as described today.

Subsequent reports described similar effects in workers in a range of workplaces and processes including manganese mines, ore crushers and separating mills, ferromanganese and silicon-manganese plants, and in welders. Some research groups have attributed subclinical effects to exposure. It has been hypothesized that exposure to manganese may accelerate the onset of Parkinson’s disease. These remain controversial areas and are discussed under Occupational manganism (p. 207).

**PATHOLOGY AND RESULTING CENTRAL NERVOUS SYSTEM DYSFUNCTION IN MANGANISM**

The causal relationship between exposure to manganese and specific effects on the nervous system was established in 1919 when, for the first time, detailed clinical, laboratory and epidemiological information were brought together.

The brain normally contains very little manganese. Manganism is due to overexposure to manganese, usually over a protracted period, and, put simply, to it accumulating in and damaging principally dopamine receptor cells in the basal ganglia deep in the brain. This provides specific appearances on magnetic resonance imaging (MRI) of the basal ganglia (see below under Diagnostic features of manganism). In contrast to idiopathic Parkinson’s disease (IPD), dopamine generation is left intact (as demonstrated by the absence of a good response to L-dopa medication). In consequence, there is dysfunction of dopamine and other neurotransmitter-dependent facilitating and inhibiting chains which exert controls over movement. It is not yet understood how mood and cognitive function are affected.

Following cessation of exposure, manganese is cleared slowly from the brain with a variable time course. Within neurons, it is sequestered within mitochondria and these can clear a manganese load only very slowly. With inhalation exposure, the lungs may act as a reservoir of manganese to be absorbed once external exposure has ceased. All these factors may contribute to the progression of clinically apparent manganism even after cessation of manganese exposure.

**DIAGNOSTIC FEATURES OF MANGANISM**

It can be useful to consider manganism as having up to four stages. This should not be taken to imply that the disease will present at stage 1 as stages may be bypassed, nor that the stages will form a continuum as there is insufficient consistent evidence to reach a firm conclusion on that point.

Progress is usually slow, extending over years before the full blown syndrome is apparent, with the rate and extent of progression related loosely to the level of dose of manganese received, but subject to the vagaries of individual susceptibilities in those who appear to be doing the same or similar work. These may be constitutional or due perhaps to differences in working and hygiene habits, alcohol intake and/or coexistent liver disease.
Advanced manganism is a chronic crippling disease with permanent disability, particularly with regard to the use of the legs, but does not appear to be life-shortening.

Manganism bears a superficial similarity to idiopathic Parkinson’s disease but, as summarized in Table 25.1, can be distinguished from it by careful clinical examination and appropriate imaging investigations. Differentiating these two conditions is an important practical consideration for several reasons, but possibly none more vital than preventing further exposure if manganism is shown to be the correct diagnosis as the longer the delay the more likely it is that symptoms will persist or worsen. In practice, in the current state of knowledge it may be thought prudent to at least consider preventing occupational exposure to manganese in all those found to have idiopathic Parkinson’s disease as the possibility of an additive effect cannot be excluded and no safe threshold has been established.

### Stage 1

Subclinical performance deficits may be the first manifestations. These may be undetectable without special neuropsychological testing and occur at exposures much lower than those at which clinical manganism has been observed. It is important to be able to detect the disease at this stage as this will allow intervention by stopping exposure. Reviewers have concluded that insufficient soundly based evidence of a consistent pattern of significant test outcomes or of a dose–response relationship has been published to permit subclinical identification of occupational manganism in isolation, as part of a continuum of disease or as a basis for health surveillance of potentially exposed workers. That said, the published conclusions drawn in some of the studies cast sufficient doubt on the level of protection afforded by the then extant occupational exposure standards to have prompted changes in regulatory action (see under Workplace exposure limits, p. 208).

### Stage 2

There is often a prodromal clinical period with insidious onset of non-specific symptoms. It is not seen in idiopathic Parkinson’s disease. Diagnosis relies on awareness to include manganism in the differential diagnosis then recognizing a source of exposure through taking and using a good occupational history.

### Table 25.1 Key features differentiating idiopathic Parkinson’s disease and manganism

</tbody>
</table>

MRI, magnetic resonance imaging; PET, positron emission tomography.
Symptoms include the onset of general weakness, irritability, anxiety, nervousness, anorexia, headache, sleep problems and confusion. These may be accompanied by or progress to loss of libido and/or autonomic symptoms, such as impotence, bladder and sphincter dysfunction. Specific to the disease, there may be ‘manganic madness’ and ‘locura manganica’ – disorientation, indifference and apathy, lethargy, emotional lability such as uncontrollable laughter or tears, impulsive/compulsive behaviour, aggressive/hostile behaviour, bouts of excitability, excessive and incoherent garrulity, hallucinations, illusions and delusions, accompanied by heaviness or stiffness in the lower limbs. The emotional symptoms may be the first indication of toxicity.

**Stage 3**

The intermediate clinical stage is marked by the appearance of more specific signs and symptoms related to dysfunction of the basal ganglia. This may be the first indication if the subtle changes of the first stage have been missed and, as appears to happen in some cases, the second stage has been ‘bypassed’. The voice becomes quiet and monotonous; speech is slow and halting without tone or inflection; the face vacant, mask-like, dull and expressionless with a fixed stare. The victim may be euphoric with, perhaps, uncontrolled laughter or crying. Tremor may develop at this or the next stage. It is less common than in idiopathic Parkinson’s disease, so normal T1-weighted MRI images. Functional imaging of patients with manganese intoxication, the scan will show a high signal in the globus pallidum on 

**Stage 4**

The final clinical stage may be seen only a few months later. The patient’s condition deteriorates noticeably and various disorders, especially those affecting the gait, grow steadily more pronounced. The patient’s mind works only slowly. There may be a postural tremor, frequently in the lower limbs but even generalized. As the disease progresses, walking and turning round become increasingly difficult and the handwriting becomes irregular with some words illegible. Soon the patient cannot walk backwards, falling if this is attempted; has difficulty in maintaining his balance with his feet together and in walking downhill, going uncontrollably faster and faster until he has to run and then will fall over if he cannot catch hold of something to stop and steady him. Attempts to counter this unsteadiness may result in a broad-based slapping gait. Alternatively, as a result of increasing muscular rigidity, there may be development of the characteristic ‘cock gait’ – slow, spasmodic, unsteady, walking or strutting on extended feet and toes, putting weight on the metatarsus, with elbow flexion and a straight spine. Tendon reflexes become exaggerated. Sensorial functions remain normal. At this stage, the disease becomes evolutive and irreversible or may worsen even after withdrawal from exposure, although some affected workers may show limited recovery.

**IMAGING**

Imaging of the brain using MRI and, to detail the function of dopamine cells, positron emission tomography (PET) with fluorodopa (a radioactive form of levodopa) can contribute to the diagnosis of manganism and assist in differentiating it from idiopathic Parkinson’s disease, although this may be difficult in the early stages.

The arrangement of electrons in the manganese ion ($\text{Mn}^{2+}$) results in it having a large magnetic moment allowing it to be imaged by MRI scan to provide evidence of its accumulation and deposition in the brain. Characteristically, in manganese intoxication, the scan will show a high signal in the globus pallidum on T1-weighted images, but with no alteration on the T2-weighted image. It is likely that this reflects recent manganese exposure rather than toxicity. Patients with idiopathic Parkinson’s disease have normal T1-weighted MRI images. Functional imaging of patients with manganism, using 18-fluorodopa-labelled PET, does not show the reduced striatal uptake typically seen in idiopathic Parkinson’s disease, so normal uptake favours the diagnosis of manganism rather than IPD.

These typical manganese accumulation images may be seen in patients with occupational overexposure to manganese (even without symptoms), liver disease (and thus accumulated manganese), and those receiving total parenteral nutrition with excess manganese intake. The signals must be differentiated from increased intensities due to other causes such as fat, iron deposits, haemoglobin breakdown products, melanoma, lesions of neurofibromatosis and calcification.
The T1 changes in the MRI in manganism tend to start to disappear within some eight months of withdrawal from the source of manganese accumulation, despite there being permanent neurological damage and even progressing clinical manifestations of the intoxication.

**OCCUPATIONAL MANGANISM**

The occupational groups in which manganism has been described include miners, ore mill workers, smelter workers, workers exposed to high doses of manganese dioxide in the manufacture of dry batteries, enamellers and potters, those coating welding electrodes, and welders using these and other manganese-containing consumable electrodes or filler metals.

Mining was the original major cause of manganism but, usually, this is now a much more controlled environment where dust exposure is minimized. Cases, usually from mines using dry methods of extraction, especially dry drilling, were described in Silesia, Morocco, Chile, Cuba, Egypt, and India. By 1924, there had been so many cases associated with ore crushing, sorting and grinding in Germany that factory regulations had been modified to prevent the workers coming into contact with ‘brownstone’ ore dust containing manganese dioxide. Reports of adverse effects of exposure to these and associated processes were seen elsewhere, for example in baggers in Singapore and in a range of tasks in mills in the United States, notably after concern in the 1930s and 1940s that more than 90 per cent of the manganese ore used there was imported prompted a successful national campaign to stimulate domestic production of manganese.

Whereas studies may not have provided definitive evidence of manganism in workers involved in the production of manganese salts and oxides or manganese-containing enamels, it does seem to have occurred, mainly but not always at the subclinical stage, in workers exposed to high concentrations of powders rich in manganese compounds during the manufacture of dry cell batteries. Rarely, cases may have occurred in those exposed to manganese compounds while making, glazing or firing pottery and other ceramics.

Exposure to manganese compounds through work in smeltering and ferromanganese foundries and other steel works has been linked to development of clinical and subclinical manganism. Manufacture of cast iron, which may contain small concentrations of manganese, or its recycling, can expose foundry workers to excessive amounts and has been said to be associated with reversible non-specific neurological symptoms of manganism.

Metal cutting and arc welding have been centres of attention as putative causes of clinical and subclinical manganism and/or causing or accelerating the onset of idiopathic manganism. Several thousand lawsuits that allege neurological effects in current or former welders had been filed in courts throughout the United States by 2005. ‘Welding’ is an occupation that involves highly diverse environments and mixed exposures to numerous chemicals. Moreover, those who describe themselves as ‘welders’ may actually be more involved with metal cutting or other processes allied to welding rather than joining metal – the traditional and correct usage of ‘welding’. This is an important distinction as it is thought likely that, unlike particles from other processes, a substantial proportion of the manganese compound-containing particles in fume from welding have a complex shell-core structure which may seal manganese within the core to a degree which reduces its bioavailability (see Chapter 44, Welding).

Of the 45 workers said to have had clinical manganism in case and group study reports in the literature between 1965 and 2005, a maximum of 29 (and possibly only 15) had been engaged in welding as a joining process. The other processes through which the workers may have been exposed to fumes and dust containing manganese compounds included hard facing and arc burning, cutting or gouging. It has been asserted that only five of the 29 met sufficient criteria for manganism to even just cross the diagnostic threshold and even then they carry a degree of doubt with them.

Individual and group studies have been reported seeking to determine that some workers exposed to welding fume are at risk of developing subclinical manganism, i.e. neuropsychological effects of occupational exposure to manganese. It has been said that some of the studies are flawed. The results of more focused analysis of data do not weigh sufficiently to tip the balance of the conclusions of an earlier meta-analysis that a convincing argument has yet to be made for there to be a causal relationship between occupational exposure to manganese as the source of an individual’s cognitive, sensory or motor impairments based on neuropsychological testing or symptom reports. It would, however, be imprudent to dismiss the warnings which have been sounded and not to act to minimize exposure and introduce effective exposure monitoring and health surveillance for those employed in welding and cutting.

As mentioned earlier, a hypothesis was advanced that employment as a welder was causally associated with early onset of Parkinson’s disease. The suggestion was that manganese in the fume was the caustive agent. A number of large case-control studies of occupational risk factors for Parkinson’s disease, cohort studies of welders and literature reviews have been conducted. These have failed to find evidence of an increased risk of Parkinson’s disease among welders or any other evidence to support the hypothesis that manganese causes Parkinson’s disease. In fact, the evidence leads to the conclusion that manganese-induced parkinsonism and Parkinson’s disease are distinct and separate disease entities.
WORKPLACE EXPOSURE LIMITS

Neither a dose–response curve for manganism nor a threshold for exposure effects on the central nervous or respiratory systems has been defined. This is due in part to species differences rendering data from most existing animal studies of limited relevance for the risk assessment of chronic low level manganese exposure in humans; the marked variation in exposures to manganese compounds which can occur between different people doing the same job, and differences observed in individual susceptibility to the effects of exposure. Such hypersusceptibility has been reported in infants and people of advanced age,115 patients with iron deficiency anaemia,116 liver dysfunction including rarer conditions such as portal-systemic shunt,117 hereditary haemorrhagic telangiectasia118 and genetic polymorphism CYP2DL119.

In the face of growing concern about the significance of reported subclinical effects, several prudent authorities have reduced their recommended or mandated standards for tolerable exposure to airborne manganese. The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned respirable manganese the threshold limit value of 0.2 mg/m³ as a time-weighted average.120 The UK work exposure limit (WEL) for manganese has been set at 0.5 mg/m³ (eight-hour time-weighted average),121 while the exposure limit (WEL) for manganese has been set at 0.2 mg/m³ as a time-weighted average.120 The UK work exposure limit (WEL) for manganese has been set at 0.5 mg/m³ (eight-hour time-weighted average),121 while the German maximale Arbeitsplatz-Konzentration (MAK value) or maximum concentration at the workplace122 for manganese (inhalable fraction) is 0.5 mg/m³.

HEALTH SURVEILLANCE

There is so far no reliable and practicable health surveillance regime for exposed workers to detect at a very early, hopefully reversible, stage any signs of excessive absorption of manganese or its accumulation in the central nervous system.

Clinical methods are certain to be insufficiently sensitive, although technology, such as laser-based systems to quantify tremor in workers exposed to low levels of manganese, may have been inadequately explored and have undeveloped potential to assist in detection.123

Biomarkers and biological monitoring are not yet helpful. Concentrations of manganese in biological samples, such as blood and urine, do not correlate sufficiently with exposure, absorption or effect to permit reliable individual biological monitoring,124 but may distinguish between exposed and unexposed groups.125

Brain imaging using MRI has been suggested as a monitoring tool. This would involve significant time and expense – perhaps too much for it to be used as a screening tool. While research has indicated a possible continuum of appearances from normality to clinical stages in workers occupationally exposed to manganese, the degree of variability is too high for this to be applied usefully.126

Neurobehavioural tests do not yet meet requirements. The literature on a manganese neuropsychological/behavioural effect is quite consistent and offers potential for development of a reliable surveillance tool. This would require better structured, more comparable evaluation methods with the proven ability to detect and track changes at an early, reversible stage than are available at the time of writing. A core battery of tests has been suggested for evaluation.127

Overall, there is insufficient good quality evidence for recommending health surveillance of workers exposed to manganese. There may, however, be benefit in checking for anaemia in those occupationally exposed as those who are iron deficient are more likely to absorb manganese.116

TREATMENT

The management of suspected manganism in an exposed worker should include withdrawal from further exposure and action to protect others. The treatment of manganese intoxication is challenging and therapeutic options are limited. There is no recognized standard regime.

Beneficial effects have been reported with levodopa,128 but others have found that in true manganism it was not effective at all or any apparent benefit was not lasting.129,130 It seems likely that the apparent improvement which some authors observed was due to a placebo effect.129 Indeed, that lack of response may be used to assist in the diagnosis of manganism. Mena reported great improvement in one manganese miner treated with 5-OH tryptophan, but no follow-up data were provided on this patient.128

Some have advocated treating severe cases by removing manganese from the body by chelation. Promising results have been reported with CaNa₂EDTA131,132 but, where removing manganese from the body has been achieved, this has not been associated with improvement in signs and symptoms.133–136 Others have used p-amino salicylic acid (PAS) with some success in animal studies and treatment of humans with severe chronic exposure,137,138 with a significant persisting alleviation of effects of intoxication over a 17-year follow up of one woman treated.139

Key points

- Manganese is an essential trace element.
- It is the fourth most widely used metal in the world; 90 per cent is used in steelmaking.
- Many potential sources of exposures with welding steel make it now probably the most ubiquitous.
- It is relatively non-toxic to adults.
- It can cause respiratory disease and the specific central nervous system disorder of manganism – as distinct from Parkinson’s disease.

INTRODUCTION

Mercury (Hg) is a metal that is liquid at room temperature under normal pressure, with a high specific gravity (sg 13.59 at 20°C), high expansion coefficient and large surface tension. Many metals can be mixed with mercury to form amalgams. The various uses of mercury include thermometers, electrical appliances (lamps, switches, batteries), extracting gold, and the restoration of teeth (dental amalgam). It has found its way into the manufacture of energy-saving, compact fluorescent lamps (CFLs), as it makes the bulb's inner phosphor coating fluoresce, and the recycling of these presents an opportunity for occupational exposure, as broken bulbs emit mercury vapour. Mercury is present as inorganic or organic compounds, with the latter containing at least one covalent carbon–mercury bond. Because of its toxicity, the use of mercury and mercury compounds is decreasing sharply. Among the inorganic compounds, mercuric sulphide (HgS) is used as a pigment (vermilion). In the past, inorganic mercury was used widely as a medicine (disinfectant, laxative and diuretic). Methyl mercury, a typical organic mercury compound, was used in the past as a fungicide. Dimethyl mercury may be used as a standard in nuclear magnetic resonance in mass spectrometry. Environmental pollution by mercury has occurred from industrial sources and toxic waste in the past, but active volcanoes are ever present emitters of mercury on land and under the sea.

HISTORICAL ASPECTS

Mercury, like lead, was one of the metals of antiquity and it also has a long history of inflicting harm upon those who use it or work with it. The quicksilver mines in Spain, which the Romans exploited, had an even more terrible reputation than the lead mines, and all the uses to which mercury was put until recent times involved great risk to health. Mercury gilding and the silvering of mirrors were two especially dangerous occupations. Gold or silver was amalgamated with mercury and applied to a manuscript or to glass and the mercury was allowed to vaporize with or without the application of heat. Exposures of artist or artisan were consequently considerable. Ramazzini, in his De Morbis Artificum Diatriba, had something to say about both gilders and mirror makers. Of the former he states:

We all know what terrible maladies are contracted from mercury by goldsmiths, especially those employed in gilding silver and copper objects ... craftsmen of this sort very soon become subject to vertigo, asthma and paralysis. Very few of them reach old age, and even when they do not die young their health is so terribly undermined that they pray for death.

Of the mirror makers, he wrote:

They learn by experience just like gilders how malignant is mercury when, as is the custom, they coat with quicksilver huge sheets of glass so that the other side may give a clearer reflection. Those who make mirrors become palsied and asthmatic from handling mercury.

Kussmaul’s classic work of 1861 on mercury poisoning was based on his experience among the silverers of mirrors in Fürth and Nuremberg. Mirrors were backed with an amalgam of tin and mercury. The working conditions were
so bad that he was hardly able to find an adult male in the trade with a single tooth in his head. In addition to salivation and stomatitis, he described reddening of the pharynx (Kussmaul’s sign) and ulceration of the buccal mucosa and palate. He described how the condition advanced in three clinical stages: erethism (abnormal irritability), tremor and cachexia. Publication of his findings led to stringent regulations which resulted in the mercurial silversing of mirrors being abandoned altogether. During the nineteenth century, mercurial poisoning was so common among hat makers, who used mercuric nitrate in the carotting of felt—a process in which the hairs obtained from rabbit pelts were flattened and meshed together to form felt, that phrases such as ‘hatter’s shakes’ and ‘mad as a hatter’ passed into common use. As an aside, the Mad Hatter in Alice in Wonderland almost certainly did not have mercurial poisoning despite the many assertions that he did. The toxicity of mercury became clearer during the eighteenth century, when the use of mercurial ointments to treat syphilis became popular. When the patient complained of excessive salivation or his teeth began to blacken and fall out, his physician could be sure that he was complying with the therapeutic regimen and that large amounts of mercury were being absorbed. Ramazzini noted that the surgeons who themselves rubbed ointment into their patients were by no means immune from its harmful effects.

Mercury is unique among all the toxic metals in that it has accounted for several epidemics of environmental poisoning. The best known of these, but by no means the most serious, was Minamata disease which was first noted at the end of 1953 when an unusual neurological disorder began to affect the villagers living on Minamata Bay on the south-west coast of the most southerly of the main islands of Japan. It was commonly referred to as ‘kibyo’, that is, the mystery illness. Both sexes and all ages were affected, and the signs and symptoms were those of a polyneuropathy with cerebellar ataxia, dysarthria, deafness and disturbance of vision. The prognosis for the condition was poor; many patients became disabled and bedridden and the case fatality rate was about 40 per cent. The elucidation of the cause of the disease owed much to the work of Donald Hunter and his colleagues, who first reported cases of occupational methyl mercury poisoning in a British factory manufacturing mercury seed dressings. Four workers were affected among 16 who were exposed to dusts containing methyl mercury (nitrate and iodide salt). Three to four months after first exposure, they began to have sensory difficulties in the extremities and loss of peripheral vision, with problems walking and speaking. On examination, visual field constriction, ataxia, dysarthria, hearing impairment and sensory disturbance (vibration and two-point discrimination) were observed. In one autopsied case, localized atrophy in the cerebrum (area striata) and cerebellar atrophy associated with profound loss of granular cells were found. It was subsequently suggested by Douglas McAlpine that Minamata disease resembled this syndrome and a source of organic mercury should be sought. It was eventually confirmed that the fishermen and their families who were the main victims of the disease, had been intoxicated with methyl mercury due to the consumption of contaminated fish. The first case was officially reported in 1956 from the Minamata Bay area (Kumamoto Prefecture), and in 1964–65 in the Agano River basin (Niigata Prefecture) where the pollution was less severe than in the Minamata area. In each area, it was caused by discharges of methyl mercury into the sea from a factory. Tsubaki, who examined many patients in the Niigata area, emphasized the following as important symptoms and signs: sensory impairment (bilateral, marked in extremities), ataxia and dysequilibrium, weakness, perioral sensory impairment, abnormalities in eye movement, narrowing of the visual fields and hearing difficulty.

Importantly, there was a cluster of births of children with cerebral palsy in mothers suffering from Minamata disease – clear evidence of a teratogenic effect of methyl mercury.

The largest outbreak of organic mercury poisoning occurred in 1971–72, when at least 6000 people were poisoned and 459 persons died in Iraq, where in the midst of a famine they had knowingly consumed toxic wheat and barley seeds that had been treated with methyl mercury. In the United States, a family was poisoned by eating contaminated meat from a hog which had been inadvertently fed on seed grains dressed with methyl mercury. Four children showed very severe neurological disturbances 22 years later. The two eldest had cortical blindness or constricted visual fields, diminished hand proprioception, choreoathetosis and attention deficits. The two youngest suffered from quadriplegia, blindness and severe mental retardation. One of them, who was exposed at age 8 and died aged 30, had brain mercury levels over 50 times those of the control patients, whereas mercury levels in systemic organs were comparable with controls. These and other similar incidents have led to the use of organic mercury as a seed dressing being prohibited in most countries.

PRESENT-DAY EXPOSURES TO MERCURY

The toxicity of mercury is so well known nowadays in high economy countries that exposure to mercury metal and its compounds in industrial processes has become sufficiently well controlled to pose few problems to the limited number of workers involved in its use. Mercury is still a serious hazard in developing countries, for example in gold extraction in remote prospecting areas using liquid mercury (vapour hazard). Inadvertent high exposure to workers can still occur through a failure in control measures or awareness, or in the general population as a result of accidental contamination of offices or homes, as well as to a failure to adequately decontaminate industrial buildings or laboratories before being put to other uses.

Next to dietary sources, such as fish, the main source of exposure to mercury in the general population is from dental amalgam. Mercury vapour is released from dental amalgam fillings into the oral cavity from where it is
inhaled and absorbed by the lungs. Blood and urine mercury concentrations in amalgam bearers are usually below one-tenth of the critical values described above and inside the range found in the general population, although small increases are detectable after dental procedures involving fillings. However, some people have been found to have high mercury uptake from their fillings equivalent to the work exposure limit (see below), when removal of the fillings has been recommended. Thus, dental fillings may have a bearing on the monitoring of workers and others exposed to mercury vapour or mercury compounds at work.

Mixing of dental amalgams is no longer done by hand and should no longer present a mercury hazard in modern, well-equipped dental surgeries. Pregnant dentists or dental nurses do not need to be restricted from dental practice as long as best occupational hygiene practice is followed.

**UPTAKE OF MERCURY**

Mercury is encountered in many different forms, as the metal, and as mercurous, mercuric or organic compounds, the last of which are grouped into alkyl, aryl and alkoxyl categories. The different forms have very different properties which help to determine their uptake, distribution and toxicity; the elemental, inorganic and alkyl forms are much the most toxic.

Mercury and its compounds generally cross biological membranes with ease and they may be absorbed by any of the three common routes: inhalation, ingestion and the skin.

**Inhalation**

Mercury vapour and compounds are well absorbed from the lung (80 per cent of inhaled mercury is absorbed), and so the inhalation of vapour, aerosol or dust poses a high risk. This applies particularly to the metal itself which has a relatively high vapour pressure at room temperature: saturated air contains 20 mg/m³ of mercury (2.37 ppm) at 25°C, i.e. 1000 times the UK workplace exposure limit. Few of those who regularly come into contact with elemental mercury, such as laboratory workers and dental nurses, realize that the metal vaporizes at room temperature and is readily absorbed through the lungs. Compounds of mercury are also rapidly absorbed through the lungs.

**Ingestion**

The organic compounds of mercury are more readily absorbed from the gut than are the inorganic. Metallic mercury may be swallowed safely because only 0.01 per cent of an ingested dose is absorbed. Ingested methyl and phenyl mercury are taken up quickly and virtually completely. About 10 per cent of an ingested dose of mercuric salts is absorbed, but uptake of mercurous salts is about 80 per cent less. Many inorganic and aryl compounds including bichloride, nitrate, phenyl and butyl salts are corrosive when swallowed.

**The skin**

Mercury vapour is not absorbed through the skin, but soluble and insoluble mercury compounds, both inorganic and organic, appear to be absorbed at similar rates. Absorption is, however, too slow to cause acute poisoning but may lead to chronic intoxication.

Some organic mercury compounds, such as phenyl or butyl salts, can cause chemical burns and blistering (Figure 26.1).

**DISTRIBUTION IN THE BODY**

After uptake, any form of mercury may undergo chemical changes, such as oxidation and reduction. For instance, metallic mercury is oxidized in erythrocytes and lungs and converted into a divalent cation (Hg²⁺). Absorbed inorganic mercury compound may be reduced and excreted in the expired air as metallic mercury. Organic mercury compounds, such as phenyl mercury and alkox mercury, may be rapidly converted to Hg⁺⁺. Methyl mercury entered into the brain may be demethylated into the inorganic form and may persist within the brain over a long period.

Mercury has a great affinity for thiol groups and is distributed bound to sulphur-containing ligands. Its affinity for thiol groups explains a number of its toxic effects for, like lead, it is able to combine with, and inhibit the action of, enzymes containing -SH groups. Following the absorption of elemental mercury, it is transformed intracellularly into the divalent ionic form; the aryl, alkoy and alkyl compounds also tend to release divalent mercuric ions in

![Figure 26.1](image-url) Blister on the finger of a chemist who worked with butyl mercury nitrate. Courtesy of the late Professor RI McCallum.
the tissues. In the blood, inorganic mercury is distributed almost equally between the red cells and the plasma, whereas the alkyl compounds (such as methyl mercury) are concentrated 10- or 20-fold in the red cells. The principal target organs for mercury are the central nervous system and the kidney. Within the kidney, mercury binds to metallothionein and the resultant metal protein complex may protect against the toxic effects of the free metal, and only when the metallothionein receptors are saturated does renal damage occur. The blood–brain barrier is crossed rapidly and readily by elemental mercury and by alkyl mercury compounds, but not so well by inorganic compounds. The post-mortem findings in a man who developed classical signs of mercurialism after working for 18 months filling mercury thermometers, and who died 16 years later after a slow but incomplete recovery, are interesting. While there was no histological evidence of mercury toxicity, mercury was detected in lysosomal dense bodies in many nerve cells. It is not clear, however, how the presence of neuronal mercury was related to the mental and psychological state of the patient.18

By contrast, inorganic mercury accumulates rapidly in the cortex of the kidney, but more slowly in the brain. These differences in distribution obviously contribute to the different toxic effects exerted by the various mercury compounds, but it is not merely a matter of tissue concentration. Methyl mercury concentrations in the kidney, for example, are considerably higher than those in the central nervous system but, whereas the brain may be severely affected in methyl mercury poisoning, renal damage occurs only rarely.19

EXCRETION

Mercury is excreted in the urine and faeces and may also be found in the sweat, saliva and breast milk. The concentration of mercury in breast milk may be as much as 5 per cent of the concentration in the blood and so be a risk to breast-fed infants of mothers who are exposed to mercury. Organomercury compounds are excreted in bile and reabsorbed from the gut. The half-life of mercury compounds in the body is about 70 days; thus, the excretion of absorbed material is slow and there is a tendency for the metal to accumulate with time. The urinary excretion of mercury shows considerable circadian variation and urinary concentrations are not always a good indicator of acute exposure, but are used for the monitoring of exposed workers over a period of time. Blood mercury concentration, on the other hand, reflects absorption well, once equilibrium has been achieved,20 and is a suitable marker for acute exposure.

MERCURY POISONING

Acute poisoning

Acute poisoning usually results from the accidental or deliberate ingestion of mercury compounds and seldom from occupational exposure. The toxicity of inorganic compounds is proportional to their solubility in the gastric juices and, for example, the ingestion of less than 100 mg of mercuric chloride (corrosive sublimate) may cause severe symptoms. Soon after taking it, vomiting and abdominal pain may develop and watery diarrhoea, haematemesis, and then shock cause death. Even without these, oliguria (renal tubular dysfunction) associated with unconsciousness may occur in 48 hours. In severe cases, acute papillary necrosis will occur. A chemical colitis may develop after 24–72 hours with the passage of bloody diarrhoea containing mucosal slough. There may be shock, oedema, tremor and ataxia. Specific diagnostic tests are of limited value, but will demonstrate raised blood mercury levels and increased urinary and faecal excretion. Poisoning from the inhalation of large amounts of mercury, including the vapour from exploding mercury lamps, may cause an acute, life-threatening chemical pneumonitis with cough, dyspnoea, retrosternal pain, basal, late-inspiratory crackles, abnormal blood gases and patchy shadowing on chest radiograph. In severe cases, there may be fever, expectation of blood-stained sputum and pulmonary oedema.

Chronic poisoning

The classic symptoms of chronic mercury poisoning (noted by Kussmaul) are tremor, gingivitis and erethism (Greek erethismos, irritate). In addition, there may be evidence of renal damage and organic damage to the central nervous system. The earliest findings are usually gingivitis, hypersalivation (mercurial ptyalism) and an unpleasant, bitter, metallic taste in the mouth. A bluish line on the dental margin of the gums, similar to that seen in lead workers, and a slate-grey or reddish, punctate pigmentation of the buccal mucosa are sometimes described, but rarely seen. Gingivitis is most marked in those with poor oral hygiene and may be severe enough to cause loosening or loss of teeth. Tremor, generally considered to be the first neurological indication of poisoning by elemental mercury or its inorganic compounds, is usually present at rest especially in the hands. It may be slight and accompanied by mild motor retardation (mercurial micro-parkinsonism). There is often an intentional component to the tremor, resembling that seen in cerebellar disease, which may seriously impair the ability to carry out fine and complex movements, such as handwriting. The tremor in mercury poisoning may fluctuate in severity and be accompanied by ataxia resulting in difficulties in walking and in speaking. In poisoning with methyl mercury, cerebellar ataxia and dysarthria predominate, sometimes with constriction of the visual fields as the result of damage to the visual cortex. The clinical picture may resemble parkinsonism, multiple sclerosis or cerebellar disease, but nystagmus is not a feature. Inability to release an object gripped in the hand has also been reported but, unlike the situation found in myotonia, it persists after repeated movements. When
the term ‘erethism’ was first coined, towards the end of the eighteenth century, it was used to describe the whole range of symptoms of mercury poisoning, but it is now reserved for the psychogenic manifestations. It is a form of toxic organic psychosis characterized by excessive timidity, morbid irritability, mental hyperactivity and outbursts of temper. There may be other features such as impairment of memory, difficulty in concentration, depression and somnolence. Short-term memory may also be slightly impaired in workers exposed to mercury who are otherwise normal.23 Mercury poisoning may present as a peripheral neuropathy which is predominantly sensory and is most common in those with organic mercury poisoning. Prolonged distal latencies in nerve conduction have been reported in some asymptomatic mercury workers and the neurophysiological changes correlate with time-integrated urinary mercury concentrations.22 In advanced cases, there are paraesthesiae of the extremities and around the mouth. In fatal cases, the dorsal and ventral roots of the spinal cord have been found to have undergone axonal degeneration and to have suffered a loss of myelin (see Chapter 87, Neurotoxic effects of workplace exposures).23

The usual effect on the kidneys is tubular damage. Necrosis is more common in inorganic than organic poisoning. The glomerulus may also be damaged, leading to albuminuria in workers who have been exposed to mercury for many years. Rarely, a nephrotic syndrome may present as a manifestation of inorganic mercury poisoning.24 Poisoning by mercury or a compound of mercury is a prescribed disease in the United Kingdom (see Chapter 8, Compensation scheme).

LABORATORY DIAGNOSIS

The finding of mercury in the urine or blood of those exposed to elemental mercury or to its inorganic or organic compounds confirms that absorption has occurred. Blood mercury concentrations in those exposed to methyl mercury are a good index of exposure. If poisoning has occurred, the blood mercury concentration may be well above 95 µmol/L and the urinary level above 120 nmol/mmol creatinine for inorganic compounds and 15 nmol/mmol creatinine for organic compounds.

Diagnosis of organic mercury poisoning depends on its characteristic clinical picture and diagnostic radiology, especially magnetic resonance imaging (MRI).25 In cases of methyl mercury or dimethylmercury intoxication, MRI may reveal atrophic changes in the occipital lobe, cerebellum and post-Rolandic region in the cerebrum.

TREATMENT OF MERCURY POISONING

Acute poisoning by elemental, inorganic and organic mercury compounds is a medical emergency and is dealt with in texts on poisoning. The purpose of treatment is to encourage the excretion of mercury and to limit gastrointestinal and renal damage. First-aid treatment involves the administration of four glasses of milk as an emulsient. If there is corrosive damage to the oropharynx as in the case of mercurous and mercuric chlorides, attention must be paid to the patency of the airway. Emergency tracheotomy may be required if the airway cannot be secured by endotracheal intubation. A stomach tube should be passed and gentle (bearing in mind the corrosive action of some mercury compounds) gastric lavage carried out using, preferably, warm, 10 per cent sodium bicarbonate solution. If organo-mercury is involved, between three and six sachets of the basic anion-exchange resin cholestyramine should be administered before the tube is withdrawn, as sequestration of bile salts increases faecal excretion of these compounds. Chelation therapy should be started, using oral penicillamine (1–4 g daily, in four divided doses). It has been suggested26 that in chronic mercury poisoning, although penicillamine may hasten the excretion of an easily mobilized extracellular fraction, it does not increase the excretion of mercury over a long period of time. Care must be exercised as the chelation of mercury may enhance its passage across the blood–brain barrier and for this reason the use of dimercaprol (BAL) is contraindicated in poisoning with organic mercury compounds.27 It is, however, extremely effective in the treatment of acute poisoning with inorganic mercurials when given by intramuscular injection. The recommended dose is 2.5 mg/kg body weight, repeated at four-hour intervals for two days; after this, the injections are given twice daily for ten days or until recovery is complete. In the absence of these drugs, intravenous administration of 100 mL of 5 per cent sodium sulphate or 500–1000 mL of Ringer–Locke solution may be helpful. There is some evidence that alkaline diuresis, as described for salicylate poisoning in standard medical textbooks, with physiological saline, 5 per cent dextrose and 1.26 per cent bicarbonate solution affords the kidney some protection against mercury damage and might prevent the onset of anuria. This technique, however, is not without serious risk and ought to be carried out under continuous observation of fluid replacement and of electrolyte and acid-base status, as in an intensive care or high dependency unit.

Inhalation of large quantities of mercury vapour may lead to the onset of chemical pneumonitis 24–48 hours after exposure which may require treatment with bronchodilators. Intercurrent infection will necessitate the use of appropriate antibiotics. If the condition is severe and respiratory failure threatens, mechanical ventilation with positive end-expiratory pressure will be required. If the risk of permanent damage is high, it would be prudent to give steroids prophylactically, but these have no proven value once the condition has developed.

There is no effective treatment for chronic mercury poisoning. Penicillamine and BAL may be tried, but are unlikely to alter the course of the illness, and the neurological effects of intoxication may never completely reverse. Mercaptopropionyl glycine has been used for the treatment of organic
mercury poisoning in Japan. This drug produces a sustained increase in urinary excretion, but has little effect on the clinical picture.

**EVALUATING MERCURY EXPOSURE**

For workers exposed to inorganic mercury, the Health and Safety Executive workplace exposure limit (eight-hour time-weighted average (TWA)) is 25 µg/m³ with a corresponding urine value of 20 µmol/mol creatinine and a blood threshold of 45 nmol/L mercury. The monitoring of workers exposed to mercury is generally based upon the periodic measurement of mercury in the urine. Urine levels provide a measure of low level or cumulative exposure and are usually preferred over blood levels, which are more appropriate measures after acute exposures to inorganic mercury vapour. This also applies to people in the general population who may have become accidentally exposed to vapour from liquid mercury. Mild and reversible proteinuria is the most sensitive clinical indicator of mercury vapour toxicity, followed by non-specific symptoms and increase in urinary excretion, but has little effect on the first clinical symptoms in workers (rarely seen anymore in high economy countries) are proteinuria and slight hand tremor. Testing the urine for reversible proteinuria by a simple dipstick method was widely used in routine exposure monitoring and was surprisingly sensitive to increases in exposure.

In evaluating mercury levels found in an unexposed working population in the UK, the upper 95 per cent limits for urinary mercury are <2 µmol/mol creatinine for unexposed people; the equivalent unexposed blood range is 0.6–19 nmol/L (Health and Safety Executive, unpublished data). These limits are also useful when checking individuals who may have had a brief, inadvertent exposure to mercury vapour and who need reassurance.

Pregnancy and work with mercury is contraindicated on general precautionary grounds unless a risk assessment shows that exposure can be kept to negligible levels. There are no consistent findings of adverse reproductive effects in laboratory animals or in epidemiological occupational studies for elemental mercury exposure (see Chapter 89, Workplace exposures and reproductive health), but methyl mercury is teratogenic in humans.

Although mercury is being phased out of thermometers and sphygmomanometers in hospitals, breakages leading to spillages may still occur. Airborne concentrations of mercury vapour are usually low and insignificant in these small spills, which can be dealt with by a spills kit for removing liquid mercury. Large spillages in a home or workplace will require exposure assessment and specialist treatment.

**Key points**

- Acute inorganic mercury poisoning is rare in modern industry due to awareness of the hazards of metallic mercury vapour and mercury compounds. Organic mercury, such as methyl mercury, is no longer used in seed dressings, following incidents of mass organic mercury poisoning around the world.
- Clinicians need to be aware of the effects of chronic overexposure to low levels of mercury, the first clinical symptoms of which are classically proteinuria and tremor. Measuring urinary mercury is a simple and effective means of monitoring inorganic mercury exposure and checking the control of exposure to metallic mercury vapour. With accidental exposure to mercury vapour in, for example, incidents in laboratories or after breakages of mercury-containing equipment, testing for blood mercury levels soon after the event are the best guide to exposure.
- The apparent threshold for early clinical findings in chronic mercury exposure is 20 µmol/mol creatinine in the urine and 45 nmol/L in the blood, which correspond to the current UK workplace exposure limit (25 µg/m³ eight-hour TWA), so actual exposures should be kept consistently below this level.
- Mercury spillages should always be cleaned up using special spillage kits or otherwise expertly removed for toxic waste disposal. Accumulation of mercury in the fabric of old laboratory buildings or dental surgeries has presented exposure issues to workers who subsequently use the same work areas.

**REFERENCES**

Along with arsenic, phosphorus and antimony, molybdenum is one of a group of previously important occupational toxins, but which is now largely of historical interest in the workplace setting. While this is true in most developed countries, where good workplace control has eliminated them as major causes of disease, this is not necessarily the case in newly developing countries. In addition, some of these substances, such as inorganic arsenic, have become more important as causes of disease in the environmental health setting, as their importance in the workplace has waned.

Molybdenum is a silver-white metal which is mined mainly in the form of molybdenum ore (MoSO₄). It is an essential element for humans and is required for the enzyme xanthine oxidase. It is used as a hardener in steels, in the production of some special alloys, ceramics and pigments, and in electrical wire. Other sources of occupational exposure include fertilizers, coal-powered electricity generation, and as a byproduct of copper smelting, pigments and paints. It forms many soluble and insoluble compounds, including molybdenum trioxide (MoO₃), sulphides and halides.

Most evidence for toxicity comes from animal studies, with effects in several body systems, including anaemia, stunted growth, deformities of the bones and joints and degeneration of the central nervous system. In humans, the type of toxic effect is dependent upon the molybdenum compound involved and the duration of exposure. Acute exposure to molybdenum trioxide is known to be irritant to mucous membranes of the eyes, nose and throat, while chronic exposure is thought to cause a type of hard metal lung disease and allergic alveolitis.¹ There may also be other, as yet, unrecognized health effects from molybdenum exposure. For example, a recent study has found evidence for adverse effects on sperm concentration and morphology and molybdenum exposure in a dose–response relationship, after adjusting for the effect of potential confounders and other metals.²

The International Agency for Research on Cancer (IARC) has concluded that there is limited evidence for the carcinogenicity of metal alloys containing cobalt, chromium and molybdenum in experimental animals;³ however, a case–control study has found an association between occupational exposure to molybdenum and lung cancer.⁴ The American Conference of Governmental Industrial Hygienists (ACGIH) has set a threshold limit value (TLV) for molybdenum of 5 mg/m³ for soluble compounds and 10 mg/m³ for insoluble compounds, the latter being the nuisance dust level.

**Key points**

- Occupational exposure to molybdenum is known to cause mucous membrane irritation.
- There is also evidence for longer term effects in the respiratory system, such as hard metal disease.
- There is limited evidence that molybdenum causes cancer.

**REFERENCES**

Nickel is a hard silvery metal. It was first isolated by Cronstedt in 1751 and takes its name from ‘Old Nick’ because of the ‘devilish’ difficulties it caused during the refining of Saxony copper ores.

It is a transition metal and is thus capable of having a number of oxidation states with markedly different properties. Some of the water insoluble or slightly soluble salts are soluble in biological matrices. Nickel forms important alloys, a number of oxides and also organometallic compounds. Nickel tetracarbonyl is remarkable in being a gaseous metallic compound at ambient temperatures. Although nickel tetracarbonyl was known to be acutely toxic, little was known of any other hazards associated with the refining or use of nickel until in 1923 when a case of nasal cancer at a refinery in Wales saw the beginning of modern nickel toxicology. The cancer problem was subsequently noted in other refineries processing sulphide ores at high temperatures.

Nickel is widely distributed in the Earth’s crust. Mining, crushing and grinding and flotation followed by pyrometallurgy and then electrodeposition, or the carbonyl process are used to recover the metal. Ninety per cent of nickel is used in alloys, mostly stainless steel, but the high nickel alloys (containing around 30–50 per cent nickel) are important in the aero engine industry, desalination plants and where corrosion resistance is needed. Other uses include plating, foundry work and catalysts. Electroplated nickel silver (EPNS) is used on cutlery. Nickel powders find application in rechargeable batteries and other uses include the coating of fibres and foam for use in electronics. In combination with other metal oxides, nickel oxide forms commercially important alloys, called spinels.

Markedly increased risks of pulmonary and nasal sinus cancer have been found to be associated with high temperature oxidation of nickel matte and nickel–copper matte and with electrolytic refining of nickel. The problem in some of these refinery studies was first thought to be associated with arsenic exposure or nickel carbonyl gas, but more recently the cancer effects have been attributed to the very high levels of dust and fume pertaining in these early workplaces. A major epidemiological study concluded that nickel sulphides (especially the subsulphide) and oxides involved in the processes were the principal culprits. A later cohort study of workers at the Kristiansand refinery in Norway has found that soluble nickel salts, such as nickel sulphate, are also human lung carcinogens, but it is possible that the role of arsenic has not been fully accounted for in this study.

The National Toxicology Program in the United States undertook an animal inhalation study, and exposed both rats and mice to three different nickel compounds. The investigators found that nickel subsulphide was the most potent metal species, nickel oxide less so and nickel sulphate, which is a soluble salt, did not cause cancer under the conditions of the study. Modern processes technology has essentially eliminated the exposure of workers to the hazards. There is no firm direct evidence of any excess cancer risk in user industries, including welding of stainless steel, nickel plating and the production of nickel alloys.

Primary sensitization may result from close and prolonged contact which may be occupational or domestic, especially skin piercing with the subsequent use of nickel in ‘sleepers’ to maintain the patency of the skin. The skin reaction may be local or remote. Sensitized people may subsequently react to contact with nickel at work or in clothing or jewellery. Since the introduction of automation and improved hygiene in the workplace, as well as new legislation limiting nickel in jewellery, ‘nickel itch’ is now less common, but occupational nickel contact dermatitis has been observed in people handling nickel-plated instruments or tools. Clinical diagnosis is by patch tests and the lymphocyte proliferation test.

Asthma may be associated with the inhalation of droplets of soluble nickel and also possibly the fine nickel oxide fume resulting from welding of nickel-containing nickel carbonyl.
alloys. As with dermatitis, if a causal relationship is clearly established, then affected workers should be removed from further exposure.\textsuperscript{7}

Ingestion of soluble nickel is toxic and has occurred in the workplace, due to accidental contamination of the drinking water supply.\textsuperscript{8}

Biological monitoring cannot differentiate between inhalation or ingestion. It is not therefore recommended as a routine procedure in the absence of skilled interpretation, except in nickel carbonyl poisoning where it has a health guidance value and in exposure to soluble nickel, such as in nickel platers.\textsuperscript{9}

**NICKEL CARBONYL**

Nickel tetracarbonyl gas was discovered by Ludwig Mond and co-workers in 1888. It is formed when carbon monoxide is passed over finely divided nickel at ambient temperatures and it decomposes at 180°C to deposit nickel metal of extremely high purity. This is the basis of the Mond process. The gas is acutely dangerous and similar in toxicology to phosgene. Its use is limited to a few refineries and to coating applications.

It has an immediate acute effect including giddiness, nausea and headache followed after an interval of 12–18 hours by a severe chemical pneumonitis. Treatment is discussed in Chapter 39, Gases.

Poisoning by nickel carbonyl is a prescribed disease in the United Kingdom (see Chapter 8, Compensation schemes).

**Key points**

- Nickel is widely distributed in the earth’s crust.
- Nickel is extracted for use in alloys.
- Some nickel processes have shown clear excess risks of lung cancer and nasal cancer.

**REFERENCES**

Phosphorus is among a group of previously important occupational toxins, but which are now largely of historical interest in the workplace setting. While this is true in most developed countries, where good workplace control has eliminated them as major causes of disease, this is not necessarily the case in newly developing countries.

Phosphorus is highly reactive, as it oxidizes extremely rapidly on contact with air. There are three allotropes of phosphorus: white (or yellow), red and black, of which the white variety is the most toxic. In modern industry, phosphorus and its compounds have many uses including the manufacture of munitions and other incendiary devices, the production of fertilizers, detergents, animal foods, pharmaceuticals and pesticides. They are also used in engraving, electropolishing, photography, metal cleaning, as scale inhibitors in water treatment and in the manufacture of semiconductors, so exposure may occur in many industries.

The use of white phosphorus in match-making began in 1832 and ushered in what Donald Hunter referred to as ‘the greatest tragedy in the whole story of occupational disease’. This was phosphorus-induced necrosis of the jaw, known as ‘phossy jaw’. The onset of the disease was slow, taking an average of about five years for the symptoms to develop after first exposure. Phossy jaw was an extremely painful and disfiguring condition with the mandible becoming necrotic and the formation of abscesses which discharged foul-smelling pus. The mortality rate was about 20 per cent, usually due to septicaemia. Surgical removal of the mandible was often required. A complete ban on white phosphorus was slow to be introduced, one of the last countries being the United States in 1931, although the Berne Convention of 1906 prohibited the manufacture and import of all white phosphorus matches into Europe.

Phossy jaw is now very uncommon and when it does occur, such as in the manufacture of munitions, it is a much milder disease. Interestingly, osteonecrosis in the oral cavity, with features similar to those of phossy jaw, has recently been found to occur in patients treated with bisphosphonate for multiple myeloma or secondary cancer in bone, which demonstrates the importance of retaining knowledge of what might be considered historical occupational diseases, which may recur in modern times in new guises.

Another important effect of white phosphorus is burning on contact with the skin and such burns must be washed as rapidly as possible with a solution of a suspension of 5 per cent sodium bicarbonate and 3 per cent copper sulphate in 1 per cent hydroxyethyl cellulose. The resultant blackened appearance facilitates the removal of the phosphorus particles from the skin. Phosphoric acid and phosphoric compounds are irritant to the eyes, the mucous membranes and the respiratory tract. On this basis the American Conference of Governmental Industrial Hygienists (ACGIH) has set a threshold limit value (TLV) of 1 mg/m³ and a short-term exposure limit (STEL) of 3 mg/m³.

Key points

- Phosphorus causes ‘phossy jaw’, an important disease in the history of occupational medicine, which has now virtually disappeared as an occupational disease.
- Phosphorus is also a potent cause of skin burns, which require specialist treatment.
- Some patients treated with bisphosphonate for cancer have been found to develop a type of bone necrosis with features similar to phossy jaw.

Platinum group metals

PETER LINNETT

INTRODUCTION

Six elements constitute the group collectively referred to as the platinum group elements (PGE) or metals (PGM). They are platinum (Pt), palladium (Pd), rhodium (Rh), iridium (Ir), ruthenium (Ru) and osmium (Os). They occur together in mineral bodies in variable ratios.

Platinum was first identified as a precious metal in 1751 and was present as a contaminant of silver (plata) from South America from which it derives its name.1

Early reports indicate that the PGM existed as native metals in rich ore bodies in South America and the Urals. They are now found in complex mineral bodies, especially the copper and nickel sulphide ore bodies of South Africa, Siberia and Canada in which there may also be present several other metals and metalloids, e.g. arsenic which has well-known toxic properties. Recovery of the PGM involves mining, crushing and milling of the ore, then concentration by a hydrometallurgical or pyrometallurgical route followed by refining. The process risks are common to extraction of several metals,2 but the hazards during refining are specific to platinum.

PGM are rare metals and, as they have high value, there is considerable recovery and recycling of the metals from industrial use3 and consequently minimal loss to the environment.

PLATINUM

Platinum is a bright, silver-coloured, very dense metal which is malleable, ductile and electroconductive and has exceptional catalytic properties. It is corrosion resistant and resistant also to molten glass. It is a rare metal and more valuable than gold.

Its properties determine the major uses for platinum as catalysts for the chemical (e.g. nitric acid, silicone production), petrochemical (reforming and isomerization) and pharmaceutical industries, as well as for catalysis of exhaust emissions from the internal combustion engine – autocatalyst which uses about 46 per cent of Pt produced.3 Other uses include fuel cells, thermocouples and chemical sensors, lining of moulds for the production of glass, coating of turbine blades and tips for spark plugs. Being a noble metal and biologically inert, platinum is used in medical implants, e.g. vascular stents, pacemaker electrodes and dental prostheses, but certain complex Pt compounds are effective as cytotoxic agents, e.g. cisplatin, carboplatin, oxaliplatin for the treatment of solid tumours. Platinum has long been used for investment and jewellery and there is increasing consumption in electronics.

Occupational toxicology

Separation of the PGM from each other and other metals, e.g. gold, is achieved by a chemical approach. The metals, though resistant to corrosion, are soluble in aqua regia (concentrated nitric acid and hydrochloric acid) and also in concentrated hydrochloric acid supplemented by chlorine. Chloroplatinic acid (H₂PtCl₆) is thus produced. This is an extremely potent allergen causing symptoms of type I allergic reactions, including asthma, rhinitis and urticaria.
Chloroplatinate salts produced by subsequent treatment of the liquors are equally allergenic and platinum refinery workers have a very high risk of becoming sensitized to these salts.4,5 The risk of naive workers being sensitized has been as high as 50 per cent in the first five years of employment,6 although the risk has been reduced by new technologies, such as solvent extraction and improved containment of liquors and suppression of airborne aerosols and powders. The allergenicity is restricted to the halogeno-complex salts of platinum, such as ammonium hexachloroplatinate (yellow salt) which is reduced thermally to the non-toxic metal, while other neutral platinum compounds such as tetraammine platinum dichloride are non-allergenic.6,7

**Occupational exposures to platinum compounds**

Exposure to the halogeno-complex salts of platinum occurs mainly in the refining of platinum and precious metals and production of platinum catalysts. All workers associated with these activities may be at risk of sensitization. Chloroplatinic acid may be used for coating of electrodes and in specific manufacturing processes, e.g. silicone production. Small quantities are used in research laboratories.

**Medical surveillance**

Personal risk factors have been studied at pre-placement medical examination. Originally, atopy was considered to be relevant but this has not been confirmed, although smoking is a significant risk factor.6,8-10 Some human leukocyte-associated antigens (HLA) have also been studied and shown to correlate with sensitization.11 Eczema and dermatitis is aggravated by the work conditions and rapidly leads to sensitization and asthma is aggravated by the irritant environment during refining.

Medical surveillance of workers exposed to chloroplatinates is directed to the early identification of sensitization. This includes direct questioning for symptoms of respiratory and dermal sensitization, as well as skin prick testing with a standardized dilute solution of sodium hexachloroplatinate $10^{-3}$ g Pt salt/mL.12-14 The suggested frequency of testing is at least annually, but should be more frequent if the exposure levels are high and if there is a high rate of sensitization in the exposed workforce.

Immediate cessation of exposure following diagnosis of sensitization by skin prick test prevents the development of asthma.13,15 Investigation of occupational asthma in the absence of a positive skin prick test requires monitoring of peak flow16 and confirmation by specific bronchial challenge. In cohort studies, specific IgE has been shown to correlate with skin prick test, but only for grouped results and the complicated test is not useful for investigation of an individual.

Refining of platinum is associated with exposure to other respiratory irritants, e.g. chlorine and ammonia which will aggravate pre-existing respiratory disorders especially asthma. Appropriate respiratory surveillance is required for this.13 Biological monitoring in workers exposed to chloroplatinates has not been found to correlate with evidence of absorption with sensitization.17 A significant confounder may be the presence of PGM in dental prostheses. Platinum in blood has been determined in nurses in an oncology unit who administer platinum-containing chemotherapy, but this reflects exposure and not sensitization.

**Exposure limits**

The UK workplace exposure limit for platinum salts is 0.002 mg/m³ with a notation that the halogeno-platinum compounds are sensitizers. Even at the exposure limit, the risk of sensitization is significant and stringent control measures need to be maintained to minimize exposure, as well as to conduct medical surveillance. Only the complex chlorides of the halogeno-platinum compounds are used in any significant amount. There is limited use of the other halogenated Pt compounds in research and development laboratories.

**Environmental risks**

The environmental risk posed by release of platinum into the environment, particularly from autocatalysts, was reviewed by the International Programme on Chemical Safety of the World Health Organization in the 1991 Environmental Health Criteria 125 – Platinum.18 The levels of platinum in the environment are too low to be a risk to human health.

**PALLADIUM**

Palladium like platinum is a lustrous, malleable, ductile and electroconductive metal with good catalytic properties. It is used as a catalyst in the chemical industries, as well as in autocatalysts. Significant amounts are used in electronic components.3 Palladium is used in dental prostheses with geographic variations in the amount used.

**Occupational toxicology**

Reports on patch testing from dermatology clinics indicate a high potential for people who are allergic to nickel to
react also to palladium chloride, though not to palladium metal. As there have been positive patch test cases with no previous exposure to palladium compounds, a cross-reactivity between nickel and palladium has been suggested. Cross-reactivity between palladium and cobalt may also occur. Palladium chloride may induce sensitization in guinea pigs by repeated open application, but this does not occur with the metal. Cases of stomatitis have been attributed to the presence of palladium in the alloys of dental prostheses. A case of asthma has been reported in a worker exposed to palladium tetraammine dichloride.

**Occupational exposures to palladium compounds**

Exposure to palladium compounds occurs in the refining process and production of chemical process catalysts and autocatalysts. Palladium plating solutions are used in the electronics industry. Dental technicians may be exposed to metal dusts in the preparation of dental prostheses, but no adverse consequences have been reported.

**Medical surveillance**

Routine medical surveillance for people exposed to palladium compounds has not been prescribed. In many occupational situations, exposure to palladium compounds occurs together with exposure to platinum compounds. These workers will normally be under regular medical surveillance for platinum exposure. In some cases, e.g. the electronics industry, platinum may not be present, although salts of other metals may be used. Increased attention should be paid to dermal health with special concern for cross-reactivity to palladium chloride in people who are allergic to nickel.

**Exposure limits and environmental risks**

There are no workplace exposure limits for palladium compounds. The environmental concerns about the potential effects of palladium released from autocatalysts was reviewed in the IPCS Environmental Heath Criteria 226 – Palladium and palladium compounds. The environmental levels are very low and do not pose a risk to the community.

**RHODIUM**

Rhodium is a bright, lustrous metal resistant to corrosion with good catalytic properties. It is harder than platinum and more difficult to work with. It is used for thermocouple wires, in jewellery often as a surface plating to provide a hard bright finish and in the glass industry for production of thin glass sheets for flat screens.

Rhodium compounds have a deep rose hue. Its major use is in the production of autocatalysts.

There are a few reports of dermatitis attributed to rhodium compounds.

The occupational exposure limit assigned to rhodium compounds of 0.001 mg/m³ has not been supported by epidemiology. The value was extrapolated from the limit value for platinum and, as rhodium has half the atomic weight of platinum, it was assigned half the exposure limit value of platinum compounds.

No specific medical surveillance has been advised for workers exposed only to rhodium compounds; however, many of them will have mixed exposures to other PGM and will be subject to medical surveillance for platinum compounds.

There have been no reviews of the environmental risks. Rhodium is rarer than platinum and is considerably more valuable so losses to the environment are minimized and environmental levels are insignificant.

**IRIDIUM**

Iridium is a hard shiny metal. It is resistant to corrosion and has a high melting point.

It is used in chlor-alkali production for anode coating. Iridium crucibles are used for the production of high purity crystals for electronics. Its resistance to heat has encouraged the use of iridium tips in spark plugs for internal combustion engines and iridium compounds may be used as process catalysts in the chemical industry.

Positive skin prick test reactions to iridium salts have been reported.

There are no workplace exposure limits set for iridium.

No specific medical surveillance has been advised for workers exposed only to iridium compounds; however, many of them will have mixed exposures to other PGM and will be subject to medical surveillance for platinum compounds.

There have been no reviews of the environmental risks from iridium. Environmental levels are insignificant.

**RUTHENIUM**

Ruthenium may be used as a catalyst and is also used in the electronics industry in the production of resistor chips and hard disks. Ruthenium tetroxide is used as a fixative in electron microscopy.

There are no reports of adverse reactions in workers exposed to ruthenium metal or its compounds, but fumes of ruthenium tetroxide are corrosive, affecting the cornea and conjunctiva, as well as the respiratory mucosa.
No medical surveillance has been recommended, but many ruthenium workers will also be under surveillance for concomitant exposure to platinum salts.

No studies have been made of environmental levels of this rare metal.

**OSMIUM**

Osmium metal is silvery blue in colour and very hard. It is recovered in the refining process as a fine grey powder which oxidizes in air to produce osmium tetroxide. It is therefore stored in a sealed container with an inert atmosphere. It may be used with iridium to produce a very hard alloy, osmiridium. Osmium tetroxide in air forms osmic acid. It is used in electron microscopy and in histology for staining fat especially in neural tissue.

**Toxicology**

Osmium tetroxide is very irritant to the respiratory tract. Acute exposure causes conjunctivitis and corneal oedema with the effect of causing the appearance of haloes around bright lights. Impaired vision lasts for one or two days. Inhalation causes severe pain in the nose with rhinorrhea and difficulty in breathing. Transient haematuria, proteinuria and pyuria have been reported. Chronic exposure has been associated with corneal ulceration and opacification, as well as contact dermatitis.

**Occupational exposures**

Major exposures may occur in refining of PGM and release of osmium tetroxide. Minor exposure episodes may occur in electron microscopy and in histology laboratories.

**Exposure limits**

No workplace exposure limits have been set for osmium.

**Medical surveillance**

Routine medical surveillance has not been advised. Symptomatic treatment is suggested for acute exposures.

**Environmental risks**

Environmental risks due to this very rare metal have not been investigated.

Polonium

IAIN BLAIR

INTRODUCTION

Polonium (Po) is a rare, unstable radioactive element that was discovered in 1898 by Marie Curie and named after her native land of Poland. Polonium has 25 known isotopes, all of which are radioactive. Polonium-210, an alpha emitter, is the most widely distributed isotope and it decays directly to its daughter isotope lead-206, with a half-life of 138 days. Polonium dissolves in dilute acids and will readily form compounds including oxides and halides. It vapourizes in a few hours at 55°C. Polonium can be detected and measured by alpha-particle spectroscopy.

Polonium is found in uranium ores at about one part in 10. These amounts are not harmful. Polonium is present in tobacco smoke from tobacco leaves grown with phosphate fertilizers. Synthetic polonium can be created in nuclear reactors by bombarding bismuth with neutrons. About 100 g are produced each year in this way, nearly all in Russia.

USES

A single gram of polonium-210 generates 140 watts of power and because of this property it has been used as a heat source for space travel. As a source of charged particles polonium-210 is used in anti-static devices. When mixed with beryllium, it is a source of neutrons that can be used as a trigger for nuclear weapons. Because of its very high toxicity, polonium has been used as a poison (see under Health effects, p. 232).

EXPOSURE, ABSORPTION AND TOXICITY

Following ingestion about 10 per cent of polonium is absorbed into the bloodstream and is subsequently cleared by the kidneys with a biological half-life of 30–50 days. Clearance may be accelerated using chelating agents, although significant amounts of polonium-210 are deposited in tissues within a few hours of ingestion.

The main hazard is its intense radioactivity (166 TBq/g). Alpha particles emitted by polonium will readily damage tissue if it is ingested or inhaled, but do not penetrate the skin and so are not hazardous if the polonium remains outside the body. The median lethal dose (LD50) for acute radiation exposure is about 4.5 Sv and this dose can be delivered by ingesting about 50 ng of polonium or inhaling about 10 ng.

The general population is naturally exposed to small amounts of polonium in food, water, tobacco smoke and as decay products of indoor radon. Increased exposure to polonium-210 from environmental sources is unlikely, although polonium-210 is present in devices that are easily available. Potentially lethal amounts of polonium are present in anti-static devices that are readily available in photographic stores or by mail order. Polonium-210 from a static eliminator source contaminated equipment and flooring at a soft-drink manufacturing plant. Disposal of solid radioactive waste at a waste disposal facility did not appear to result in increased environmental levels of polonium. Follow up of a large cohort of workers employed at a nuclear plant between 1944 and 1972 when polonium-210 operations were being conducted did not show any
excess mortality. Among workers specifically monitored for polonium-210, mortality was less than expected, although more lung cancers were observed. No dose–response trends were observed.4

EXPOSURE LEVELS

Maximum exposure levels for polonium in food and for the workplace have been published by national and international authorities including the US Nuclear Regulatory Commission,5 the International Commission on Radiological Protection6 and the Food and Agriculture Organization of the United Nations.7 For example, the maximum allowable body burden for ingested polonium-210 is only 1.1 kBq, which is equivalent to a particle weighing only 6.8 pg. The maximum permissible workplace concentration of airborne polonium-210 is about 10 Bq/m3.

HEALTH EFFECTS

Alexander Litvinenko, a Russian living in London, died in November 2006 after being poisoned with polonium-210 a few weeks earlier. Litvinenko was probably the first person ever to die of the acute alpha-radiation effects of polonium-210.

Following ingestion, polonium distributes widely through the tissues of the body leading to whole body radiation exposure. Most exposure occurs in the first 30 days. After a minimum lethal dose, no initial illness would result due to the time it takes for exposure to accumulate, but death would be expected from the poisoning within two or three months. However, Litvinenko was ill on the day he was poisoned, was seriously ill on day 11 and died on day 23. This indicates that he was poisoned with many times the lethal dose of polonium-210 with the initial burden of exposure falling on the gastrointestinal tract. Two other people who were with Litvinenko on the day of the presumed poisoning became ill about 36 days after Litvinenko, which is consistent with absorption of a sublethal dose.

There are unsubstantiated reports that Irène Joliot-Curie, the Nobel prize winning chemist and daughter of Marie Curie, died from leukaemia in Paris in 1956 as a result of exposure to polonium in a laboratory accident ten years earlier. Similarly, it has been suggested that four deaths among staff at a research institute in Israel between 1957 and 1969 were due to a polonium leak.

STUDIES

Following the death of Litvinenko, there has been intense interest in the radiotoxicity of polonium-210 on the human body. A large number of people were identified who may have had low-level exposure as a result of working at or visiting places that were contaminated with polonium-210. Many of these provided samples for measuring 24-hour urinary excretion of polonium-210. By applying biokinetic models, it was possible to calculate intakes by ingestion or inhalation and the resulting radiation doses. Of the 695 people examined, 560 had urinary levels of 30 mBq per day or less which is the natural background level. Eighty-five had levels greater than this, but had received an estimated dose of less than 1 mSv, 34 had received an estimated dose of more than 1 mSv but less than 6 mSv, and 16 had received an estimated dose of 6 mSv or more. For those who had received doses of more than 1 mSv, it was estimated that their lifetime risk of death from cancer was increased by between 0.03 and 0.5 per cent.8

Extrapolating from animal studies indicates that ingestion (or inhalation) of a few tenths of a milligram of polonium-210 is likely to be fatal to all exposed persons. Such intakes will cause fatal damage to the bone marrow and other organs, including the kidneys and liver. Deaths will occur within about a month with levels of >1 MBq/kg body mass, but will occur over a longer period for lower exposures. Below 0.02 MBq/kg body mass, deaths from deterministic effects are not expected to occur, but the risk of cancer could be significant.9

One study has estimated that Litvinenko might have ingested between 27 and 1408 MBq (0.2–8.5 μg).10 A second study concluded that 0.1–0.3 GBq absorbed into the bloodstream of an adult male would probably be fatal within one month. Assuming 10 per cent absorption into the bloodstream, this would correspond to ingestion of 1–3 GBq. There would be reductions in white cell count due to bone marrow failure complicated by damage to other organs, such as the kidneys and liver. Damage to these other organs would most probably be fatal even if the bone marrow could be rescued.11

Key points

- The general population is naturally exposed to small amounts of polonium in food, water, tobacco smoke and indoor radon.
- Synthetic polonium has commercial uses.
- Polonium is highly toxic when ingested or inhaled due to the emission of alpha particles.
- Alexander Litvinenko was fatally poisoned with polonium-210 in November 2006.

Silver

PETER LINNETT

INTRODUCTION

Silver is a precious metal which occurs throughout the world sometimes in its native form, but also in mixed ore bodies especially with lead and zinc ores. Thus, the initial recovery of silver from a mixed ore is also associated with the risks attributable to the other minerals, e.g. lead, cadmium, selenium and tellurium.

Impure silver is melted and cast into anodes for electro-refining using a nitrate liquor. Pure silver is collected on titanium anodes, while impurities collect in anode slimes which require further treatment.

PROPERTIES AND USES

Silver is a soft white metal which takes a high polish. It is ductile and malleable. Pure silver has the highest electrical and thermal conductivity of all metals with the lowest contact resistance. Silver metal is used in jewellery, silverware, electronic components, solders and dental amalgams. Silver halides react to light and have extensive use in photography, including x-ray plates. Silver and silver compounds have bactericidal properties and other uses include catalysts, window coatings, mirrors, electroplating and sanitation.

OCCUPATIONAL TOXICOLOGY

Ingestion is the most common route for acute absorption. Soluble compounds cause acute gastric irritation. Other effects are decreased blood pressure, diarrhoea and decreased respiration. Respiratory effects following inhalation of soluble compounds include irritation of the upper and lower respiratory tracts, although this may not be due to the silver component of the compounds so much as the chloride or nitrate ion.

Chronic absorption of soluble silver compounds, which may be due to self-medication with colloidal silver or silver-coated pills, results in widespread deposition of silver throughout all organs of the body. The clinical condition is termed ‘argyria’. The dermal manifestation is a gradual darkening of the skin to a bluish grey colour. Microscopy of the skin has shown that there is silver deposition in the basement membrane with a profusion of melanocytes. This pigmentation is irreversible. The normal tanning reaction on exposure to sunlight is enhanced by the profusion of melanocytes. The sclera become dark blue-grey and silver is deposited in Descemet’s membrane deep to the cornea and may be detected by slit-lamp examination. The impairment of night vision with haloes around lights may be reported. Although there is widespread pigmentation in all tissues and organs, there is an absence of adverse systemic effects and argyria is mainly a cosmetic impairment. There is no effective treatment for argyria which is irreversible.

In occupational settings, fine particles of soluble compounds may enter the eye and stain the conjunctiva and caruncle. Ocular burns with silver nitrate may result in permanent blemishes on the sclera. In the absence of generalized effects, the localized ocular effect is termed ‘argyrosis’.

Splashes of silver nitrate are common in workplaces where it is used. The compound is corrosive and causes a chemical burn. Copious irrigation of the affected area with
water is required. If the burn is superficial, there is initial erythema. On exposure to light, the colour then deepens to black. The skin dries and following the process of desquamation is replaced by normal healthy skin. If the silver compound is in contact with subcuticular tissues, there will be staining deep to the epidermis. Such cases have been reported from the excessive use of silver sulphadiazine for the treatment of wounds and burns.

Intradermal or implantation of splinters of silver metal during the fabrication of metal products may result in localized pigmentation causing a cosmetic change with no systemic effect.2

OTHER OCCUPATIONAL EXPOSURES

Refining of silver may be accompanied by exposure to fumes of other metals. Melting of scrap silver may release fumes of, for example, cadmium which have been incorporated in alloys to impart strength to the silver which is otherwise soft. Adequate extraction ventilation and filtration of the exhaust is required.

Silver solders may also contain cadmium and should only be used with adequate ventilation.

EXPOSURE LIMITS

The American Conference of Governmental Industrial Hygienists (ACGIH) exposure limit3 for silver metal is 0.1 mg/m³ and for soluble silver compounds it is 0.01 mg/m³. This reflects the differences in absorption of silver from soluble compounds compared with the limited absorption from insoluble compounds and metallic silver.

MEDICAL SURVEILLANCE

No specific measures have been advised for medical surveillance for silver exposure. Compliance with the exposure limits will prevent systemic absorption and argyria. Examination of the sclera and mucous membranes of workers handling soluble silver compounds may indicate if there is some staining, although early changes are very subtle and difficult to identify.

Biological monitoring has been performed and determination of silver in blood has demonstrated that workers exposed to soluble silver compounds as in plating processes have higher levels than those whose exposure is to silver metal or fume alone.4 The levels reported were not associated with argyria and routine biological monitoring has not been recommended as integral to a medical surveillance programme.

Most cases of argyria now reported are the result of self-medication.

Key points

- Chronic absorption of soluble silver compounds leads to argyria with widespread deposition of silver in all organs.
- In the skin, there is deposition of silver in the basement membrane with a profusion of melanocytes resulting in an exaggerated tanning response.

Thallium is a soft, malleable, bluish-white metal with the symbol 'Tl', atomic number 81, atomic weight 204.38 and specific gravity 11.85. Although the annual global production of thallium reduced from 15 to 10 tons between 1995 and 2004, its use is wide-ranging, including semiconductors, optical fibres, optical lens, imitation jewellery, fireworks and as a rodenticide. Radioisotope $^{201}\text{Tl}$ is used for cardiac imaging. In addition, due to recent research and development activities, the use of thallium may greatly expand in the future as a material for high-temperature superconductors. Since thallium and many thallium salts are highly toxic and yet tasteless and odourless, accidental or intentional thallium poisoning has occurred. Cases with clinical effects that may have resulted from occupational thallium exposure have been described. These include a worker engaged alone in the production of a ‘new type of special glass’ containing thallium. The worker deployed to replace him also succumbed to similar effects. Thallium can be absorbed through the gastrointestinal tract, respiratory tract and skin, and is then rapidly distributed to all organs. It passes through the placenta and blood–brain barrier. In the early phase of poisoning, its concentration is high in the kidneys, but low in adipose tissue and the brain, but the cerebral concentration increases subsequently. In an autopsied case (from a patient who died nine days after taking 5–10 g of thallium nitrate), the thallium concentration exceeded 100 mg/g in the colon, testis, cardiac ventricles, pituitary and several regions of the brain (thalamus, corpus striatum, cerebellar cortex and cerebral cortex). Thallium may be excreted into the gastrointestinal tract, kidneys, hair, skin, sweat, saliva and breast milk. Reabsorption takes place in the gastrointestinal tract (mainly the colon). The biological half-life in humans is estimated to be approximately ten days, but can be as long as 30 days. Characteristic features of thallium poisoning are gastrointestinal disturbance, neurological impairment and alopecia. In acute poisoning, initial symptoms are nausea, vomiting and abdominal pain, which may be associated with the passage of bright red blood per rectum. Tachycardia and hypertension may result from autonomic (vagus nerve) dysfunction. Characteristic symptoms of paraesthesia and pains in the lower limbs, reflecting polyneuropathy, appear after several days. Decrease of sensation in the distal extremities and weakness, especially in the lower limbs, may be present. There can be difficulties with swallowing and speech, as well as other cranial nerve effects (e.g. optic nerve, ocular movement and facial muscle dysfunction). Central nervous system involvement leads to seizures, unconsciousness, ataxia and involuntary movements. Alopecia appears approximately two weeks later. It is usually most evident in the scalp, but hair in other parts of the body can also be lost. This latent period for alopecia to appear corresponds to the maturation period of the new epithelial cells of the hair matrix. Mees lines (transverse white stripes) in the nails appear three to four weeks later. In subacute or chronic poisoning, the onset is associated with loss of appetite, headache, irritability, insomnia and loss of body weight.

The lethal dose varies from 6 to 40 mg/kg, but on average is between 10 and 15 mg/kg. Death occurs within 10–12 days if not treated. In extreme cases, death occurs within hours.

Thallium poisoning should be considered if there is a history of exposure, and the clinical effects are gastrointestinal disturbances followed by neurological impairment and then alopecia. Alopecia is seen only two to three weeks after the neurological signs have appeared. Microscopic examination of the hair root by polarized light may show black discoloration at the base, but this is non-specific. Determination of thallium in urine and saliva can provide an important clue for the diagnosis. Blood thallium levels may be elevated, but it does not reflect the tissue concentration because thallium is rapidly taken up by the cells.

To treat thallium poisoning, Prussian blue is administered orally, dissolved in 10–15 per cent mannitol,
250 mg/kg body weight, per day in three to four divided doses. Prussian blue forms an insoluble complex with thallium, suppresses its reabsorption and enhances excretion of thallium via faeces. Without treatment, the excretion half-life of thallium is approximately eight days, but the administration of Prussian blue shortens it to three days.2

In the early stages (within 48 hours after exposure), charcoal haemoperfusion and haemodialysis is used, although it has been suggested that haemodialysis can be effective even in the third week of poisoning.10 Forced diuresis may also be effective. Chelators, such as dimercaprol, EDTA and penicillamine, are not effective and dithiocarbamate is contraindicated because it enhances the distribution of thallium into the brain. Following recovery from thallium overexposure, hair growth usually reappears, whereas neurological disturbances, such as ataxia, tremor, dementia and mental signs, often persist.

Key points

- Thallium has wide-ranging applications, with a potential for use in high-temperature semiconductors.
- Thallium poisoning is characterized by gastrointestinal effects, neurological impairment and alopecia.
- The lethal dose for thallium is from 6 to 40 mg/kg body weight.
- Oral administration of Prussian blue and mannitol is used for treating thallium poisoning.

Tin

TAR-CHING AW AND HIDEKI IGISU

INTRODUCTION

Tin is a malleable, silvery-white metal with the symbol 'Sn', atomic number 50, atomic weight 118.69, melting point 232°C and a boiling point of > 2000°C. Metallic tin is used for protective coatings including tin-plated steel containers to preserve food, in the manufacture of solder, and in alloys such as bronze, brass, pewter and gunmetal. Tin compounds exist in two valency states – valency II (stannous compounds) and valency IV (stannic compounds). Stannous chloride is used as a stabilizer in soaps and perfumes, as a mordant for textiles, and in toothpaste with stannous fluoride to prevent dental caries. Organotins, which have at least one covalent carbon–tin bond, are deployed mainly as stabilizers for polyvinyl chloride polymers, catalysts in the production of polyurethane foams, and as biocides. Triphenyltin is used in disinfectants, molluscs and anti-fouling agents in marine paints.

INORGANIC TIN COMPOUNDS

Acute effects following consumption of foods contaminated with inorganic tin include nausea, vomiting and diarrhoea. There is no evidence that inorganic tin damages the immune or the nervous system or that it is mutagenic or carcinogenic in humans. Chronic exposure to dusts or fumes of inorganic tin such as stannic oxide causes a benign form of pneumoconiosis (stannosis) in which widespread mottling appears on a chest x-ray due to the high radiodensity of tin, but lung function is not compromised despite the x-ray changes. Patients with stannosis are also asymptomatic.

ORGANIC TIN COMPOUNDS

Organotins, in comparison to the inorganic tin compounds, are relatively toxic to humans. Tri-organotin compounds are more toxic than mono- and di-organotin compounds, with the toxicity of trialkyltins decreasing with an increase in the number of carbon atoms in the alkyl chain. Organotin compounds are skin and eye irritants. Tributyltin, dibutyltin and dioctyltin are immunotoxic in rodents, and organotins have been shown to be embryotoxic and teratogenic in laboratory animals, with cleft palate and other facial malformations as the most common abnormalities. Alterations of enzyme activities in sex hormone synthesis and haematological effects by organotins have been reported in vitro and in vivo, but there is no evidence of similar effects in humans.

By contrast, the neurotoxicity of organotins, especially triethyltin (TET) and trimethyltin (TMT), has been clearly shown in humans, as well as in animals. Lethal poisoning due to TET or TMT has also been observed in humans. TET and TMT are colourless liquids under normal pressure, and the boiling point is relatively low for TMT (18°C). Both compounds are soluble in organic solvents but not in water, and they can be absorbed via the respiratory and gastrointestinal tracts, as well as through the skin. Poisoning by TET or TMT has occurred following occupational exposure.

Triethyl tin

In 1954 in France, approximately 1000 people took stali-non (an oral preparation containing 15 mg of diethyltin...
diiodide) to treat a variety of clinical conditions, such as staphylococcal skin infections, osteomyelitis and acne. As a result, more than 200 individuals were poisoned and there were approximately 100 deaths.\(^3,7\) Impurities identified in stalinon were monoethyltin triiodide and triethyltin iodide. Triethyltin iodide, approximately 1.5 mg per capsule, was believed to be the primary cause of the poisoning. Judging from these cases, oral intake of 70 mg of triethyltin iodide over eight days will lead to tin intoxication. The clinical features of poisoning are severe headache approximately four days from initial exposure and absorption, with associated vomiting, dizziness, dysuria and visual disturbances, such as photophobia. Loss of appetite, hyperthermia, somnolence and mental signs may also be seen. Disturbance in consciousness leading to coma may occur in severe cases. On spinal tap, the cerebrospinal fluid pressure is often elevated, but cell count, sugar and protein concentrations in the cerebrospinal fluid are normal. Death may follow coma, epileptic attacks or cardiopulmonary insufficiency.

Triethyl tin has been well recognized as a cause of cytotoxic brain oedema.\(^8\) In laboratory animals, vacuoles occur diffusely in white matter. These are associated with splitting of myelin lamellae, but no changes in major chemical compositions of the myelin are observed. In human cases of TET poisoning, the main signs reflect diffuse leukoencephalopathy without any localized abnormalities. Fundoscopy and cerebrospinal fluid pressure may be normal.\(^7\) The severe headaches and vomiting reported are most likely due to increased intracranial pressure.

From the effects observed in animals, magnetic resonance imaging (MRI) (especially T\(^2\)-weighted images) may be a useful tool for following up patients with TET intoxication,\(^9\) although experience of the use of MRI in affected humans is limited. In a Japanese worker intoxicated with TET while engaged in manufacturing a large amount of tetraethyltin over a period of about ten days, the organotin level was elevated in whole blood, but not in serum or urine.\(^7\)

There is no specific antidote for TET poisoning. In cases of stalinon poisoning, surgical decompression to relieve the increased cerebrospinal fluid pressure was considered the only clinically effective treatment.\(^1\)

As for prognosis, complete recovery may take place, but in many cases it takes a long time and the recovery may be incomplete, leaving disabilities including paraparesis and visual disturbances. In the case of the affected Japanese worker, it took approximately six months before the cerebrospinal fluid pressure returned to normal.\(^7\)

**Trimethyl tin**

Pathological lesions are limited to the nervous system with the major affected site being the limbic system.\(^6,10\) The clinical picture appears to reflect this, presenting as aggressiveness, hyperphagia, disturbed sexual behaviour, disorientation, memory impairment and complex partial seizures. Animals given TMT also show aggressiveness, seizures, learning and memory impairment, and self-mutilation (biting their own tail). Central nervous system changes in affected animals revealed changes in the hippocampus, cerebral cortex\(^6\) and the cerebellum.\(^11\) The clinical presentation includes nystagmus and ataxia. Tinnitus and hearing difficulty may develop due to impairment of the brainstem and/or inner ear.

In the case of two individuals who consumed contaminated wine (containing an unknown quantity of TMT), tinnitus began within 10 minutes and abnormal behaviour, such as agitation, occurred three hours after drinking the wine.\(^10\) It is uncertain how much of the alcohol consumed contributed to the behavioural effects.

Determination of organotins in urine may provide an important clue for the diagnosis. In six workers exposed to TMT vapour, while cleaning a tank in Germany, urinary organotin levels reached a peak within four to ten days.\(^11\) (A mean normal urine level for tin has been reported at 16.6 \(\mu\)g/L.\(^12\)) Electroencephalography (EEG) may show abnormalities in the temporal regions (spikes and/or slowing of EEG waves). Complete recovery occurs in mild cases, but clinical abnormalities often persist. In the above six workers, one died and two remained seriously disabled following the incident.\(^11\) In a 23-year-old postgraduate student accidentally exposed to TMT while performing laboratory experiments, memory impairment and EEG abnormalities (slow waves in the temporal region) were observed 43 months later, but with no MRI changes.\(^13\) Hence, the prognosis is poor for severely affected individuals.

### Key points

- Tin exists as the pure metal (inorganic stannous (valency II) and stannic (valency IV) compounds) and as organotins.
- Exposure to inorganic tin dust leads to ‘stannosis’ – a benign effect despite widespread mottling on chest x-ray.
- Organotins are generally more toxic than inorganic tin compounds. They are irritant to the skin and eyes, and are neurotoxic.

### REFERENCES

Tungsten (wolfram) is a naturally occurring element. Two kinds of tungsten-bearing mineral rocks, called wolframite and scheelite, are mined commercially. Tungsten is an extremely hard metal and highly resistant to heat. It is used in the filaments of incandescent light bulbs and in the steels for producing metal tools. Most of the tungsten used in industry is in the manufacture of sintered tungsten carbide (cemented carbides). In this process, a mixture of powders, including tungsten carbide, cobalt, nickel or chromium metal, are shaped into the form of cutting tools and then heated at high temperatures to produce machine tools that are almost as hard as diamond. Some of the soluble compounds of tungsten, such as tungsten molybdenate, are used in the textile industry as mordants or fireproofing agents, and some of the highly coloured tungsten salts are used as pigments in paints, inks, ceramics and textiles.

In the hard metal manufacturing industry, there is exposure to:

- tungsten carbide in the forming, pressing and sintering workshops;
- a combination of tungsten carbide, tungsten oxide and tungsten metal in the tungsten carbide production workshop;
- tungsten metal alone in the powder processing department.

Grinders are exposed to tungstenate during wet grinding, and to tungsten oxide and carbide when dry grinding is carried out. Despite its low solubility, tungsten carbide is bioavailable. The bioavailability increases in the order: tungsten metal, tungsten carbide, tungstenate. Tungsten concentrations in urine of hard metal-producing workers were shown to vary greatly between the different workshops. The highest tungsten concentrations excreted in urine were found in grinders who had a mean value of 94.4 μg/g creatinine and a maximum value of 177.5 μg/g creatinine. High urinary tungsten concentrations were also detected in workers from the departments producing tungsten carbide (mean, 42.1 μg/g creatinine; maximum, 79.9 μg/g creatinine) and heavy alloys (mean, 24.9 μg/g creatinine; maximum, 84.8 μg/g creatinine). The 95th percentile for the general population is 1 μg/g creatinine.

Exhaled breath condensate (EBC), obtained by cooling exhaled air under condition of spontaneous breathing, has also been proposed as a matrix to assess target tissue dose and effects of inhaled cobalt and tungsten.

The main hazard associated with the use of tungsten carbide is hard metal disease (see Chapter 19, Cobalt and Chapter 82, Metal dusts and fumes). Although cobalt probably plays a critical role in the pathogenesis of hard metal lung disease (HMLD), it is suggested that tungsten carbide has a contributory synergistic effect. Animal experiments have shown that pure tungsten carbide is inert. In lung biopsy samples from patients with HMLD, tungsten particles were found to be mainly distributed in centrilobular fibrosing lesions, suggesting that inhaled hard metal was trapped at the bronchioles and triggered the inflammation seen in HMLD.

A case of tungsten-induced occupational asthma, with immediate hypersensitivity reaction at the scratch test has been reported. However, tungsten as a cause of allergy is rare.

Key points

- Tungsten (wolfram) has no beneficial function in humans yet reported.
- Tungsten and its compounds show low toxicity, but data are scant.
REFERENCES

Uranium

IAIN BLAIR

INTRODUCTION

Refined uranium is a silver-grey weakly radioactive metal that is 70 per cent more dense than lead, but not as dense as gold or tungsten. Uranium is found naturally in low concentrations in soil, rock and water and is more plentiful than tin or silver. The worldwide production of uranium in 2006 amounted to 39 603 tonnes of which 28 per cent was mined in Canada and 23 per cent in Australia. Other important uranium mining countries are Russia, Niger, Namibia and Kazakhstan. In nature, uranium is mostly the isotope uranium-238 (>99 per cent), with small amounts of uranium-235 and very small amounts of uranium-234. Uranium isotopes have very long half-lives. They decay slowly through a series of decay products by emitting alpha particles.

USES

Historically, uranium was a byproduct of radium production, which was used to make luminous paints for clock and aircraft dials. It was used as a colourant in the glass and pottery-glazing industries.

Contemporary uses for uranium rely on its unique nuclear properties. Uranium-235 is naturally fissile and can produce a sustained nuclear chain reaction which is exploited in nuclear reactors and nuclear weapons. One kilogram of uranium-235 can produce as much energy as 1500 tonnes of coal and as little as 7 kg can be used to make an atomic bomb.

To be used as a nuclear fuel, uranium must be enriched, so that the uranium-235 concentration is increased to between 3 and 5 per cent. The enrichment process produces large amounts of uranium that is depleted of uranium-235, but with correspondingly more uranium-238, so-called depleted uranium (DU).

When alloyed with 1–2 per cent of other elements, DU produces a very dense, low cost, material that is easily machined or cast. It has many uses in the defence industry, including ammunition, armour plate and counterweights in various devices.

The use of DU has become controversial following the widespread use of DU munitions by the United States, United Kingdom and other countries during recent wars in Iraq, the Balkans and Afghanistan. Although less radioactive, DU behaves chemically and toxicologically like natural uranium. The toxicity of DU has been studied mostly as a health issue for military personnel, but many tons of DU have been left in war-affected areas where the local civilian populations continue to be exposed to DU mainly in the form of dust. Although no conclusive epidemiological data have linked DU exposure with specific human health effects, such as cancer, DU remains controversial because of unanswered questions about potential long-term health effects (see under Health effects, p. 244).

EXPOSURE, ABSORPTION AND TOXICITY

Exposure to uranium and its radioactive decay products including radon gas may occur during the mining and processing of uranium ore, the enrichment of uranium for reactor fuel or as a result of transport or storage accidents. Excessive worker exposure to uranium is unlikely in workplaces where good occupational hygiene measures are in place.
Military personnel and local civilians may be exposed in areas where DU munitions have been used. Exposure may also occur in areas where soil and groundwater have high levels of naturally occurring uranium. The main routes of exposure are by inhaling dust, ingesting contaminated water and food, or in the case of DU munitions, through injury causing open wounds and embedded fragments.

Absorption of uranium from the gastrointestinal tract is low and depends on the solubility of the particular uranium compounds. Over 95 per cent is eliminated in the faeces and two-thirds of the absorbed fraction is filtered by the kidney and excreted in the urine in 24 hours. Uranium within the body deposits at bone surfaces and is slowly cleared via blood and kidneys with a half-life of up to one year. Inhaled uranium particles may be retained in the lung and may lead to irradiation damage and lung cancer as they are slowly absorbed into the bloodstream. Exposure to uranium can be monitored by measuring urinary uranium excretion. Chelation is ineffective.

Uranium is weakly radioactive, but of greater significance is its chemical toxicity which it shares with other heavy metals. The health effects of uranium which are known from animal studies and human epidemiology include lung cancer, kidney damage and DNA damage. Uranium is less toxic than lead.

The World Health Organization (WHO)\(^1\) and most national regulatory agencies\(^2\) have set minimum, recommended or permissible exposure limits for soluble and insoluble uranium compounds by ingestion and inhalation. These limits consider both renal toxicity and radiation exposure and apply to both the general population and the workplace. Levels are also available for air and drinking water. The levels vary depending on the methodology that is used and the levels of risk and uncertainty that are deemed acceptable. For example, the WHO recommends that the general public’s intake of soluble uranium compounds should not exceed 0.5 μg/kg of body weight per day by ingestion and 1 μg/m\(^3\) by inhalation. Occupational exposure to soluble and insoluble uranium compounds, as an 8-hour time-weighted average should not exceed 0.05 mg/m\(^3\).

### HEALTH EFFECTS

Epidemiological studies have shown an association between uranium mining and lung cancer. It is exposure to radon gas and other radioactive decay products rather than uranium per se that explains this association.\(^5\) Radon exposure also explains the increase in lung cancer seen in other groups of miners. Uranium miners may also have an increased risk of developing leukaemia as a consequence of radon exposure,\(^5\) although this outcome may require lengthy occupational exposure to longer-lived radionuclides and gamma-radiation.\(^6\)

Only a few humans have had sufficiently large acute intakes of uranium compounds to lead to kidney failure. Studies of these few cases indicate that kidney failure is likely to occur within a few days at concentrations above about 50 μg uranium per gram of kidney. The levels of kidney uranium that may cause minor kidney dysfunction in humans are not well established, but are considered to be at least ten-fold less than the value of 3 μg uranium per gram of kidney that has often been used as the basis for occupational exposure limits. Acute exposures that lead to concentrations of about 1 μg uranium per gram kidney have been associated with minor kidney dysfunction, but the levels that can occur for short periods without causing long-term kidney damage have not been defined.

Epidemiological studies have examined the health of workers potentially exposed in uranium-processing plants and community studies have examined health outcomes in populations living near uranium plants. Lack of exposure data, confounding factors and the expected ‘healthy worker’ effect make interpretation of the results difficult. Generally, there is no consistent evidence for any increase in cancer or serious kidney disease due to uranium exposure in these settings.

Incidents involving acute or subacute exposure to uranium have occurred in a variety of settings. Workers at a uranium-processing plant where there was poor dust control had evidence of increased urinary uranium levels and impaired renal function.\(^7\) Following the uranium enrichment process, large quantities of depleted uranium hexafluoride (HF) are produced and have to be stored indefinitely in steel containers. Inevitably accidental releases occur. In one such release in 1986, one worker died from HF inhalation and 31 other workers were exposed and showed evidence of short-term kidney damage. None, however, had lasting kidney toxicity from the uranium exposure. Magdo and others reported nephrotoxicity with raised beta-2-microglobulin excretion rate in a three-year-old child as a result of drinking water from a well at their home in Connecticut with naturally elevated concentrations of uranium (866 and 1160 μg/L).\(^8\)

Depleted uranium has been widely studied as a possible contributory factor in ‘gulf war syndrome’: the immune system disorders and other wide-ranging symptoms reported in about 25 per cent of combat veterans of the 1991 Gulf War. There have been several authoritative reports and a precautionary approach is advised.\(^9\)

Thirty-five American Gulf War I veterans who had significant DU-retained shrapnel burden as a result of combat were assessed 16 years after initial exposure. They continued to have elevated concentrations of urinary uranium with minor abnormalities of renal tubular function and bone formation, but without clinically significant related health effects.\(^10\)

A follow-up study after eight years of 2499 firefighters, police officers and hangar workers who were potentially exposed to uranium from the balance weights of a crashed aircraft in the 1992 Amsterdam air disaster found no evidence of higher urinary uranium concentration or disturbed renal function.\(^11\)
Animal studies suggest that DU is a teratogen and there is some evidence that human parental DU exposure may be associated with an increased risk of abnormality in their progeny. Persistent chromosome abnormalities have been reported in a cohort of uranium miners.

**Key points**

- Uranium is a very dense, weakly radioactive metal which, when enriched, is used in nuclear reactors and nuclear weapons. Depleted uranium-238 is used in the defence industry and is controversial because of its potential health effects.
- Exposure to uranium can occur in various settings by inhalation, ingestion or embedded fragments.
- Although poorly absorbed, like other heavy metals, uranium is toxic to kidney and other tissues.
- Inhaled uranium particles may lead to irradiation damage and lung cancer.
- In epidemiological studies, the health effects of uranium exposure are often confounded by radon exposure.

Vanadium

FINLAY D DICK

INTRODUCTION

This transition metal was discovered in Mexico in 1801 by del Río and called vanadium by Sefström, who purified vanadium oxide in 1830. Vanadium is found in the blood of sea cucumbers and sea squirts. Whether vanadium is an essential element for humans remains unclear.

SOURCES

Commercially important vanadium ores include carnotite, patronite and vanadinite and the main reserves are in South Africa, Russia, China and the United States. The primary source of vanadium is vanadium-bearing steel slag, with vanadium ores as a secondary source. Crude oil contains trace amounts of vanadium with Venezuelan oil being (relatively) vanadium rich. Oil combustion concentrates vanadium in the residual oil fuel ash which can contain up to 40 per cent vanadium by mass. As a consequence, this ash has commercial value and 8 per cent of world vanadium production comes from refining such ash.

USES

Owing to its hardness, fatigue resistance and corrosion resistance vanadium has been widely employed, as ferrovanadium, in the production of steel alloys used in the manufacture of high speed hard steel tools and in aviation. It is used as a catalyst in sulphuric acid production, in the manufacture of yellow pigments, in microelectronics, ceramics and batteries. It is a highly reactive metal and so it is not found as the pure metal in nature.

Exposure to vanadium as vanadium oxide dust can occur during vanadium refining and manufacture of steel alloys. Industrial boiler cleaning is an important occupational exposure owing to the high level of vanadium in the residual oil fuel ash.

HEALTH EFFECTS

Vanadium pentoxide (V₂O₅) is a skin and respiratory irritant which may cause respiratory and skin sensitization. Acute exposure leads to eye and skin irritation, rhinitis, epistaxis, a metallic taste, pharyngitis, a productive cough, breathlessness, chest pain, haemoptysis and pneumonitis. Some have reported fine tremor, but the evidence for this is inconclusive. Many authors describe exposed workers as having a greenish-black or greenish-yellow tongue, although this is thought to be an index of exposure rather than toxicity.

Lees observed that workers exposed to residual oil fuel ash showed reductions in both FEV₁ and FVC and suggested that such changes would resolve over ten days. In contrast, Kiviluoto found no evidence of impaired lung function in workers exposed to relatively low vanadium in air levels (0.01–0.04 mg/m³), but exposures had previously been much higher at 0.1–3.9 mg/m³. A study of US boiler makers exposed to relatively low levels of vanadium (median full shift dose estimate 53.2 µg) found an excess of upper and lower respiratory symptoms among boiler makers when compared with utility workers. Vanadium exposure has been associated with the development of occupational asthma in workers in a vanadium pentoxide plant exposed to Na₃VO₃ vapour, NH₄VO₃ powder and V₂O₅ fumes and dust, and one case report has described...

References 247
a metal fume fever-like syndrome in a man exposed to a catalyst containing vanadyl pyrophosphate dust. Skin sensitization to vanadium, confirmed on patch testing, has also been described in a worker in a vanadium pentoxide manufacturing plant exposed to dust containing vanadium. Vanadium interferes with iron metabolism and haem synthesis causing elevated zinc protoporphyrin (ZPP). Barth et al. suggested that vanadium pentoxide has short-term effects on cognitive function, but these findings have yet to be replicated.

In 2006, vanadium pentoxide was classified as a ‘possible human carcinogen’ (2B) by the International Agency for Research on Cancer (IARC) based on animal studies showing an excess of lung adenomas and cancer. This assessment has, however, been disputed. Recent work has shown increased DNA damage in a group of workers exposed to vanadium pentoxide dust with median serum vanadium of 2.2 μg/L.

**TREATMENT**

Treatment for overexposure to vanadium or its compounds is mainly supportive. There are no specific antidotes that have been shown to be effective in humans.

**Measuring exposure**

The current United States Occupational Safety and Health Administration (OSHA) exposure limit for vanadium respirable dust (as V₂O₅) is 0.5 mg/m³ and the exposure limit for vanadium fume (as V₂O₅) is 0.1 mg/m³. The American Conference of Governmental Industrial Hygienists (ACGIH) has assigned respirable vanadium pentoxide a threshold limit value of 0.05 mg/m³ as an eight-hour time-weighted average based on the upper and lower respiratory tract irritancy of vanadium pentoxide. The UK work exposure limit (WEL) for vanadium pentoxide is 0.05 mg/m³ (eight-hour time-weighted average). There is currently no German maximale Arbeitsplatz-Konzentration or maximum concentration at the workplace (MAK value) assigned for vanadium.

**HEALTH SURVEILLANCE**

Biological monitoring may be undertaken using post-shift urinary vanadium at the end of the working week. Creatinine-adjusted urinary vanadium is highly correlated with serum vanadium values. Vanadium is rapidly excreted in the urine and in workers with long-term exposure most vanadium is excreted within 24 hours. Ingested vanadium is largely excreted unabsorbed in the faeces. Blood and serum values of around 1 nmol/L and urinary vanadium values of 10 nmol/L have been proposed as likely normal values in unexposed populations, although these will be influenced by environmental factors such as residency near steel works or oil-burning power stations.

**Key points**

- Vanadium pentoxide (V₂O₅) is a skin and respiratory irritant.
- Industrial boiler cleaning is an important occupational exposure owing to the high level of vanadium in the residual oil fuel ash.
- Vanadium exposure has been associated with occupational asthma.
- Skin sensitization to vanadium has very rarely been described.
- Treatment for overexposure to vanadium is mainly supportive.
- Vanadium pentoxide is classified as a ‘possible human carcinogen’ (group 2B) by the International Agency for Research on Cancer (IARC).

Zinc

PETER AGGETT

Properties and uses 249  Exposure and health effects 250
Essentiality and metabolism 249  References 250

PROPERTIES AND USES

Zinc is the twenty-fifth most abundant element in the Earth’s crust and is the fourth most widely used metal. Zinc is more reactive with oxygen than either iron or steel, and it is therefore used to coat (galvanize) these to protect them from oxidation and corrosion. Half of zinc’s production is used for galvanizing. It is also used in alloys, such as: brass; wrought zinc (zinc, copper and titanium) for example in roofing; ‘nickel silver’ type-writer metal and other die casting alloys with copper, aluminium and magnesium; catalysts, batteries and, with a copper coating, in coins. Other uses include pigments, medicines, ointments and topical lotions such as calamine, eye drops (zinc sulphate), cosmetics, deodorants containing zinc chloride and anti-dandruff shampoos with zinc pyrithione. Organic zinc is used as a fungicide and zinc phosphide, which releases phosphine, as a rodenticide. It is also found as feed additives and in over-the-counter mineral supplements.1,2

Zinc occurs naturally in soils and in most rocks as the sulphide (ZnS) in blende and sphalerite, which accounts for 95 per cent of that used commercially. Other sources include calamine, zinc spar, wilemite and zincite (zinc oxide). Many of these ores also contain copper, lead, iron and silicate.

ESSENTIALITY AND METABOLISM

Zinc is an essential trace element. It has a single oxidation state and therefore does not transfer electrons, but it readily acts as a Lewis acid, and forms complexes with oxygen, nitrogen and sulphur donors. These characteristics enable it to have catalytic, structural and regulatory roles in enzymes, and structural and regulatory roles in other proteins, histones, nucleic acids (zinc finger proteins) and receptor binding. The metal is involved in over 200 enzymes representing all classes of activity and involving every metabolic pathway and function in the body, including for example protein digestion and synthesis, vision, carbohydrate metabolism, bone health, free radical protection, cell turnover and new tissue synthesis.

Zinc is absorbed predominantly in the proximal, but also throughout the small intestine. There are specific carrier-mediated pathways and also diffusional routes for its uptake and transfer. It is distributed in the circulation to the liver, and systemically from the liver bound to albumin, transferrin and alpha-2-macroglobulin.

Zinc is in pancreatic and biliary, and other intestinal secretions. This contributes to an enteroenteric circulation of zinc, within which the intestinal reabsorption of the secreted zinc is an important regulator of systemic zinc accumulation and an important component of zinc homeostasis. Thus the principal route of zinc loss is in the faeces, which also contain unabsorbed dietary zinc.1,3

No specific systemic zinc store has been identified. It accumulates in the liver where it induces and binds to a low molecular weight cysteine-rich protein, metallothionein. At high exposures or when the system has no need for zinc, its systemic accumulation is further regulated by down-regulation of the mucosal zinc transporters to reduce uptake and the induction of enterocyctic metallothionein which blocks transfer of the element and traps it in the mucosa.3
EXPOSURE AND HEALTH EFFECTS

There are few reports of zinc toxicity, particularly as a result of occupational exposure. Contact dermatitis to zinc salts occurs and prolonged or repeated exposure might cause a papular folliculitis. Acute exposure to zinc from drinking contaminated food or water, such as drinks that have been stored in galvanized containers causes acute nausea, vomiting, abdominal pain and faintness. Zinc sulphate solutions may cause simply upper gastrointestinal discomfort and symptoms; zinc chloride is more corrosive and can cause pharyngitis and oesophagitis, as well as haemorrhagic gastritis. These effects are ameliorated by the simultaneous ingestion of food. The metallic taste of zinc solutions is evident at 15 mg Zn/L. The regulatory limits for the zinc content of water supplies are around 5 mg Zn/L. High acute exposures can lead to renal damage and pancreatitis.

Prolonged oral exposure to zinc interferes with the metabolism of copper, and to a lesser extent, iron. The mechanisms for this are thought to involve competition at carrier sites and, in the case of copper, the induction of intestinal metallothionein which blocks its onward transfer to the body. In some instances, this has led to symptomatic copper deficiency manifest by hypocupraemia, impaired iron metabolism, anaemia, leukopenia, neutropenia, reduced erythrocytic superoxide dismutase activity, and reduced caeruloplasmin. This intake of zinc at which this phenomenon occurs depends on the effects of the dietary matrix on the availability of zinc to interact with the gut mucosa; it is probably in the region of 30–50 mg of elemental zinc daily which is about three to five times the daily requirement. Some workers galvanizing metals have been reported to have reduced circulating copper levels, but no other clear evidence of an increased systemic load of zinc or other features of clinically significant copper deficiency.

Zinc salts, such as the oxide, are volatile at low temperatures. White fumes of zinc oxide are produced when the metal is being worked in welding and galvanizing. This can precipitate metal fume fever. Inhalation of zinc chloride has been associated with pneumonitis and respiratory distress syndrome. Inhalation exposure to particles can produce nasopharyngeal damage and inflammation, as well as upper gastrointestinal effects. These are variably described as Brass founder’s ague, zinc chills, Spelters’ shakes, metal shakes and zinc fever: common with those using non-ferrous metals or ferrous alloys.

There is limited experience with treating systemic overload of zinc. The recommended chelator is calcium disodium ethylenediaminetetraacetate (CaNa2EDTA).

Key points

- Occupational zinc toxicity is principally metal fume fever.
- Exposure from drinks stored in galvanized containers is a common cause of zinc toxicity.
- Acute exposure is associated with gastrointestinal symptoms and acute high exposure is associated with renal and pancreatic damage.
- Chronic exposure impairs normal copper and iron metabolism and simulates deficiencies of these.
- Treatment is seldom needed. The recommended chelator is calcium disodium ethylenediaminetetraacetate (CaNa2EDTA).

INTRODUCTION

Inhalation accidents have been a threat to workers since early times from encounters with gases in fires, mines and fermentation processes. Volcanic and geothermal gases formed the earliest atmosphere of the Earth. Scientists laid the foundations of the chemical industry with the isolation and identification of individual gases. One of the foremost of these, Joseph Priestley (1733–1804), while working as a schoolmaster in England, is credited with the discovery of ‘alkaline air’ (ammonia), vitriolic acid air (sulphur dioxide), nitrous oxide, nitrogen dioxide and methane, as well as isolating what he called ‘dephlogisticated air’ in 1774. Lavoisier, after meeting Priestley, gave the latter the name oxygen and demonstrated its role in respiration and combustion, though the disputed claim for priority for its discovery is one of the most famous episodes in the history of chemistry.

Early experience with gases in manufacturing industries inevitably included avoidable deaths among workers from leaks or as a result of faulty working practices; today, however, deaths from occupational exposure to gases are rare in high economy countries, even though inhalation incidents are not uncommon. In the United Kingdom during the period 1990–3, a total of 1180 inhalation incidents was reported to SWORD, a national scheme for the surveillance of work-related and occupational respiratory diseases involving occupational and chest physicians. Gases and combustion products comprised by far the largest group of agents (45 per cent), with chlorine and oxides of nitrogen the most commonly reported gases.1 Irritant gases (unspecified, 42 per cent) again dominated reporting in 1992–2001.2

Flammable and toxic gases stored in large quantities under pressure are an important cause of disaster. In 1974, an explosion at a chemical plant in Flixborough, England, caused by a leak of cyclohexane vapour, had an explosive force equivalent to 32 tonnes of TNT, destroying the plant and killing 28 workers on site, with extensive damage to houses and shops as far as 10 km away. This event profoundly influenced the approach to regulating major hazards (see under Exposure to gases in major industrial incidents, p. 256). In 1984, over 500 people died in Mexico City when a liquid petroleum gas plant exploded. Even greater hazards are posed by the release of a cloud of toxic irritant gas, which may cause death or pulmonary injury in populations for many kilometres downwind, as highly toxic irritant gases can be extremely dangerous in even very dilute concentrations. The disaster at Bhopal, India, in 1984, involving the release of methyl isocyanate was the world’s worst industrial incident of this kind, resulting in over 10 000 deaths either immediately or subsequently from their lung injuries, while hundreds of thousands have been reported to be suffering from disabling chronic respiratory symptoms. These incidents have led to a concerted and successful worldwide effort by national and international agencies to reduce the hazard of accidental toxic releases during chemical manufacture, storage and transport.3
Chemical and other industrial installations may also become military or terrorist targets. The first recorded mass civilian casualty incident due to a toxic release in warfare was during the London Blitz, when 47 people were overcome by ammonia gas. They were sheltering in a brewery cellar which received a direct hit in a heavy air raid and a fragment of flying metal pierced a pipe of an ammonia condenser. The use of gases as military weapons has a long history, but in modern combat dates from the First World War (see Chapter 41, Deliberate use of chemicals in warfare and by terrorists).

In recent years, renewed attention has been given to air pollution and respiratory health with the recognition of the effects that exhaust emissions from the growing number of motor vehicles are having on air quality. Carbon dioxide, carbon monoxide, sulphur dioxide and nitrogen oxides are produced in the combustion of fossil fuels, whether as coal or petroleum products, and so are common pollutants of the outdoor and indoor air. The worst episodes of air pollution occurred during the era when coal burning was the prime source of energy. The most dramatic of these was the London smog of December 1952 when there were an estimated 4000 excess deaths over a five-day period provoked by a dense blanket of pollutants which included smoke and sulphur dioxide. This episode was a defining moment in Clean Air legislation in the UK, eventually followed by many other countries in the world.

**DEFINITIONS**

A gas is any gaseous substance that is above its critical temperature and therefore is not capable of being liquefied by pressure alone. A vapour is the gaseous form of a substance which may condense at high concentrations, or is capable of being liquefied by pressure alone; aerosol (particulate) forms may coexist with the vapour. A vapour diluted with air behaves like a gas, as long as none of the substance is available in the liquid form. The same sampling devices can be used for the collection of gases and vapours.

Not all industrial ‘gases’, however, are true gases according to this definition. Examples are chlorine, ammonia, propane and butane which when handled in bulk are liquefied under pressure. Examples of ‘true’ or ‘permanent’ gases that require cooling as well as pressure to turn them into liquids are oxygen, nitrogen and methane.

Aerosols are solid or liquid particles dispersed in the atmosphere as dust, fumes, smoke, mists and fogs. Stability is an essential characteristic.

A fume, as strictly defined, is the solid particles generated by condensation from the gaseous state, generally after volatilization from melted substances and often accompanied by a chemical reaction such as oxidation. A cloud, or mist, of acid droplets (e.g. formed by the contact of hydrogen chloride gas with moist air) is often, but technically incorrectly, referred to as a fume.

The concentrations of gases and vapours in the air can be expressed in three main ways:

1. As the ratio of the volume of the gas to the volume of air in which the gas is contained usually expressed in parts per million (ppm) or parts per billion (ppb);
2. As the mass of gas in a specified volume of air usually expressed as mg or μg per cubic meter (mg/m³ or μg/m³);
3. In physiological terms as the partial pressure of a gas, such as in the oxyhaemoglobin dissociation curve.

The mass concentration as expressed above will be dependent on the ambient temperature and pressure. The volume mixing ratio is independent of the ambient temperature and pressure, if ideal gas behaviour is assumed. The two systems of units are interchangeable using a conversion formula:

\[
\text{Concentration in ppm} = \frac{\text{molecular volume}}{\text{molecular weight}} \times \text{concentration (as mg/m}^3\text{ or }\mu\text{g/L)}
\]

where molecular volume \(= 22.41 \times T/273 \times 10^{15}/P\ L\)

\((T\text{ is the ambient temperature (K) and } P\text{ is the atmospheric pressure (in millibars).})\)

From a toxicological standpoint, the pathophysiological response on exposure to a gas is not dependent on the mass of the molecules, but on the number present. It is therefore more appropriate in this chapter to express the concentration in the air as ppm or ppb, but in many official publications mg or μg/m³ are used instead. This can give rise to considerable confusion.

The available human evidence may or may not be adequate for determining a no observable adverse effect level (NOAEL) or a lowest observable adverse effect level (LOAEL) on exposure to a gas. Workplace exposure limits (WELs) are concentrations of hazardous substances in the air, approved by the UK Health and Safety Commission (HSC). UK employers have a responsibility to ensure that these limits are not exceeded in order to protect the health of workers. WELs are not necessarily purely health based, and are set by committees generally faced with a situation of uncertainty and who take scientific data from a wide range of sources, where available, and also consider the economic and engineering feasibility of achieving a limit when setting a new WEL. This is why published WELs for exposure to a gas in the workplace can be higher than the LOAEL derived from published data. Nevertheless, WELs do reflect a level at which most people at work will be reasonably well protected. WELs and the measured concentration of a gas in the workplace are therefore very useful as an aid to interpreting symptoms in a worker who may or may not be
especially susceptible to a particular irritant gas, for example, because they suffer from asthma. All the exposure limits cited for individual gases in this chapter are taken from published Health and Safety Commission Workplace Exposure Limits, unless indicated otherwise.

CLASSIFICATION OF GASES ACCORDING TO THEIR HEALTH EFFECTS

Most of the common gases described in this chapter may be categorized according to the original classification of Henderson and Haggard.5

Irritant gases

As a rule, the irritant gases are substances which chemically are regarded as corrosive. They injure surface tissues and induce inflammation of the air passages and the parenchymal region. Primary irritants are those which have little or no systemic toxic effect in the concentrations that cause death. Secondary irritants produce systemic toxic effects in addition to the surface tissue irritation.

Workers may sometimes be exposed to a mixture of irritant gases, for example in welding. In these circumstances, there is little information on how different gases interact, but additive or synergistic effects should be allowed for when comparing the concentrations of gases in the air to their work exposure limits. Thus, if the effects of the different gases are believed to be additive, the mixed exposure should be assessed using the formula:

\[ \frac{C_1}{L_1} + \frac{C_2}{L_2} + \frac{C_3}{L_3} \]

where \( C_1, C_2, \) etc., are the concentration of contaminants in the air and \( L_1, L_2, \) etc., are the corresponding exposure limits. The sum of the \( C/L \) fractions should not exceed unity.

Asphyxiating gases

This group of gases interferes with the supply and utilization of oxygen in the body. Simple asphyxiants, for example methane and hydrogen, exclude oxygen from the lungs. Chemical asphyxiants cause death by preventing the transportation of oxygen by the blood (e.g. carbon monoxide) or inhibit cellular respiration (e.g. hydrogen cyanide). Many simple asphyxiants are odourless and are not readily detectable. They are not given occupational exposure standards and the best means of ensuring safety is by monitoring the oxygen content of the air. Under normal atmospheric pressures, the oxygen content of the air should not be allowed to fall below a minimum of 18 per cent by volume.

Gases with a drug-like action

This group includes anaesthetic gases, hydrocarbons and solvents. They can have systemic effects after they have been absorbed through the lungs into the blood.

Thus, in this chapter, gases have been classified as follows:

1. asphyxiating gases: simple asphyxiants, chemical asphyxiants;
2. irritant gases: primary irritants with little or no systemic toxic effects, secondary irritants which produce systemic effects;
3. low-irritancy gases with a systemic drug-like action.

CHARACTERISTICS OF HAZARDOUS GASES

The general characteristics of gases which most relate to their health hazard are their density, water solubility and flammability. The air has a relative molecular mass of about 29 and the relative density of a gas compared with air is important in determining its tendency to disperse or accumulate at normal temperature and atmospheric pressure. When released from an industrial point source, denser than air gases, such as carbon dioxide or chlorine, can displace the air and flow under gravity or be blown by the wind along the ground, adding to their danger to workers and the population in the vicinity.

Flammable gases also have lower and upper flammable (explosive) limits within which the resultant mixture with air may ignite. When ignited in a confined space an explosion may result, but in an unconfined space, such as the open air, the consequence may be a flash fire. Most flammable gas clouds cease to be dangerous when diluted to about 2 per cent by volume. Alarm levels for flammable gases are set at 20 per cent of the lower explosive/flammable level so as to avoid the risk. Liquefied petroleum gases are stored or transported by road, rail and sea in large amounts and are major fire and explosion hazards. The flammability limits of flammable gases are usually much higher than the toxic levels, except for gases which spontaneously ignite on contact with air (pyrophoric gases), such as silane. Other exceptions are the flammable, simple asphyxiating gases such as hydrogen and methane whose lower flammable limits are exceeded before they can cause asphyxia by displacing air.

The localization of the effects of irritant gases in the respiratory tract depends upon the water solubility and concentration of the gas. At low-to-moderate concentrations of highly soluble gases, such as ammonia, hydrogen chloride, hydrogen fluoride and hydrogen bromide, injury is greatest from the nasopharynx to the bronchi. Nose breathing of these gases may confine injury to the nasal passages. For less water-soluble gases, for example, nitrogen dioxide, the main localization is from the proximal to the distal acinus. At high concentrations of soluble gases,
or if the gases are dissolved in fine aerosols, damage may extend throughout the respiratory tract. Solubility will also determine whether the gas will be rapidly taken up by suspended droplets in the workplace atmosphere, for example hydrogen chloride and hydrogen fluoride will readily combine with water to form hydrochloric and hydrofluoric acids, respectively. Acid gases rarely exist in a purely gaseous state, but in a form that is partitioned between the gas and aqueous phases. Inhalation kinetics are dealt with further in Chapter 10, Occupational toxicology: general principles.

Hydrogen chloride and sulphur dioxide, being soluble in water, readily form acid aerosols. Occupations, such as battery-making and galvanizing, used to be associated with dental erosion in people working above acid baths, but the condition is now seen more commonly in low economy countries where exposures to aerosols are less controlled.

**OCCUPATIONAL EXPOSURE TO GASES IN INDUSTRY**

In practice, zero exposure to chemical agents at work is an unattainable goal in industry and instead exposure limits are set to protect the worker. Under UK legislation the Health and Safety Executive defines a work exposure limit as the concentration that is not likely to be injurious, averaged over a reference period. These limits for many gases are long-term time-weighted average (TWA) (eight hours) and short-term exposure limit (STEL) (15 minutes) for peak exposures. STELS are typically used to protect against effects which may occur rapidly, such as irritation of the eyes or nose/throat. A worker’s sense of smell is not a reliable guide to the presence of a gas, let alone a safe level. Apart from individual variability some gases, for example hydrogen sulphide and hydrogen cyanide, actually induce olfactory fatigue at higher and more dangerous concentrations. Nevertheless, information on olfactory levels may be useful for a clinician when taking a patient’s history. Objective measures of exposure require the use of chemical sensors or infrared detectors, colorimetric detection tubes and other specialized measuring devices.

**EXPOSURE TO GASES IN THE OUTDOOR AND INDOOR AIR**

The main sources of outdoor air pollution in high economy countries are motor vehicle emissions. Primary pollutants are those released directly into the air, and include carbon monoxide and nitric oxide, as well as benzene and particulate material. Diesel engines burn an excess of air and so produce little carbon monoxide, but they do give out more nitrogen dioxide and fine particles. The main single sources of sulphur dioxide in the UK are coal-fuelled electric power stations. Secondary pollutants are those formed by chemical changes to the primary pollutants. Thus, nitrogen dioxide is produced by rapid atmospheric oxidation of nitric oxide emitted by motor vehicles, and subsequently may undergo photochemical oxidation to form ozone. Important combustion sources of gases in the home are gas cookers, which produce much higher concentrations of nitrogen dioxide inside houses compared with the ambient air, and faulty gas or paraffin heaters emitting carbon monoxide. Ambient air quality standards for pollutants set on health criteria alone are almost invariably lower than occupational exposure standards, including for gases. No standards have yet been established for indoor air.

A different concept again is the exposure to gases as pollutants of indoor air in offices and homes. No limits or guideline values have as yet been set for indoor air and in such cases where workers are being inadvertently exposed to gases in indoor or outdoor ambient air, then separate air quality criteria should be applied, not occupational exposure limits, which are inappropriate for this type of exposure. Carbon dioxide levels are sometimes used in office buildings as a surrogate measure of the rate of air exchange.

**EXPOSURE TO GASES IN MAJOR INDUSTRIAL INCIDENTS**

Major chemical disasters can be caused by large vapour or flammable gas explosions, fires and toxic releases. The accidental release of gases and chemicals during their distribution by pipeline, water, rail or road can also have severe consequences. The gases that most often feature in toxic releases from plants are chlorine, ammonia, sulphuric acid, hydrogen chloride, phosgene, hydrogen sulphide and nitrous fumes.

In modern industry, with control measures in place, the plant operative, engineer or technician is only likely to receive heavy exposure to an industrial gas through a failure in the plant or other inadvertent event. Occupational exposure limits are set for workers who receive repeated daily exposures to hazardous substances on the basis of eight-hour work days over a working lifetime and are set to protect as far as is reasonably practicable against acute and chronic effects. They are obviously not set to protect against risks of unconsciousness, incapacitation or intolerable irritation which would greatly reduce the chances of escape in an emergency arising from a chemical release or a fire.

Information on the effects in humans of a single exposure to substantially higher levels of toxic gases and vapours under these life-threatening circumstances is sparse and consists mainly of case reports almost invariably without the recording of the level or duration of the acute exposure. Yet it is following just such inadvertent incidents that the physician will be consulted for advice, as the consequences may be life-threatening or lead to concerns about
long-term respiratory or systemic health effects. Toxicity data relating to routes of exposure other than inhalation, such as contact with the skin in some gases, should be treated with caution unless it is known that the toxicokinetics and sites of action for the different routes are comparable. Knowledge of the long-term effects of single exposures, such as carcinogenicity, teratogenicity and other target organ damage, is very inadequate. Extrapolation from single exposure studies in animals to humans is also fraught with problems, such as species difference.

The ultimate harm caused by an acute high exposure to a toxic gas will depend primarily upon the concentration of gas and the period of exposure. Experimental studies suggest the following general relationship may hold for acute lethality for many gases and vapours:

\[
\text{toxic load} = \text{concentration}^n \times \text{time}
\]

where \( n \) is any number other than zero. Thus the toxicity of an inhaled irritant gas is not necessarily the product of the concentration in the inhaled air and duration of exposure, which is known as Haber’s rule, a simple relationship that applies to some gases and vapours. For hydrogen chloride \( n = 1 \), sulphur dioxide \( n = 2 \), and hydrogen sulphide \( n = 4 \). For chlorine, \( n = 2 \), and so for incidents involving exposure to chlorine lasting between 5 and 20 minutes, it is the concentration which is more important than the duration in determining the effects on health. In practice, most releases will last a short time until emergency measures at the plant bring the release under control, but the risk of death and risk of dangerous dose for chlorine, ammonia (\( n = 2 \)), hydrogen fluoride (\( n = 1 \)) and sulphur dioxide, can be calculated for different time periods and exposure conditions (Table 39.1). These irritant gases have a similar toxic mechanism acting on the respiratory tract and lungs.

Unplanned releases of gases may lead to exposure off-site in a sudden large release from a tank failure or a pressurized leak of long enough duration. For emergency planning for such an eventuality and for land use planning around a major hazard site (all part of a ‘safety case’ which has to be prepared before a plant under the Control of Industrial Major Accident Hazards (CIMAH) Regulations is allowed to operate) can be derived by using animal data (e.g. LC50 data over a known duration) to estimate the specified level of toxicity for land use planning purposes, which the Health and Safety Executive calls the LUP SLOT and defines as the concentration at which there is:

- severe distress to almost everyone on the area;
- substantial fraction of the exposed population requires medical attention;
- some people are seriously injured requiring prolonged treatment;
- highly susceptible people are possibly killed.

A similar procedure can be used to derive a toxic load equation to predict exposure conditions for any other specified level of toxicity, such as the mortality of 50 per cent of an exposed population: this is known as the Specified Level of Death Dangerous Toxic Load (SLOD DTL). For land use planning, allowance needs to be made for the proportion of the population indoors, as this will provide a level of protection compared to being outdoors.

Any assessment of the toxic impact of a release into the general population must take into account the presence

SLOD DTL, Dangerous toxic load for significant likelihood of death (mortality of 50% population); SLOT DTL, Dangerous toxic load for specified level of toxicity (land use planning value).

ERPG levels: Exposure up to 1 hour without causing in most people:
- ERPG-1, More than mild transient and reversible effects.
- ERPG-2, Irreversible effects or effects that may affect the ability to take preventive action.
- ERPG-3, Life-threatening effects.

Table 39.1 Health effects levels for the most common irritant gases
of the young, old, pregnant and individuals with pre-existing illness, particularly those who may be already suffering from acute or chronic respiratory conditions at the time of the release. Little information is available about the susceptibility of these vulnerable groups, and the toxicity data used for these planning criteria contain significant uncertainty.

The American Industrial Hygiene Association’s Emergency Response Planning Guidelines (ERPGs) are another attempt at setting community exposure limits for use in community emergency response planning for anticipating the adverse health impacts from chemical release emergencies; they are planning tools, as there is usually no time for making exposure measurements and acting upon these in an actual release. One use of such data, for example, would be to model the health consequences in a population living near a plant who would be told in an emergency to shelter inside their houses in the event of an unplanned gas release. The ERPGs are maximum airborne concentrations below which nearly all individuals could be exposed up to one hour without experiencing or developing:

- **ERPG 1.** More than mild, transient adverse health effects or without perceiving a clearly defined objectionable odour;
- **ERPG 2.** Irreversible or other serious health effects or symptoms that could impair an individual’s ability to take preventive action;
- **ERPG 3.** Life-threatening health effects.

Experience in making evacuation decisions in actual chemical emergencies is still very limited.

In accordance with the EC Seveso Directive 1982 (revised as Seveso II in 1996), the UK introduced the Control of Industrial Major Accident Hazards (CIMAH) Regulations 1984 which included a requirement for emergency planning to be undertaken for on-site and off-site air releases at plants storing or using dangerous substances in larger than the threshold quantities laid down in the regulations; these chemicals include commonly used toxic or flammable gases. The CIMAH regulations were superseded by the Control of Major Accident Hazards (COMAH) regulations in 1999, which treat risks to the environment as seriously as those to people. Chlorine is the most widely used gas for which emergency planning and land use planning to mitigate the effects of a major incident on the local population is undertaken; it is an example of a denser than air, highly corrosive gas that can cause injury to the respiratory tract ranging from irritation to incapacity or death from bronchospasm, laryngeal oedema or toxic pulmonary oedema.

Fortunately, no large-scale releases of chlorine gas have occurred in recent times, the last being in Romania in 1936 when 40 people were killed. While engineering measures directed towards successful containment of stored gases, such as chlorine, are clearly proving to be successful, small-scale releases of gases and other chemicals do inevitably occur from fixed sites or during their transportation. Thus, in the United States, one of the few countries with comprehensive reporting, chlorine remains the most common substance involved in hazardous chemical releases resulting in personal injury.

Computer models of the dispersion of chlorine and other dense gases can be applied to determine risk contours, so that the impact of a gas release on a nearby populated area can be predicted for different likely wind and weather conditions (Figure 39.1). The outer contour defines the consultation distance around major hazard sites, outside of which the risk to the population is not deemed as significant. The probability and size of preventable releases can be estimated to determine the serious but reasonably foreseeable event, such as a fracture of a liquid gas pipe or failure of a road tanker delivery coupling to a storage tank (Figure 39.2). Plotting the concentration contours for a predicted plume on to maps of the area around a plant is a useful planning guide for police, fire brigade and ambulance services, as COMAH requires on-site and off-site response plans to be prepared by emergency services as part of the consent process. Engineers can provide well-established failure rates for tanks, pipes and process functions, including human factors, which are used to quantify risks using gas dispersion modelling.

In the UK, the Buncefield explosion and fire in 2005, not long after the fatal Texas City refinery explosion in the same year, led to an important re-evaluation of the operation of COMAH and the interested reader is referred to the Major Incident Investigation Board Report for further information.

**EXPOSURE TO GASES IN FIRES**

The main threats to life in fires are toxic gases, heat and oxygen deficiency. The temperature in a room in a house fire can easily reach 500–1000°C, and as many as 400 toxic compounds can be demonstrated in the smoke. The principal toxic constituents of smoke are soot, carbon monoxide, carbon dioxide, nitrogen oxides, hydrogen cyanide, hydrogen chloride, sulphur dioxide, hydrogen fluoride, hydrogen sulphide, isocyanates, acrolein, benzene, phenol, formaldehyde and a range of chlorinated hydrocarbons. Carbon monoxide is an important factor in 50–80 per cent of all fire fatalities. The role of hydrogen cyanide is less clear, although it is formed in many fires especially those involving wool, silk, nylon and polyurethane products.

The chemistry involved in combustion reactions is extremely complex, even in the simplest example, such as the burning of a jet of natural gas or methane in oxygen or air, when numerous reactive species, including free radicals (such as OH, O and CH₃) are produced which eventually form mainly carbon dioxide, water and large particles of carbon (soot).

Figure 39.2 Chlorine storage tank in a chemical factory.
Smoke comprises a mixture of gases, liquid and solid particles which arise as combustion and pyrolysis products. Predicting the products of combustion (oxidative degeneration) and pyrolysis (thermal decomposition) of burning materials and hence determining in retrospect the effects of exposure of firemen or other victims to the constituents of a smoke plume is not straightforward. Some general principles can be considered. Materials consumed by fires contain carbon, hydrogen and oxygen as their main elements, and hence the bulk of all combustion products will consist of compounds formed from these, for example carbon monoxide and carbon dioxide. The next important elements are halogens (mostly chlorine) and nitrogen, with smaller amounts of elements such as sulphur and phosphorus. Almost all the inorganic anions are released as the irritant acid gases, hydrogen chloride and hydrogen fluoride, if fluorine is present. For the nitrogen present the products depend upon the availability of oxygen: in well-ventilated fires oxides of nitrogen are released, but in large fires in buildings, where the ventilation is poorer, a larger proportion of the nitrogen is released as hydrogen cyanide. Organic compounds may form a number of partially decomposed products, for example formaldehyde, acrolein, crotonaldehyde and possibly free radicals that add to the irritancy of the smoke. Other compounds, such as decomposition products from isocyanates, styrene and phenol, may also be important. Fires in warehouses storing chemicals will potentially release a cocktail of irritants and toxic substances which may greatly add to the hazard of the fire plume.

Polyvinyl chloride (PVC) is the most widely used plastic and fires involving large amounts of this material at storage sites and recycling installations are not uncommon and attract notoriety because they are difficult for the fire services to put out while they generate toxic plumes. At over 300°C, PVC decomposes to form hydrogen chloride and carbon monoxide together with small amounts of about 50 various hydrocarbons. About 50 per cent of the polymer’s weight comes off as hydrogen chloride, and the irritancy of the plume is added to by the presence of acrolein, ammonia, sulphur dioxide, nitrogen dioxide, aldehydes and particles. Phosgene is produced only in rare circumstances. There is now no doubt that dioxins are formed whenever chlorinated plastics are burned: in a large-scale plastics fire typically involving 500–1000 tonnes of PVC as much as 1–2 kg of dioxins could be produced.

In February 1991, during the Gulf War, about 600 naturally pressurized oil wells were set alight in Kuwait. Close to the fires the smoke rained oil drops which coated large areas of desert. The plume contained carbon dioxide, carbon monoxide, sulphur dioxide and particles, including soot. The major health concern revolved around the particle fallout that contained elemental carbon, rock/soil particles, metal oxides, silicates, vanadium, nickel and polycyclic aromatic hydrocarbons. Exposure studies and air monitoring started too late to ascertain the health risk to ground troops or the general population. Aplastic anaemia has been reported in a Gulf War veteran and a Kuwaiti child exposed to the fumes. Fortunately, the fires were extinguished by November 1991, and since then the debate on whether there were any chronic ill effects from this incident has not been resolved. In contrast, the massive unplanned explosion and fire at a large fuel storage site in Buncefield, England, which supplied London Heathrow airport, in 2005 set off a blaze and a huge plume of smoke on 11 December that traversed southern England and was blown across the English Channel to France until it was extinguished on 14 December. Analysis of the plume using a special aircraft showed that it mainly comprised harmless soot particles as the burning was very complete; fortunately the weather allowed the buoyant plume to remain aloft and no significant particulate air pollution occurred at ground level. There were 660 firefighters deployed during the burn phase, about three-quarters of whom reported inhaling smoke, but no major acute health symptoms were identified in a comprehensive occupational health surveillance programme.

Even if not directly fatal themselves, carbon monoxide and hydrogen cyanide singly or in combination may lead to the rapid incapacitation of the individual who is then unable to escape. The other toxic gases can cause acute airways and lung injury or may obscure vision through causing eye irritation. An elevated carbon dioxide level will induce hyperventilation and hyperpnoea, and increase exposure to the combustion gases. In most fires, these toxic factors are usually more important to survival than heat. However, intense fires can lead to severe burning from hot convected air or thermal radiation and in some fires direct burning from the heat of the flame can be the cause of death. Thermal injury to the airways and lungs is not as common as toxic damage, since the upper respiratory tract rapidly conducts heat away from the inspired air. Nevertheless air containing hot, respirable particles or steam can cause injury as deep as the bronchioles. Less important is oxygen depletion except in major conflagrations or in intense building fires.

Firefighters

In the past, many firefighters did not always use respiratory protection equipment, but nowadays as the equipment and training have improved, breathing apparatus and chemical suits are routinely donned at fires emitting toxic smoke (Figure 39.3). As a result, firefighters are now much less likely to be exposed to the injurious effects of smoke than in the past. However, accidental inhalation exposure may occur if the firefighters make a faulty judgement on their assessment of the fire conditions, or if the smoke plume unexpectedly blows towards unprotected firefighters, or if an immediate rescue of a victim has to be made. Skin contamination by noxious combustion products may also occur when the protective clothing is removed unless decontamination procedures are adequate.
The effects of single and repeated inhalation exposures to smoke therefore need to be considered. A fire victim will have a history of smoke exposure and the skin and clothing may be stained by smoke. The possibility of inhalation injury must be considered if there is production of carbonaceous sputum, reactive conjunctivitis and a hoarse voice. If the skin on the face and in the inside of the mouth or pharynx has been badly burned, then thermal injury to the airways and lungs should be suspected; oedema of the glottis and larynx may develop rapidly and upper airways intubation with continuous positive airways ventilation should be urgently considered. Smoke can cause a chemical tracheobronchitis, the inflammation of the airways being associated with denudation of airway epithelium, ulceration and oedema with cellular infiltration. The inflammatory changes may give rise to an increase in airways reactivity even in patients without a previous history of asthma, and despite an apparently full clinical recovery the patient may go on to develop mild airways obstruction which can persist for months. Firefighters who have received acute exposure to smoke should therefore be considered for early referral for an assessment of lung function as it may be advisable to begin early treatment with inhaled anti-inflammatory drugs.

Reports of neurological symptoms following smoke exposure are uncommon. A group of firemen heavily exposed to the fumes of toluene diisocyanate for several hours developed persistent poor memory, personality change, emotional instability or depression; however, no further incidents of a similar nature appear to have been reported. However, medical attendants should be alert to the possibility of injury to other organs as well as the lungs in fire victims, particularly as it may be impossible to confirm the identity of materials and other combustion and pyrolysis products in fires, for example at warehouses or chemical plants.

In the 1970s and 1980s, the concerns of firefighters that they were at high risk of premature death became a subject of epidemiological investigation and a greater awareness of the hazards led to an improvement in measures to protect the firefighter from smoke and toxic substances inhalation. The extensive and routine use of respiratory equipment to protect against smoke exposure is now widely adopted and so the exposure to hazardous chemicals and particulate pollution should be, in theory at least, much reduced compared with in the past. No consistent trend of ill health in firefighters has been demonstrated despite suggestions in earlier studies of a more rapid loss of lung function than expected and an increase in non-specific respiratory symptoms. The risk of cancer of the respiratory tract may be theoretically increased by respiratory irritants impairing ciliary clearance mechanisms, thereby enhancing uptake of carcinogens adsorbed on particles, or from direct exposure to inhaled carcinogenic chemicals or polycyclic aromatic hydrocarbons in smoke. Overall, the findings on cancer mortality studies in firefighters show no consistent trends.

An analysis of the deaths occurring in on-duty US firefighters in the 11 years up to 1994 (excluding the terrorist attack on September 11, 2001) found that the risk of death from coronary heart disease was substantially higher during certain emergency firefighting duties compared with non-emergency duties; one-third of the deaths from heart disease occurred while firefighting, which takes up no more than 5 per cent of the average firefighter’s time. The evidence from other studies shows that firefighters have a low risk of heart disease, so the findings starkly reflect the well-known link between psychological and physical stress with fatal heart disease.

In 2001, 344 firefighters died in the events of September 11 at the World Trade Center (WTC) in New York City. A study of the 10,116 firefighters involved found increases in acute and chronic respiratory symptoms (cough, wheeze, phlegm production) related to exposure to the WTC dust in the debris. The high alkalinity of the resuspended WTC concrete dust (pH 9.0–11.0) and the smoke which were abundant in the two days after the attack were thought to be responsible for provoking bronchial hyper-reactivity, persistent cough and increased risk of asthma. The extent of wearing respiratory protection was unclear.

**Nuclear reactor incidents**

The processing of uranium involves a variety of hazardous substances. Hydrazine, chlorine and ammonia are used in
nuclear power facilities and may be released into the atmosphere in an incident and threaten local populations. In 1985, a uranium processing plant in Gori, Georgia, released a cloud of hydrogen fluoride. A plume from a nuclear reactor incident may contain radioactive inert gases which are fission products of uranium. At Three Mile Island in 1979, very slight amounts of krypton-85 and xenon-133, together with iodine-131, were emitted following core damage to this commercial reactor. In the fire in the graphite reactor at Chernobyl in 1986, which lasted for several days, several million curies of these gases, together with radioactive iodine-131 and -133, caesium, strontium and plutonium, were released in radioactive clouds that blew across Europe, making this event the worst nuclear accident in the world.\(^{29}\) During the following eight days, the iodine-131 was absorbed by the thyroid glands of people living nearby. More than 350 000 people were relocated. Since 1990, a marked rise in cases of thyroid cancer in children has occurred in the Belarus region around Chernobyl, a condition which unfortunately has a good survival rate with early treatment.\(^{30}\)

**PRINCIPLES OF FIRST AID AND TREATMENT IN GASSING INCIDENTS**

Regardless of the kind of gas involved, the victim should be moved immediately to fresh air and given life support. If breathing has stopped or cardiac arrest has supervened then cardiopulmonary resuscitation should be begun. If hydrogen cyanide poisoning is suspected, then a manual resuscitator should be used to maintain respiration so that mouth-to-mouth resuscitation is avoided.

Simple asphyxiant gases or lack of oxygen will cause loss of consciousness without irritation of the eyes or mucous membranes of the respiratory tract, but complications may include patchy consolidation of the lungs. Unless the hypoxia is severe, the victim will recover consciousness in fresh air. If the patient is breathing and if oxygen is available, 100 per cent oxygen should be given by oronasal mask until more specific treatment can be instituted. The treatment of overexposure to anaesthetically active gases is similar. Oxygen reverses hypoxaemia and accelerates the elimination of carbon monoxide and helps to support persons poisoned by cyanide or hydrogen sulphide.

Inhalation of irritant gases and smoke gives rise to similar effects on the respiratory tract ranging from mild irritation to mucous membranes lining the airways, leading to cough and bronchospasm, to severe non-cardiogenic pulmonary oedema and respiratory failure. Sensory irritant potency depends upon the interactions between the substance and irritancy nerve receptors. Acid gases, such as the halogens and hydrogen halides, dissociate forming high concentrations of hydrogen ions that, along with the chemical nature of the reactive base, give rise to the tissue response. The irritant potency is mostly accounted for by acidity, associated with a range of properties, such as aqueous and lipid solubility, and other tissue components that may compete with receptor stimulation. Other pathophysiological mechanisms will relate to the special properties of individual gases, such as free radical formation with chlorine. The stimulation of nerve receptors in the airways triggers subjective sensations such as cough, chest tightness and breathlessness and also reflex responses that can provoke bronchoconstriction, increased mucous secretion and vascular engorgement, all of which may contribute to symptoms. These effects can be very rapid following even a single, brief exposure.

Irritant gases in high concentrations may kill the victim outright after a few deep breaths and before pulmonary oedema has had time to develop, an effect probably due to oxygen having been displaced from the air: there may be no sign of a death struggle. Exposure of the eyes or skin to corrosive gases should be treated by thorough irrigation or washing with water or sterile physiological (0.9 per cent) saline, and all contaminated clothing must be removed.

Victims of gassing accidents should be initially considered to be hypoxic. Central cyanosis (a blue colouration of the tongue and mucous membranes) is a variable clinical finding and when present is a sign of central hypoxia, although hypoxia may occur in the absence of cyanosis. Methaemoglobinemia is another cause of cyanosis and hypoxia. In poisoning by carbon monoxide and hydrogen cyanide, the skin retains its pink colour even in the presence of tissue hypoxia.

Even in the absence of clinically obvious signs of hypoxia or respiratory distress, the patient can nevertheless be severely hypoxic and may collapse on slight exertion. This was first emphasized in First World War casualties in the management of phosgene gassing on the battlefield, and which was attributed to the increased efflux of pulmonary oedema fluid during exertion.\(^{31}\) In hospital, arterial blood gases should be tested at the earliest opportunity to assess the degree of hypoxaemia (\(\text{PaO}_2\)), partial pressure of carbon dioxide (\(\text{PaCO}_2\)), and acid-base state. Hypoxaemia is treated with oxygen therapy, but in advanced respiratory failure the patient may require endotracheal intubation and mechanical ventilation. Positive end-expiratory pressure is recommended in the presence of pulmonary oedema (acute chemical pneumonitis).\(^{32}\) The possibility of laryngeal oedema causing respiratory obstruction should not be forgotten, for example after ammonia exposure, but it may also be present in fire victims if burns are present on the face and around the mouth and lips, or if soot is found in the anterior nares and larynx.

High concentration oxygen treatment (100 per cent given by a tight fitting oronasal mask or intermittent positive-pressure ventilation (IPPV) and hyperbaric oxygen in severe cases) is essential in carbon monoxide poisoning despite a normal \(\text{PaO}_2\), as the oxygen will compete with carbon monoxide for haemoglobin binding sites and reduces...
the half-life of carboxyhaemoglobin from about 320 to 80 minutes. Pulse oximetry can be misleading in carbon monoxide poisoning as it detects carboxyhaemoglobin as oxyhaemoglobin, and thus may overestimate the actual concentration of oxyhaemoglobin; erroneous readings may also arise in methaemoglobin states.\textsuperscript{33} The use of hyperbaric oxygen should be urgently considered in cases of poisoning by the chemical asphyxiant gases (carbon monoxide, hydrogen sulphide and hydrogen cyanide). Most experience of this treatment has been gained with carbon monoxide.

Skin burns from corrosive or acid gases and vapours should be treated as for chemical burns. Hydrofluoric acid burns may also need the administration of local and parental calcium antidotes. Contaminated clothes, jewellery, boots, etc., should be removed, and all affected areas should be washed or showered with water for at least ten minutes. Eye irrigation may also be needed. It is widely assumed that burns caused by corrosive gases and vapours will cause damage similar to thermal burns, for example irritation, erythema and bullae formation, but there is a dearth of hard facts on this in the literature. Certain agents, such as methyl bromide and vesicant warfare agents (e.g. mustard gas, see Chapter 41, Deliberate use of chemicals in warfare and by terrorists), are recognized as causing bullae formation, but erythematous lesions which may progress to intraepidermal or subepidermal vesicles (bullae) with sweat gland necrosis can also occur in some cases of coma caused by carbon monoxide poisoning. The mechanism of bullae formation in human skin is not understood. Bullae can occur in prolonged coma from various causes, for example in barbiturate poisoning, and could be caused by pressure, hypoxia or direct toxic effects to the tissues.

Cold injury from the accidental contact of the unprotected skin with the liquid, vapour or gas of very cold liquefied gases resembles the local effects of severe cold which are described in Chapter 49, Heat and cold, together with their treatment. The damage to the skin can be similar to heat burns, or to frostbite if exposure of unprotected parts is prolonged or severe.

The hospital management of victims of poisoning by irritant gases such as chlorine is outlined in Table 39.2. It should be noted that the treatment of the high permeability pulmonary oedema caused by irritant gases has not been well studied. In response to damage to the capillary endothelium, water accumulates in the interstitial space and then in the alveoli. The value of diuretics has not been confirmed and these should be used cautiously, if at all. Glucocorticosteroids may not be of value. Chest infection is common after severe gassing because of the denuded bronchial epithelium; vigorous antibiotic therapy is often required. The oedema fluid can have a higher protein content than in cardiogenic oedema, which may more readily coagulate and the residual coagulum then becomes the skeleton on which lung fibrosis develops.\textsuperscript{34} Convulsions caused by certain gases, e.g. methyl bromide, should be treated with anticonvulsant drugs as appropriate, although more intensive therapy may be needed if they prove resistant.

Even mild gassing incidents can induce severe anxiety if individuals suddenly experience respiratory symptoms such as acute tightening of the chest and difficulty breathing, especially if they are asthma sufferers. Further alarm can be generated if their or other lives are perceived to be at imminent risk. Health professionals called to such incidents need to be aware that affected individuals may subsequently suffer post-traumatic distress syndrome or other emotional disturbances requiring psychological support. Several of the physical conditions arising from inhalation of toxicants are described below.

### Acute lung injury and acute respiratory distress syndrome

The inhalation of irritant agents may produce a common reaction in the lungs of rapid onset referred to as high permeability pulmonary oedema, or pulmonary oedema of non-cardiogenic origin, otherwise known as chemical pneumonitis. Pathologically, there is diffuse alveolar damage.\textsuperscript{35} Mild cases recover rapidly and most without residual effects, but many authorities would nowadays regard chemical pneumonitis as belonging to the less severe end of a clinical spectrum of acute lung injury that extends to acute respiratory distress syndrome at the other. Acute respiratory distress syndrome is diagnosed in acute lung injury after inhaling a toxic fume or gas if there is acute lung injury and severe refractory hypoxaemia – using the \( \text{PaO}_2 \) to \( \text{FiO}_2 \) ratio.\textsuperscript{36}

### Bronchiolitis obliterans

This rare and life-threatening form of fixed obstructive lung disease is due to damage to the epithelium of the small airways and usually manifests itself pathologically as a proliferation of tufts or plugs of granulation tissue in the lumen of bronchioles. Diffuse alveolar damage and epithelial injury of the bronchioles may occur together after inhalation exposure to a single noxious agent leading to inflammation or fibrosis narrowing or blocking the airway. Bronchiolitis obliterans is a recognized complication in gassing accidents involving nitrogen dioxide, and sporadic cases have been reported after incidents with fire smoke, sulphur dioxide, ammonia, chlorine, hydrogen chloride, phosgene, hydrogen sulphide, hydrogen selenide and hydrogen bromide.\textsuperscript{35}

Diagnosis is made on the basis of the history, fixed airway obstruction with normal diffusing capacity, and typical findings on high resolution computed tomography (HRCT). The diagnosis is likely to be missed in the initial stages, and mistakenly identified as asthma, bronchitis, emphysema or bronchiectasis.
Reactive airways dysfunction syndrome and irritant-induced asthma

Irritant-induced asthma and vocal cord dysfunction (or irritable larynx syndrome) are conditions classified as reactive airways dysfunction syndrome (RADS) when they arise after exposure to a toxic gas. Gases reported to induce RADS following unplanned high exposure at work form a long list which includes hydrogen sulphide, nitrogen dioxide, sulphur dioxide (and sulphuric acid), ammonia, chlorine, ethylene oxide, phosgene, welding fumes and smoke. The term was coined by Brooks in 1968 to describe a syndrome of respiratory symptoms after gas or chemical exposure at work. Occupational health practitioners are quite likely to have patients referred to them at some time with suspected reactive airways dysfunction syndrome following an inadvertent exposure to an irritant substance at work, and so a detailed account of this important condition is given in Chapter 40, Reactive airways dysfunction syndrome and irritant-induced asthma.
Hypoxic brain injury

Simple asphyxiant gases will reduce the inspired oxygen concentration and cause hypoxic hypoxia, or low blood levels of oxygen. Acute, severe hypoxic hypoxia does not usually lead to brain damage or long-term neurological signs and symptoms unless accompanied by cardiac arrest, when the neurological picture resembles global ischaemia as seen after cardiac arrest from any cause.

Hydrogen cyanide and hydrogen sulphide inhibit cellular respiration and induce histotoxic hypoxia. As before, poisoning by these agents does not usually cause brain damage unless hypotension supervenes, when injury to the cerebral cortex and hippocampus may arise in a distribution resembling that seen in global ischaemia after cardiac arrest. Both gases are potent and immediate depressors of blood pressure, however, and the ‘knock down’ which occurs in sudden apnoea with hydrogen sulphide poisoning may possibly be the result of cardiac hypotension or cardiac standstill.

The action of carbon monoxide is undoubtedly more complex than either of these agents, but the mechanism is poorly understood. Focal damage to the globus pallidus and substantia nigra is more often seen in severe carbon monoxide poisoning, as is delayed neurological deterioration associated with the late destruction of white matter and demyelination. However, much the same pattern of injury may arise occasionally in patients who have suffered global ischaemia from other causes, including cyanide poisoning.38

The electroencephalogram, magnetic resonance imaging and computed tomography scans may all be normal in some patients with permanent hypoxic injury.

INVESTIGATION OF GASSING INCIDENTS

In all gassing accidents, investigations should be undertaken to determine or confirm the agent involved together with the degree of exposure whenever possible. Where biological tests for specific gases are available for verifying exposure, these are mentioned in the subsequent text. It is important that this task is done as part of the overall management of the patient and not as an afterthought. Thus, blood (5 mL EDTA (ethylenediaminetetraacetic acid)) and urine (50 mL universal container) samples should always be stored and collected at the earliest opportunity in case investigative tests are required later.

The post-mortem appearances are often non-specific. Corrosive gases will cause macroscopic injury to the airways. Pulmonary oedema, however, may be found in rapid hypoxic and anoxic deaths from any cause as well as from gassing by irritant, corrosive gases, and is due to increased capillary permeability. In asphyxiated victims, the viscera may show little change apart from congestion, oedema and petechial haemorrhages; conjunctival petechiae may also be present. Aerosol propellants, anaesthetic gases, carbon monoxide and hydrogen cyanide are volatile or unstable and may be lost from post-mortem blood.

Survivors of gassing accidents should always be followed up for the development of short- and long-term psychological and physical sequelae. Accidental exposures to gases in industry may be life-threatening and there are few follow-up studies of incidents in the literature. Pulmonary function testing should be undertaken after exposure incidents involving irritant gases, and referral for neurological and neuropsychological investigations should be considered in all patients who have experienced a severe exposure to a simple or chemical asphyxiant gas, with or without a period of unconsciousness.

GASES IN THE AMBIENT AIR

Air is a mixture of gases, the average composition of which stays remarkably constant (Table 39.3) and sustains life on Earth. This constancy is the outcome of a climate system that is fully coupled to the cycles of plate tectonics, weathering, erosion and biological activity. Fears over global warming led to the Kyoto Protocol agreement in 1997 that came into force in 2005; 187 countries have ratified the protocol, which requires industrialized nations to cut total anthropogenic emissions of the greenhouse gases carbon dioxide, methane, nitrous oxide and sulphur hexafluoride, and two groups of greenhouse gases: hydrofluorocarbons and perfluorocarbons. The Montreal Protocol (1987) required countries to phase out the manufacture of chlorofluorocarbons (CFCs) for all uses by 2010 to protect the stratospheric ozone layer that shelters Earth’s surface from harmful ultraviolet radiation. The stable CFCs synthesized by the chemical industry for use as refrigerants, propellants and solvents, eat away at the ozone; they were initially replaced by hydrochlorofluorocarbons (HCFCs) and then by the hydrofluorocarbons (HFCs), which do not. Unfortunately, HFCs are powerful greenhouse gases and are covered

by the Kyoto Protocol, as mentioned above. HFC emissions have been rising rapidly as demand for refrigerators and air conditioning grows in countries such as China. Occupational exposure to CFCs will potentially continue long after 2010 because of the continuing use of old air conditioning and fire-fighting systems that contain them.

Methyl bromide, a fumigant pesticide, is also being phased out under the Montreal Protocol.

Oxygen lack

Oxygen-deficient atmospheres can be encountered in mines and other underground or confined spaces. The main danger of suddenly entering an atmosphere devoid of oxygen is that it will lead to an almost immediate loss of consciousness without warning; even very quiet breathing will produce sudden loss of consciousness within 50 seconds when all the remaining oxygen in the lungs has gone.39

It is the partial pressure of oxygen, not its percentage, which is of physiological importance, but gas measuring instruments and alarms record volume concentrations. A drop of 3–4 per cent of oxygen by volume is of little physiological significance in humans, but it will extinguish a candle flame. (A candle flame will continue to burn at levels of atmospheric pressure well below those at which humans will be asphyxiated: it will not go out until 10 per cent of normal pressure.) The level of oxygen has to fall to 13 per cent volume (equivalent to a 33 per cent asphyxiant gas in air mixture) before symptoms become very noticeable.

The effects of low oxygen concentration (oxygen (per cent vol. in air)) are as follows:

- 16–13 per cent: Dizziness and shortness of breath on exertion; pulse rate accelerated and volume of breathing increased. Ability to maintain attention is diminished but it can be restored with conscious mental effort.
- 10–6 per cent: Nausea and vomiting. Loss of ability to perform any vigorous muscular movements or even to move at all.
- <6 per cent: Loss of consciousness with fainting or coma. Rapidly fatal.

Oxygen excess

Industrial and medical oxygen supplies can enrich atmospheres in a room to dangerous levels. At 25 per cent oxygen in air, even damp vegetation will continue to burn once a fire has started, and substances which do not normally burn easily in air may burn vigorously. Lubricants must never be used on oxygen equipment as they may react explosively with pressurized oxygen. Even in the open air, oxygen may remain trapped in clothing which can then be readily ignited and cause severe burns. Oxygen and other compressed gases should only be used in well-ventilated areas.

Anaerobic fermentation

Natural biological processes produce toxic gases in the absence of oxygen. In anaerobic fermentation, bacteria that are methanogens or sulphate reducers remove hydrogen ions in the form of methane or hydrogen sulphide, respectively. Excessive or abnormal colonic gas production has been hypothesized to play a role in the pathogenesis of irritable bowel syndrome40 and inflammatory bowel disease.41

About a litre of human flatus is produced a day and typically contains nitrogen (68 per cent), oxygen (less than 1 per cent), carbon dioxide (9 per cent), hydrogen (16 per cent) and methane (6 per cent), while the malodorous gases (ammonia, skatole, hydrogen sulphide) comprise less than 1 per cent of the total. In contrast, the rumen of animal species such as the cow, sheep, goat and deer contain mostly methanogenic bacteria.

Fermentation of human or animal excrement releases toxic gases which can be a threat to sewer workers or workers in confined spaces on farms and in swine confinement buildings, among others (Figure 39.4). Farm animal-house air can be contaminated by ammonia, hydrogen sulphide and carbon dioxide. The mixing or pumping of slurry, for example in cowsheds, can release lethal amounts of hydrogen sulphide into enclosed spaces.

Anaerobic fermentation of sheep intestines and their contents can cause hydrogen sulphide keratoconjunctivitis in sausage makers, the same condition that Ramazzini recorded in workers who emptied ‘jakes’ (privy vaults). 'Sewer gas’ is methane with small amounts of hydrogen sulphide and it also occurs in septic tanks and cesspits. JS Haldane investigated a fatal incident in a sewer in East Ham, London in 1895 and proved the deaths had been caused by hydrogen sulphide gas; he had shown earlier using bacteriological experiments that sewer gas or ‘miasma’ was not a cause of typhoid.42 The smell of putrefaction had a long history of being associated with disease and being known as ‘miasma’ or bad air, and it was a central tenet of Edwin Chadwick and other nineteenth century sanitarians. At the time of his epidemiological investigations into cholera, the celebrated pioneer of anaesthesia in England, John Snow (1813–58), used his knowledge of gases and the properties of air to support the overthrow of this ancient belief. In doing so, he used statistics from the registrar general to show that male workers in the ‘offensive trades’, i.e. malodorous ones involving animal remains, such as rendering and bone boiling, had lower mortality rates than the male general population.43

Gases from decaying fish can be a hazard to workers unloading catch from poorly refrigerated and unventilated holds. Decay of organic matter generally provides hydrogen sulphide, ammonia, methane and carbon dioxide; levels of
carbon monoxide in air can sometimes also be dangerously elevated in manure storage areas. Bacterial action on nitrogenous compounds may form nitrogen dioxide, and fermentation of silage can produce high concentrations of this gas within two days of silo filling. Carbon dioxide and methane concentrations, if elevated, depress oxygen levels, or oxygen may be depleted anyway. Following gassing accidents in confined spaces, it is important to measure as soon as possible for oxygen depletion and elevated levels of carbon dioxide, as well as the full range of gases mentioned above, to determine what was responsible for the incident.

A condition occasionally, but not exclusively, reported in hog farmers is organic dust toxic syndrome, which may present as an acute systemic illness characterized by fever, malaise, aches and pains in the limbs, vomiting and a dry cough. The onset is within a few hours of heavy exposure to endotoxin-producing Gram-negative bacteria, as may occur in swine confinement buildings. The condition, which resolves completely within 72 hours, should not be confused with the toxic effects of gases produced by fermentation. Pig farming exposes workers to a mixture of ammonia, organic dusts and high levels of endotoxins, and the types of disinfectants in regular use can contain respiratory sensitizers.44

**Confined spaces**

Confined spaces include trenches, pits, tanks, sewers, tunnels and also submarines and spacecraft. Working in enclosed spaces with inadequate natural ventilation is a well-known cause of death from asphyxia due to oxygen deficiency or from a build up of toxic gases and vapours, such as carbon dioxide, carbon monoxide, methane, ammonia, hydrogen sulphide, petroleum vapour and liquid petroleum gas. Toxic substances can accumulate where workers are welding or flame-cutting. In addition, the presence of flammable gases such as butane, propane and petrol, all of which are normally heavier than air, can be responsible for explosions in tanks. The risk of fire and explosion may be increased by enrichment of the air by oxygen in the event of a leak from an oxygen cylinder forming part of welding equipment. A fatal explosion occurred in 2007 in a compartment of a British nuclear submarine beneath the Arctic ice when an oxygen generator canister exploded after becoming contaminated with grease.

Oxygen deficiency in pits can arise from an ingress of methane or absorption of oxygen by certain constituents of soils. The rotting of vegetation and the rusting of metalwork inside tanks also consume oxygen. Manholes, tunnels and trenches in limestone soils can partly fill with carbon dioxide formed by the action of acid groundwater. Apparently safe atmospheres can become suddenly dangerous if the residues and sludges in tanks or in sewers are disturbed by the worker walking in them, or by water surges following sudden heavy rainfall. Underground spaces may be in ground which is contaminated or near old refuse tips, or they may be connected to sewers. In the construction industry, pipe-freezing work is carried out using liquid nitrogen to solidify soil to enable drilling to be performed in wet conditions and fatalities have occurred from the cold gas pushing out the available air.

In order to avoid gassing accidents, safe systems of work must be adhered to and these often require the use of electronic monitors or detector tubes to test for toxic, flammable and asphyxiating gases before initial entry to a confined space and while the work continues. The space should be well ventilated before entry, otherwise appropriate breathing apparatus has to be worn. In the UK, safe working practices are followed under the Confined Spaces Regulations (1997).45

There is no formal medical examination laid down for workers in confined spaces in the UK, but the competent person who carries out the risk assessment under the Regulations will need to consider the physical suitability of the individuals involved and to check that they are of suitable build. Medical advice on an individual’s suitability may be needed. A history of claustrophobia, fits, blackouts
and fainting attacks would be reasons for exclusion, as are chronic respiratory problems such as asthma, bronchitis or exertional dyspnoea, and other evidence of lack of fitness to wear breathing apparatus. The presence of heart disease or severe hypertension might also be a contraindication. Physical limitations, such as deafness, lack of a sense of smell, visual defects, and problems with balance (e.g. Menière’s disease) should also be considered. Prospective workers with limited mobility from back or joint trouble, certain physical handicaps or psychiatric problems may also be unsuitable.

Routine sewer work is normally safe as long as standard measures to detect toxic and flammable gases and oxygen-deficient atmospheres are performed. However, the possibility of unusually toxic substances entering sewage systems must always be borne in mind.

In an unusual incident in Aberdeen, Scotland, a group of 26 workers went down a sewer to investigate an unusual smell, and 14 became unwell. The symptoms, which included cough, chest discomfort, breathlessness and fatigue, developed over several days. The more severely affected also complained of thirst, sweating, irritability and loss of libido. Five workers with persistent symptoms were investigated and in one a desmopressin test was abnormal and he was diagnosed as suffering from cranial diabetes insipidus; other endocrine organ tests included thyroid function, follicular stimulating hormone, luteinizing hormone, prolactin and testosterone which were all normal. The causal agent and its possible source were not identified, but the coincidence of autonomic symptoms and diabetes insipidus suggested that the gas exposure was responsible. Organic sulphur compounds with intense odours, such as dimethyldisulphide, were also considered.

Watt et al.46

This episode shows the importance of all workers donning full positive-pressure breathing apparatus when investigating unusual problems in sewers.

Mines

‘Black damp’ was the name given to the residual gas encountered in mines where the oxygen has been removed by natural chemical oxidative processes such as in the oxidation of coal, timber and iron sulphide.47 It typically contains 12–15 per cent carbon dioxide but can be higher, with the rest of the gas as nitrogen. ‘Fire damp’ is methane which is present under pressure in coal seams and may be given off with carbon dioxide and nitrogen accompanied by audible hissing noises during mining. The main hazard is explosion. The introduction of a form of safety lamp by Sir Humphrey Davy in 1812 was a sensation, making the inventor internationally celebrated, as it markedly reduced the risk of catastrophic explosions in mines. The flame of the lamp is surrounded by a fine metal gauze that offers little resistance to gases, but which leads heat away from them so effectively that the flame cannot cross it. The oil flame gave warning of the presence of fire damp (1–4 per cent methane makes the flame burn taller, so the concentration of methane can be estimated from its height) and is also extinguished before the oxygen levels fall to dangerous levels. After an explosion of methane and coal dust, the mixture of gases produced in the mine is called ‘afterdamp’: it can contain toxic levels of carbon monoxide, responsible for the deaths of miners and rescuers in numerous mining disasters. JS Haldane showed that odourless carbon monoxide was the main cause of death in explosions of methane and coal dust and it was due to his advocacy that it became a legal requirement for canaries to be kept at all coal mines to give warning of the presence of carbon monoxide, which would otherwise not be detectable using the safety lamp alone.42,47

PROPERTIES AND EFFECTS OF INDUSTRIAL GASES

Simple asphyxiating gases

METHANE (CH₄)

[CAS No. 74-82-8]
Relative density: 0.56
Flammability in air: 5.0–15.4 per cent (vol.)

Methane is a colourless flammable gas with a non-detectable or a sickly sweet oily odour which is normally too faint to provide warning of its presence. The main global sources of methane are rice paddies and wetlands from the anaerobic fermentation of organic material, but it is released from coal mining, biomass burning, the leakage of natural gas from the earth, as well as pipelines and well-heads, landfills and enteric fermentation in mammals (mainly ruminants). Total global emissions of methane are about 500 million tonnes a year, two-thirds of which come from anthropogenic sources. It is second only to carbon dioxide as a cause of global warming. Natural gas contains methane as a major constituent combined with significant amounts of ethane, propane and butane, together with diethyl sulphide as a deodorant. Some natural gas sources contain substantial amounts of mercury, which can be an occupational hazard.48 Coal gas, which it replaced as a fuel, contains methane together with hydrogen and a little carbon monoxide and ethylene plus small amounts of carbon dioxide, nitrogen, oxygen, ammonia and hydrogen sulphide. Marsh gas is mostly methane with a little hydrogen, carbon dioxide and nitrogen. It has been widely believed that marsh gas can undergo a spontaneous combustion, producing a pale, ghostly light (Will o’ the Wisp or Jack o’ Lantern), but another fermentation product is likely to be responsible.
One minute it darted like a kingfisher, and the next it entirely disappeared. At times it grew as big as an ox’s head, and then straightaway shrunk to a cat’s eye ... finally ... it returned to frisk in the reeds.

George Sand 1848-49

Mixtures of methane and air do not ignite spontaneously, otherwise flames would be seen around the tails of cows. Methane burns with a hot, yellowish flame and not cold, bluish-white. Fermentation may also produce traces of phosphine, PH₃, but this does not ignite spontaneously in air either, although it commonly contains an impurity, phosphoretted hydrogen, P₂H₄, which does.

As methane is much lighter than air it does not form an explosion hazard in the open as it readily disperses, but the gas can accumulate as an upper layer in the air of poorly ventilated spaces where it may cause asphyxia by displacing oxygen or, at much lower concentrations, become an explosive risk if ignited by a flame or spark. Methane blasts in coal mines are not uncommon tragedies in Russia and China due to safety breaches: in 2007 at the Ulanovskaya mine in Russia 110 miners died in the worst mining accident in 60 years, followed by 38 deaths in a blast later that year in the same region. A major incident involving methane took place at Abbeystead, England, in 1984 when 34 local residents and eight employees were visiting the valve house at the local water pumping station. The pipe system had been drained down and, unknown to the engineers, methane gas from the surrounding methane-rich soils had permeated the pipes. When the pumping began, the methane entered the atmosphere of the valve house and exploded, killing 16 people. Carboniferous geological strata are methane rich and soil emissions may increase with rapid falls in atmospheric pressure. The air near the ground in oil-rich regions may contain as much as 1 per cent methane.

Another important methane mixture is landfill gas produced by putrefaction of municipal and other wastes buried in an excavation and covered with clay and topsoil. Huge amounts of landfill gas may be generated containing typically a methane/carbon dioxide mixture in the ratio 60:40. Volatile organic compounds may also enter and add to the toxicity of the gas. The gas can migrate long distances through the ground and cause a hazard to workers by flooding into trenches. Nearby residential areas may be at risk from soil gas. To help avoid these hazards, special vents are incorporated into landfill sites to provide adequate escape for the copious amounts of gas produced (Figure 39.5).

CARBON DIOXIDE (CO₂)

[CAS No. 124-38-9]

Exposure limits:

LTEL (8 h TWA) 5000 ppm or 0.5 per cent (9000 mg/m³)

STEL (10 min) 15 000 ppm or 1.5 per cent (27 000 mg/m³)

Relative density: 1.53

Joseph Priestley was the first to establish the biological properties of this gas and in 1772 came upon the art of manufacturing carbonated water, which was made popular by Joseph Schweppes who started a business in Bristol in 1794. The dangers of carbon dioxide were, however, known to wine producers in Roman times, if not earlier. Today, carbon dioxide is encountered in numerous ways, for example as a refrigerant, in fire extinguishers, arc welding, breweries and wineries, flue gases, fermentation processes which deplete oxygen (including in unventilated mines, wells, tunnels) and in the manufacture and use of dry ice. It is often regarded as a simple asphyxiant, yet it has been known since the turn of the last century that it has a toxic action which is independent of oxygen deficiency. The toxic

Figure 39.5 Methane outlet on a municipal waste landfill site. Note the proximity of local housing (hazard of soil seepage of gas).
properties of carbon dioxide were demonstrated on a large scale in the disaster at Lake Nyos, Cameroon, in 1986, where over 1700 people were killed when as much as a quarter of a million tonnes of carbon dioxide held in the depths of the lake under hydrostatic pressure were suddenly released and flowed down into the nearby valleys (Figure 39.6). The water was saturated with dissolved gas ready for some modest disturbance to trigger its rapid rise to the surface and exsolution. The sparse medical findings and the accounts of survivors strongly suggested that the carbon dioxide had mixed with air to give rise to prolonged states of coma due to carbon dioxide narcosis in many of the victims. Skin bullae were another unusual finding. This unprecedented massive release contrasts with incidents in industry when isolated deaths from carbon dioxide are normally attributed to oxygen lack or simple asphyxia, and there are no characteristic findings on autopsy.

Carbon dioxide is dangerous because it is colourless and odourless, but when breathed from an anaesthetic machine it has a faintly acid smell. The effects of breathing the gas are very characteristic. A 2–3 per cent carbon dioxide level in air will pass unnoticed at rest, but tidal volume is increased by 30 per cent and the minute volume by 5 per cent; on exertion there may be marked shortness of breath. At 3 per cent carbon dioxide in air, breathing becomes noticeably deeper and more frequent at rest, with the effect becoming more marked until at 5 per cent carbon dioxide in air there is severe dyspnoea, which limits exposure for most people. Subjects complain of headache and are sweaty and have a bounding pulse. At 10 per cent carbon dioxide in air, respiratory distress develops rapidly with loss of consciousness in 10–15 minutes, even though the oxygen concentration is reduced to 19 per cent only. Exposures to carbon dioxide levels above 15 per cent are intolerable, and rapid loss of consciousness ensues after a few breaths of a mixture of 30 per cent carbon dioxide in air. Even at this level, the oxygen concentration is 15 per cent, not enough to cause loss of consciousness from hypoxia, but death will occur if the carbon dioxide level is maintained. Thus, it is important to note that monitoring oxygen in air is an inadequate guide to the carbon dioxide hazard; carbon dioxide should be directly measured. A working or living area should be immediately evacuated when concentrations exceed 1.5 per cent by volume (the occupational short-term exposure limit value). Experimental studies show that carbon dioxide exerts a narcotic action at the higher concentrations through a disturbance of acid-base balance resulting in a fall in pH of arterial blood and the cerebrospinal fluid.

Industrial carbon dioxide poisoning is a rare occurrence. Survival after severe intoxication by carbon dioxide has been described (in a patient in Bristol in 1972):

A 34-year-old male worker was overcome by an accidental release of the gas from a fire extinguishing system, filling the room 'like a cold, thick fog.' There were two others present, one died and the other managed to rescue the patient and save himself. The patient was given artificial respiration, but breathed by himself within a very short time whilst remaining deeply unconscious. On admission to hospital within 15–20 minutes of the accident he was still deeply unconscious, but was maintaining a free airway. He had a respiratory rate of 24 per minute, but was grossly hypopnoeic, flushed and markedly vasodilated. He was normotensive, with a heart rate of 120 per minute, and his chest was clear. He became rousable after 35 minutes in the hospital whilst being treated with oxygen through an MC mask. Soon he was rational, and complained of headache and feeling stiff all over. He developed pre-renal uraemia, which spontaneously resolved over several days, and he was eventually discharged well.
Soil gas emissions in volcanic and geothermal areas can be a silent hazard to workers. In Mammoth Mountain, California, a popular ski resort, park rangers have been overcome due to an unsuspected increase in gas flow associated with volcanic unrest. In the largest island of the Azores, San Miguel, the town of Furnas is built in an active caldera where soil gas emissions have overwhelmed workers digging roads. The phenomenon is not new, with Loudon reporting in 1832 on the famous ‘Valley of Death’ in Java which contained the skeletal remains of many wild animals and birds that had strayed into the layer of carbon dioxide floating above the ground. Drilling boreholes in certain urban areas in Italy associated with old volcanism has triggered hazardous gas blowouts that need to be capped, placing emergency workers and other people at risk.

The danger of entering an enclosed space containing carbon dioxide is illustrated by the concentration gradient of the gas in wells on Vulcano, Sicily, a volcanic island with areas which have strong ground emissions of carbon dioxide (Figure 39.7). The breathing zone of a worker entering such a well by ladder will be at a narcotic level of carbon dioxide floating above the ground. Drilling boreholes in certain urban areas in Italy associated with old volcanism has triggered hazardous gas blowouts that need to be capped, placing emergency workers and other people at risk.

The danger of entering an enclosed space containing carbon dioxide is illustrated by the concentration gradient of the gas in wells on Vulcano, Sicily, a volcanic island with areas which have strong ground emissions of carbon dioxide (Figure 39.7). The breathing zone of a worker entering such a well by ladder will be at a narcotic level of carbon dioxide floating above the ground. The worker would lose consciousness after a few breaths and fall to the bottom of the well. The carbon dioxide gradient is so steep that there would be no opportunity for the worker to become aware himself that he was hyperventilating before consciousness was lost. Spaces where carbon dioxide may build up can therefore be much more dangerous than is commonly supposed because of diffusion of the gas. It has been known from ancient times (in wine production) that the flame of a candle can be used to give adequate warning of the presence of lethal levels of carbon dioxide. A vertically held lit candle or oil lamp is normally extinguished when the oxygen level falls to 17.6 per cent in the presence of nitrogen, but carbon dioxide has a stronger effect, causing the flame to be extinguished at 18.8–18.9 per cent (or 8–10 per cent carbon dioxide).

Carbon dioxide levels can be used to measure the quality of indoor air. At a ventilation rate of 4.6 m³/min per person the carbon dioxide level in an office would be expected to be approximately 800–1000 ppm in the absence of unvented combustion sources. Higher levels of carbon dioxide would indicate the need to increase ventilation to improve the outdoor air supply.

**ARGON A (A OR Ar)**

[CAS No. 7440-37-1]  
*Relative density:* 1.4

Argon is the most abundant ‘rare’ gas in the atmosphere and, together with helium and neon, makes up nearly 1 per cent of air: all three gases are of inorganic origin. Argon is inactive, colourless and odourless. It is used in the control of high technology refining and semiconductor processes. It is also used in lamps, as a shielding gas in welding, and in many gas-filled devices.

**HELIUM (He)**

[CAS No. 7440-59-7]  
*Relative density:* 0.14

Helium is colourless, inert, non-flammable and very light. It is found with natural gas deposits in the United States and Poland. Extraction from air is not commercially viable. It is used as a shielding gas in welding, in electric lighting tubes, as a substitute for nitrogen in diving gas mixtures and as a balloon gas.
HYDROGEN (H₂)

[CAS No. 1333-74-0]

Deuterium D₂ or ²H₂

Relative density: (H₂) 0.07

Hydrogen is very light, colourless and flammable. It is used for hydrogenation of fats and in chemical synthesis. Deuterium is a heavier stable isotope of hydrogen and is used as a tracer. Hydrogen burns with a bluish, non-luminous flame.

KRYPTON (Kr)

[CAS No. 7439-90-9]

Relative density: 2.9

Krypton is a rare gas present in the atmosphere at about 1 ppm. It is colourless, non-flammable and has applications in electrical equipment. Its radioactive isotope ⁸⁵Kr is used in respiratory and cardiac studies.

NEON (Ne)

[CAS No. 7440-01-9]

Relative density: 0.7

Neon is a rare gas present in the atmosphere at about 18 ppm. It is colourless and non-flammable, used in fluorescent tubes, and as a cryogenic refrigerant.

XENON (Xe)

[CAS No. 7440-63-3]

Relative density: 4.5

Xenon is a rare gas present in the atmosphere at about 0.086 ppm. It is colourless, non-flammable and is used for specialized lighting.

NITROGEN (N₂)

[CAS No. 7727-37-9]

Relative density: 0.97

Nitrogen is the major constituent of air, comprising about 78 per cent by volume. It is very widely used as an inerting agent and in freezing processes of many varieties including food, earth freezing in civil engineering projects and metal shrinkage in machinery manufacture. Because the uses are ubiquitous, nitrogen is not infrequently implicated in anoxic deaths or incidents. Under increased pressure, it induces narcosis.

Liquid nitrogen and argon are commonly stored in cylinders in laboratory areas, and may have to be transported in the confined space of a lift. One litre of liquid nitrogen will form ~700 litres of gas at room temperature.

A sudden loss of nitrogen into an unventilated area could rapidly lead to an oxygen-depleted atmosphere and the worst scenario would be if the full contents of a vessel are released to atmosphere over a short period of time: the hazard can be determined using an oxygen depletion calculator or by a simple calculation, described below.

Calculate the worst scenario on the basis that the full contents of the vessel are released to atmosphere over a short period of time:

\[
\% O₂ = \frac{100 \times V_o}{V_f}
\]

where for argon and nitrogen

\[
V_o = 0.2095 (V_f - V_g)
\]

and for oxygen

\[
V_o = 0.2095 (V_f - V_g) + V_g
\]

\[
V_g = \text{maximum gas release which is the liquid volume capacity of the vessel } V \times \text{gas expansion}
\]

\[
V_f = \text{room volume}
\]

Gas expansion being for

nitrogen 682.7
oxygen 842.1
argon 823.8

An example of such a calculation is:

LC 200 containing 200 liquid litres of nitrogen in a room 20 m × 20 m × 3 m

\[
V_f = 20 \times 20 \times 3 = 1200 \text{ cubic metres}
\]

\[
V_g = 200 \text{ litres} \times 682.7 = 136 540 \text{ litres}
\]

\[
= 136.5 \text{ cubic metres}
\]

\[
V_o = 0.2095 (1200 - 136.5) = 222.80
\]

\[
\% O₂ = \frac{100 \times 222.8}{1200} = 18.6\%
\]

If the calculation suggests an oxygen content in the atmosphere lower than 18 per cent, then either

- site the vessel outside the building and pipe gas to the point of use; or
- pipe the pressure release valve and bursting disc to vent gas outside the building; and/or
- fit a permanent oxygen monitor;
- ensure personnel use/wear personal monitors;
- fit a forced ventilation system triggered by the permanent oxygen monitor.

Source: British Compressed Gas Association, guidance note GN11
Chemical asphyxiant gases

CARBON MONOXIDE (CO)

[CAS No. 630-08-0]

Exposure limits:
- LTEL (8 h TWA) 30 ppm (35 mg/m³)
- STEL (15 min) 200 ppm (232 mg/m³)

Relative density: 0.97
Flammability range: 12.5–74.2 per cent (vol.)

Carbon monoxide is a colourless, odourless, non-irritating gas which is slightly soluble in water and burns in air with a bright blue flame. It is the most widely encountered toxic gas in industry and the general environment, commonly as the result of incomplete combustion of fossil fuels. Although Ramazzini (1633–1714) remarked on the danger of gases from burning coal and Harmant in France gave the first clinical description of coal gas poisoning in 1775, it was Leblanc in 1842 who identified carbon monoxide as the toxic agent. The potential for dangerous exposures to carbon monoxide arises in metal production in iron foundries, steel works and electrical arc furnaces; in the chemical industry, in the manufacture of methanol, the catalytic cracking of hydrocarbons, around gas generating and purification plant, and in the synthesis of carbon black. Vehicle exhausts may pose hazards from carbon monoxide to workers in roll-on/roll-off vehicles, as well as in multi-storey car parks and enclosed garages.

Typical carbon monoxide concentrations in gas mixtures are: blast furnace gas 20–25 per cent; coal and coke oven gas 7–16 per cent; petrol or LPG (liquid petroleum gas) engine exhaust gas 1–10 per cent; and diesel engine exhaust gas 0.1–0.5 per cent. Water gas is formed by passing steam through a bed of white-hot coke and consists of carbon monoxide and hydrogen. A mixture of carbon monoxide and nitrogen, known as producer gas, is used to fire metal-making furnaces and is produced by passing air over hot coke.

Potentially dangerous sources of carbon monoxide in homes and workplaces are faulty heaters that produce excessive fumes or burn in a restricted air supply, whether using natural gas, propane, butane, coal, coke or wood. Reducing ventilation in buildings in the winter to conserve heat may unwittingly elevate carbon monoxide levels in the indoor air to hazardous levels. Carbon monoxide from faulty gas appliances kills nearly 30 people in the UK every year, and at least 100 are known to suffer ill health from this cause. The elderly and the very young are most at risk. In the United States, approximately 600 accidental deaths due to carbon monoxide poisoning are reported each year, while the number of intentional carbon monoxide-related deaths is between five and ten times higher. The use of catalytic converters in car exhausts has reduced carbon monoxide emissions, making suicide more difficult by inhaling exhaust gases in an enclosed space; death may in certain circumstances be more likely due to carbon dioxide instead.

Propane-fuelled equipment is commonly believed to be safe, but hazardous emissions of carbon monoxide have been reported in indoor environments with the use of ice resurfacing machines and in forklift trucks with poorly adjusted carburettors. Carbon monoxide is a chemical asphyxiant because it combines with haemoglobin with an affinity some 250 times that of oxygen to form carboxyhaemoglobin (COHb). Carbon monoxide also increases the oxygen affinity of haemoglobin and causes the oxygen dissociation curve to shift to the left by impeding the release of oxygen to the tissues. With 50 per cent saturation of the blood with COHb the oxygen pressure must fall to less than half the usual value in order to dissociate half the oxygen present. The clinical manifestations of poisoning and tissue hypoxia are known to be greater than can be accounted for by loss of the oxygen-carrying capacity of the blood alone. Experimental studies suggest that carbon monoxide exerts a direct action by combining with other haem-containing proteins in cells such as cytochrome oxidase, myoglobin and cytochrome P450. The interaction with cytochrome oxidase may result in mitochondrial dysfunction and a prolonged impairment of oxidative metabolism. An alternative hypothesis is that carbon monoxide damages mitochondria by provoking the release of free nitric oxide. Central nervous system injury may also be due to reoxygenation injury as a result of the production of partially reduced oxygen species, which in turn can oxidize essential proteins and nucleic acids, and induce brain lipid peroxidation.

Normal metabolism produces some endogenous carbon monoxide and the normal COHb concentration is less than 1 per cent. Tobacco smoke contains carbon monoxide and it is the most common cause of an elevated blood COHb. Cigarette smokers on average have a COHb level of 5–6 per cent and heavy smokers can have levels in excess of 10 per cent. Typically urban non-smokers will have levels of 1–2 per cent COHb. A level greater than 5 per cent in non-smokers and 10 per cent in most smokers suggests a source of carbon monoxide in the inhaled air. Levels in excess of 10 per cent can sometimes be found in groups such as drivers, firefighters, garage employees and dock workers, especially if they are smokers.

The proportions of COHb and oxyhaemoglobin in blood depend upon the partial pressure of carbon monoxide and oxygen. Several empirical equations have been proposed for estimating per cent COHb at different levels of exposure to carbon monoxide in combination with sedentary, light or heavy work and which take into account the duration of exposure, pulmonary ventilation and the COHb present before inhalation of contaminated air. The relation is not necessarily a simple one and therefore exposure should be assessed measuring both COHb and the levels of carbon monoxide in the air, but the
following formula first proposed by Forbes and others\textsuperscript{59}
may be used:

\[
\% \text{ COHb} = k \times \% \text{ CO in air} \times \text{minutes of exposure}
\]

The constant \( k \) is 3 for an individual at rest, 5 for light activity, 8 for light work, and 11 for heavy work. More refined formulae, such as Coburn–Forster–Kane equations,\textsuperscript{60} are also available. Figure 39.8 can be used to predict COHb in an individual with a continuing exposure to a specified concentration of carbon monoxide at different levels of exertion.

Performance of light-to-moderate work (up to 70 per cent of maximum aerobic capacity) is not affected at low levels of carbon monoxide, that is COHb levels of 4–6 per cent, but short-term maximal exercise duration is reduced in young healthy men. The effect is small and is only likely to be of concern for competing athletes. Subtle impairment of mental functioning has been reported in volunteers when COHb levels exceed about 5 per cent. These changes include impairment of memory, learning ability, attention span, coordination and abstract thinking.\textsuperscript{58}

A less well-known hazard arises from the use of methylene chloride (dichloromethane), a widely used solvent and a main ingredient of commonly used removers of paint and varnish from wood. Dichloromethane is readily absorbed through skin contact and in the lungs as a vapour and is metabolized in the liver. Carbon monoxide is an important metabolite of dichloromethane and forms COHb: peak levels can occur within three hours of exposure associated with elevated alveolar carbon monoxide levels, and there is a return to pre-exposure levels in 24–48 hours after the exposure has ceased.\textsuperscript{61} Approximately 5 per cent COHb saturation is obtained following exposure of non-smokers to 200 ppm dichloromethane for four to eight hours. High exposure to this solvent by inhalation as a result of stripping paint in an inadequately ventilated working area for two to three hours may result in levels of COHb high enough to precipitate angina or myocardial infarction in workers with pre-existing cardiovascular disease.\textsuperscript{62}

**Clinical features of carbon monoxide poisoning**

**Acute poisoning**

Exposure to carbon monoxide resulting in levels of 10–30 per cent COHb may produce throbhing headaches and mild exertional dyspnoea. At 30–50 per cent, additional symptoms include dizziness, nausea, weakness and collapse. Acute heavy exposures may result in loss of consciousness without warning, followed by coma, convulsions and death. Fatal levels of COHb in healthy people are usually in excess of 50 per cent; anaemia predisposes to carbon monoxide poisoning. The classic cherry pink colour of the skin is a rare sign, and if present suggests a carboxyhaemoglobin level over 20 per cent, but venous blood frequently looks arterial. Carboxyhaemoglobin levels in heparinized blood samples are measured by dedicated co-oximeters or by spectrophotometry by second derivative.\textsuperscript{63} In post-mortem blood, gas chromatographic analysis is the preferred method because of the breakdown of haemoglobin.

There is no diagnostic symptom complex for carbon monoxide poisoning and the diagnosis can be easily missed. The clinical presentation can vary widely, with vomiting, headaches, malaise, weakness, fatigue, chest pain, palpitations and dyspnoea. It is as well to know that the signs and symptoms of non-lethal exposure may mimic those of a non-specific viral illness.\textsuperscript{64} While blood carboxyhaemoglobin concentrations are diagnostic, the levels are not a good guide to prognosis and the clinical condition is more important, especially if the patient is or has been

![Figure 39.8 Uptake of carbon monoxide by blood. Adapted from Ref. 72, with permission.](image-url)
unconscious. This is because tissue hypoxia through unmeasured tissue uptake of carbon monoxide is the primary insult and it correlates poorly with carboxyhaemoglobin levels. Without adequate treatment, 10–30 per cent of severely poisoned patients may develop late neuropsychiatric manifestations 3–240 days after exposure. The prevention of this adverse outcome is the main reason for advocating aggressive early treatment.

The half-life of COHb is normally about four hours (longer if induced by methylene chloride exposure), but without treatment coma can last for 24 hours or longer. The relatively short half-life of COHb means that by the time the patient is seen, measurement of COHb may not be a good guide to the initial exposure. Therapy is directed towards reducing the half-life of COHb which falls to 80 minutes when the patient is given 100 per cent oxygen at sea level. Most authorities now advocate giving hyperbaric oxygen where there is access to a hyperbaric chamber. Hyperbaric oxygen at 2.5 atmospheres (252 kPa) reduces the half-life to 20 minutes and increases the amount of oxygen dissolved in the blood to a concentration sufficient to meet the needs of the body even without functioning haemoglobin.

Hyperbaric oxygen should be considered for pregnant women and for patients who have evidence of:

- a period of unconsciousness;
- neurological or psychiatric symptoms;
- cardiac complications;
- carboxyhaemoglobin levels above 40 per cent.

Neuropsychiatric damage can be immediate or a clear period of several days may be followed by the development of neuropsychiatric symptoms within the next two to three weeks or longer. Carbon monoxide has a predilection for the ‘watershed’ areas of the brain where there is a meagre blood supply: the basal ganglia, with their high oxygen consumption, are most often affected. Other commonly affected areas are the cerebral white matter, hippocampus and cerebellum.

Neurological manifestations such as vegetative state, akinetic mutism, parkinsonism, agnosia, visual impairment, and amnestic-confabulatory states have all been described. The patient can develop changes in personality typified by increased irritability, verbal aggressiveness, violence, impulsiveness and moodiness. Up to 40 per cent of patients develop memory impairment, and 33 per cent can suffer late deterioration of personality. Depression and suicidal tendencies are also reported. Although many patients improve after some months, a proportion will be found not to have improved three years later. The syndrome of delayed neurological sequelae is more characteristic of carbon monoxide poisoning than other types of anoxia, and the cause remains speculative, but it seems likely that carbon monoxide has a specific cytotoxic action. Bilateral necrosis of the globus pallidus is common, and lesions may also be found in the basal ganglia, hippocampus and white matter on computerized axial tomography or magnetic resonance imaging (MRI). But delayed neurological sequelae may also occur in the absence of such findings. Positron emission tomography scanning can detect regions of the brain affected by ischaemia in the acute poisoning stage, and which may be at risk of late complications, but the technique is no better at predicting the eventual outcome. Neuropsychometric assessment will show impairment in acute poisoning and may reveal cognitive deficiency consistent with organic brain damage in the delayed syndrome. The diagnosis of delayed neurological sequelae may be missed, and the patient assumed to have even made a good recovery, until a return to work reveals a failure to perform to the expected level.

The neurological examination should include tests of fine movement and balance (finger–nose movement; Romberg’s test, normal gait and heel–toe walking), testing of short-term memory, and the ability to subtract 7 serially from 100.

**Ambient air exposure to carbon monoxide**

By far the principal source of carbon monoxide in the general outdoor atmosphere is general pollution by vehicle exhausts. Uptake of carbon monoxide from multiple sources, such as smoking and traffic, is not additive. Smokers who already have a carboxyhaemoglobin level above the equilibrium value that would be reached by breathing air in their surroundings are liable to act as ‘source’, breathing out carbon monoxide rather than absorbing more. Air quality standards therefore in effect protect non-smokers from peak concentrations close to heavy traffic. The most important adverse health impact from environmental exposure to carbon monoxide is the effect on people with angina and disease from the coronary arteries. In the EU, the air quality standard has been set at a level at which the carboxyhaemoglobin should not exceed 2.5 per cent in people breathing the air over a prolonged period, that is, 10 ppm measured as a running eight-hour average. This level equates to 25 ppm for one hour, 50 ppm for 30 minutes and 87 ppm for 15 minutes when breathing at maximum levels of activity. The reader should note that this standard is substantially below the work exposure limit for an eight-hour period, and its rationale is about the need to ensure the adequate protection of people who suffer from ischaemic heart disease if they are likely to come into contact with the gas.

Recent studies indicate that even a circulating blood concentration of COHb of 2–3.9 per cent is associated with impairment of cardiovascular function in patients with angina pectoris, who may show detectable changes in the cardiac ischaemic threshold on light-to-moderate exercise (as assessed on the electrocardiogram (ECG) by a reduction in time to the ST end point) and an earlier development of angina pectoris. In healthy workers, there is no clear evidence that these levels of COHb (or indeed levels as high as 10 per cent COHb) impair the functioning of the...
central nervous system. Nevertheless, deterioration in physical work (maximum work capacity or maximum aerobic capacity) can be demonstrated with increasing levels of COHb. It is possible that healthy individuals are able to adapt to the mild hypoxia of chronic exposure to carbon monoxide. Experimental studies have shown that carbon monoxide has an atherogenic effect in rabbits and rats, but it is not generally accepted that low-level occupational exposures contribute to atherosclerosis in man; more information is needed on the effects of carbon monoxide on vascular endothelium and lipid metabolism. An epidemiological study of a cohort of bridge and tunnel workers regularly exposed to traffic fumes concluded that carbon monoxide may be a contributory factor in increasing cardiovascular mortality, but the mechanism was not clear.74

There is no available evidence to suppose that carbon monoxide is mutagenic or carcinogenic, but exposure is suspected to be a contributory factor for low birthweight in the babies of pregnant women who smoke. The teratogenic effects of carbon monoxide have been attributed to the transfer of carbon monoxide across the placenta and a consequently reduced oxygen supply to the fetus. Studies have predicted significant changes in fetal oxygenation as a result of maternal carboxyhaemoglobin levels of about 5 per cent. Severe acute exposures have caused fetal death; and developmental and other neurological abnormalities have been recorded in live births.75

The pregnant worker should avoid occupational exposure to carbon monoxide or methylene chloride (dichloromethane) and exposure to carbon monoxide should be especially prevented in workers with symptomatic ischaemic heart disease. It is also important to appreciate that the effects of carbon monoxide in people living or working at high altitude (or at a reduced partial pressure of oxygen) are greater than at sea level.

HYDROGEN CYANIDE (HCN)

[CAS No. 74-90-8]

Exposure limit: (STEL 15 min) 10 ppm (11 mg/m³)
Relative density: 0.95
Flammability limits: 6–41 per cent (vol.)

As well as hydrogen cyanide, the gaseous cyanides include cyanogen (CN)₂, once used as a fumigant, and cyanogen chloride (CICN), a fumigant and industrial intermediate. Exposure to cyanide in industry may also be the result of the accidental or intentional ingestion of cyanide salts (e.g. sodium, potassium, calcium and copper cyanide) and from exposure to the vapour of nitrites, such as acrylonitrile (vinyl cyanide) and acetonitrile (methyl cyanide). Cyanide salts are used widely for metal cleaning or hardening, in metal refining, gold extraction and film recovery and electroplating. Historically, hydrogen cyanide used to be widely used as a fumigant, but today its main industrial usage is in the production of acrylonitrile and methyl methacrylate. The gas is also evolved when acids come into contact with cyanide salts. Firemen may be exposed to the gas in fires involving the combustion of nitrogen-containing synthetic materials. The main route of poisoning by hydrogen cyanide is inhalation, although in solution it can also readily penetrate the skin.

At room temperature, hydrogen cyanide is a clear, highly volatile liquid (boiling point 26°C). The gas has a characteristic odour of bitter almonds which is recognizable at 2–5 ppm, but its detection by odour is unreliable; at higher concentrations, it causes olfactory fatigue. At 18–36 ppm, warning symptoms of poisoning may occur, such as irritation of the eyes, nose and throat, dizziness, nausea, general weakness and headaches, flushed or occasionally pale skin, and palpitations. Rapid and sudden loss of consciousness and cessation of breathing may occur on exposure to levels over 100 ppm. Levels of hydrogen cyanide above cyanide plating baths normally vary around 1–5 ppm and workers do not complain of symptoms; headache and vertigo may be reported at slightly higher concentrations.

Cyanide paralyses mitochondrial respiration by binding reversibly with enzymes containing ferric ions, in particular cytochrome aa₃, thereby blocking intracellular respiration. Its direct action on the respiratory centre may also induce respiratory failure.

Victims of acute poisoning present with headache, dizziness and vertigo. There may be marked agitation and confusion, with nausea and vomiting. Dyspnoea is accompanied by hyperpnoea due to lactic acidosis. Acute cyanide poisoning induces sustained seizures, endogenous catecholamine release and cardiovascular shock. On examination, the external findings may be normal with a pink appearance even when the blood pressure is immeasurable. The diagnosis can be confirmed by measuring cyanide in a sample of heparinized whole blood. Cyanide is concentrated in the red blood cells and plasma cyanide measurements are not recommended. Concentrations greater than 50 mmol/L are associated with altered consciousness, and the lethal level is above 100 mmol/L. Blood thiocyanate is a metabolite which can be measured after the acute event. Other useful tests include plasma lactate and arterial blood gases. In fatal cases, there are no specific pathological changes and in particular the blood remains well oxygenated.

The treatment of cyanide poisoning remains controversial because the effectiveness of the recommended antidotes, and so the treatment of choice, is not proven. Immediate first-aid measures include removing the patient to fresh air, keeping the patient warm and at rest, and removing contaminated clothing. Contaminated skin should be washed thoroughly. Oxygen should be administered if available. First-aiders should wear suitable protective clothing, including impervious gloves, to avoid skin absorption of cyanide. Where there is the potential for a large release of hydrogen cyanide, first-aiders should be trained in the use of self-contained or airline breathing apparatus for the rescue of victims. However, in most
biological laboratories the amount of cyanide in routine use does not normally warrant this precaution.

The UK Health and Safety Executive (HSE) issued new advice on the first-aid treatment of cyanide poisoning at work in 1997, since when little has changed. The HSE no longer recommends the use of any antidote in the first-aid treatment of cyanide poisoning and does not require employers to keep supplies. Instead, the administration of oxygen is regarded as the most useful initial treatment using a bag and mask device connected to an oxygen supply. The latest advice is summarized in Table 39.4. There is growing animal and human evidence that oxygen is itself an antidote to cyanide or improves the response to treatment with specific antidotes.

The main antidotes recommended in the UK are amyl nitrite and dicobalt edetate. A conservative approach to their use is recommended. Any patient exposed to hydrogen cyanide who reaches hospital fully conscious will probably not need treatment with antidotes, their use being reserved for the patient who is unconscious or who has a clear history of exposure to cyanide and has deteriorating physical signs. To be effective, the antidotes should be administered immediately the diagnosis of cyanide poisoning is made, but the problem is that the uninhibited could readily mistake an ordinary collapse for poisoning. Accidental cyanide poisoning is rare in British industry today, but the risk of suicide bids from swallowing cyanide in solid form or in liquids, such as acetonitrile, is also a possibility of which occupational physicians need to be aware.

The rationale of treatment is the rapid fixation of cyanide ion which can be achieved by direct fixation with the antidote dicobalt edetate or by inducing methaemoglobin formation with amyl nitrite. The resultant methaemoglobin binds strongly with cyanide as cyanmethaemoglobin. Experience with gassing incidents suggests that after the unconscious casualty has been removed from further exposure, he should be observed for any deterioration of vital signs before administering cyanide antidotes as patients often recover spontaneously and quickly from apparently severe poisoning. A rapid method of diagnosing cyanide poisoning is to test the patient’s breath for hydrogen cyanide with a gas detector tube. Amyl nitrite by inhalation and oxygen delivered by face mask are relatively safe and may be administered if the patient is conscious. A capsule of amyl nitrite is broken into a handkerchief and the patient inhales the vapour for 15–30 seconds. This process must be repeated every two to three minutes until the capsule is exhausted. There is, however, little scientific evidence that it is of significant benefit. If the patient is comatose, or starts to become drowsy and has the features of cyanide poisoning, then dicobalt edetate (300 mg in 20 mL glucose solution) may be administered by slow intravenous injection over 3–4 minutes. The second-line treatment, if there is no return to consciousness, is to give sodium thiosulphate (12.5 g – i.e. 25 mL of 50 per cent solution) intravenously over 5–6 minutes. Dicobalt edetate is a chelating agent that combines with cyanide to form an inert complex, cobaltcyanide. This antidote is not innocuous and if administered in the absence of cyanide will cause cobalt poisoning, hence the need to be cautious about its use. Thiosulphate is a sulphur donor and accelerates the detoxification of cyanide by assisting in its conversion to the non-toxic thiocyanate.

If the patient is not breathing, then artificial respiration should be commenced using a manual resuscitator. Mouth-to-mouth artificial respiration may put the first aider at risk of absorbing cyanide from the patient’s mouth or breath. The manual methods of artificial ventilation, such as Holger–Nielsen, are no longer recommended because they have poor efficiency and cause problems in maintaining an adequate airway.

Hydrogen cyanide may be formed when cyanides come into contact with acids. The cyanogen halides cyanogen chloride (CNCl) and cyanogen bromide (CBrN) also have local irritant effects on the eyes and respiratory tract and can cause inflammation of the bronchioles and pulmonary oedema, as well as having a similar toxic action as hydrogen cyanide. The cyanoamines have a slower rate of intoxication than cyanide gas or cyanide salts as the cyanide is released when they are metabolized by the body over several hours; they also have their own toxic properties. Cyanide is not produced in the metabolism of isocyanates or diisocyanates.

Despite evidence that hydrogen cyanide can be inhaled in fires, the use of dicobalt edetate is not routinely recommended in the treatment of fire casualties. The relatively safer antidotes amyl nitrite and sodium thiosulphate, as well as hyperbaric oxygen, have been used to treat fire

experts as an alternative in smoke inhalation victims.77 As cyanocobalamin, is being increasingly advocated by some workers and occasionally the public is by the accidental exposure to chlorine, it is the most common hazardous chemical stored in the UK, it is the most common hazardous chemical stored in large quantities at industrial installations. In the United States, railroad tanker incidents during transit are frequent but may lead to large-scale releases of chlorine with substantial injury and deaths; wherever possible hazardous materials should be re-routed away from densely populated areas.

There are two mechanisms of action of chlorine, both involving the generation of free radicals. The chlorine atom itself is a free radical; when released, it reacts with other molecules to oxidize them. The second pathway is via the indirect generation of reactive oxygen species, by first reacting with water in the respiratory tract to form hypochlorous acid and hydrochloric acid:

$$\text{Cl}_2 + \text{H}_2\text{O} \leftrightarrow \text{HCl} + \text{HOCI}$$

The hypochlorous acid is a strong oxidizing agent and on dissolution releases hydrochloric acid and reactive oxygen species, both of which initiate inflammatory responses:

$$\text{HOCI} \leftrightarrow \text{HCl} + \text{O}$$

Despite its widespread commercial exploitation since before the First World War, human data on dose–effect relations are sparse and instead the results of animal experiments extrapolated to man are used to estimate lethal or dangerous concentrations of chlorine gas. Its odour can be detected by most people at 0.2 ppm and by some at 0.02 ppm. For irritant or potentially inflammatory effects on the upper and lower airways in fit individuals and subjects with some degree of pre-existing airway hyper-responsiveness, a NOAEL is 0.5 ppm over six to eight hours. In susceptible individuals, significant changes in lung function occur at 1 ppm after four to eight hours. Exposures in the range 15–150 ppm may be dangerous after 5–10 minutes, particularly at the higher end of this range or in susceptible individuals, for example with chronic respiratory disease. At 400–500 ppm, the gas is estimated to be fatal in 50 per cent of active healthy people exposed for 30 minutes, and exposure to 1000 ppm will be fatal after a few breaths.

The effects of chlorine are mainly confined to the respiratory system.82 Because of its moderate solubility, it will act in the upper and lower respiratory tract. Acute exposure to raised concentrations in air can cause immediate irritation of the mucous membranes of the eyes, nose and throat, producing cough, choking, substernal pain and tightness. Abdominal pain, nausea and vomiting have also been reported in inhalation incidents. Upper respiratory tract obstruction from laryngeal oedema should always be considered, but the most frequently encountered severe effect is toxic pneumonitis with interstitial oedema which leads to impairment of gas diffusion and hypoxaemia; a restrictive and obstructive defect in lung function may be due to bronchospasm or interstitial oedema. Death may occur from respiratory failure or cardiac arrest due to...
non-cardiogenic pulmonary oedema. Irritation and necrosis of the skin can be caused by contact with a jet of gas, but mild erythema resembling first-degree burns may follow lesser exposure. Most mildly affected patients will settle quickly with rest, but symptomatic treatment for cough and soreness of eyes and throat may need to be given. Symptomless casualties should rest for at least eight hours and be told to report any change in their health to a doctor. The treatment of severe chlorine poisoning is as for irritant gases in general (see under Principles of first aid and treatment in gassing incidents, p. 262).

After acute gassing incidents with chlorine, persistent reactive airways dysfunction syndrome may occur: bronchial hyper-responsiveness may persist for at least 18–24 months. Pre-existing bronchial hyper-responsiveness may also be aggravated in some individuals for weeks or months afterwards. In most people, however, the evidence of a deterioration in airway function is transient. More studies are needed to determine whether chronic low-level exposures to chlorine can lead to long-term respiratory effects. The recent follow-up studies of acute chlorine gassing among pulp mill and other groups of workers do indicate that the health effects of major incidents involving the accidental release of the gas may be much more extensive and persistent than was previously supposed for irritant exposures.

Several studies have reported a relationship between indoor chlorination swimming pools and the prevalence of wheeze, asthma, hay fever, rhinitis and atopic eczema in swimmers and swimming pool attendants. Chlorination of public swimming pools results in free chlorine reacting with nitrogenous compounds (sweat and urine) introduced by bathers to form chloramines, especially nitrogen trichloride with dichloramine (NH2Cl) and monochloramine (NHCl). These can be in the atmosphere in the form of droplets or gas and are irritant in their own right, but they may also decompose to form hydrochloric acid and ammonia. The main putative agent is considered to be nitrogen trichloride with dichloramine (NH2Cl2) and monochloramine (NH2Cl). This can be in the atmosphere in the form of droplets or gas and are irritant in their own right, but they may also decompose to form hydrochloric acid and ammonia. The main putative agent is considered to be nitrogen trichloride (NCl3), which is an upper airway irritant as powerful as chlorine and may build up in the air of indoor pools. Few direct measurements of NCl3 have been made. Free chlorine and hypochlorite are unlikely to be present in the swimming pool atmosphere. A similar type of problem can arise in the processing of green salads in water containing hypochlorite.

Cleaners have suffered near fatal pulmonary oedema from chlorine liberated by the mishandling of standard household bleaches (5.25 per cent sodium hypochlorite solution – NaOCl), for example by mixing bleach with a cleaning agent containing acids, such as phosphoric acid, when chlorine gas and water are released. Another hazard may arise in the chlorination of swimming pools using hydrochloric acid and sodium hypochlorite if the two chemicals are accidentally mixed in a way to cause a release of a cloud of chlorine gas. Mixing bleach with a solution of ammonia produces monochloramine and dichloramine, and an accident, involving cleaning agents has led to a mass casualty event involving inhalation of chlorine gas.

There is no evidence that chlorine is carcinogenic or that typical industrial exposures affect reproductive outcome. The use of chlorine to disinfect drinking water has been one of the greatest public health advances of the twentieth century, saving countless lives, but chlorine reacts with organic matter in untreated water to form trihalomethanes – of which chloroform is the most common – and these are potentially carcinogenic. Spatial epidemiological studies have not identified a significant risk.

**PHOSGENE (COCl2)**

[CAS No. 75-44-5]

*Exposure limit:*

- LTEL (8 h TWA) 0.02 ppm (0.08 mg/m³)
- STEL (15 min) 0.06 ppm (0.25 mg/m³)

*Relative density: 3.48*

Phosgene is a colourless, relatively insoluble gas. At low concentrations (1 ppm), it smells like new-mown hay, but is pungent and irritating at higher levels. The gas dissolves in water and moist air to form carbon dioxide and hydrogen chloride, but only a small amount will hydrolyse in the upper and lower airways when inhaled, most of the reaction taking place in the alveoli. It is not reported to affect the skin. The danger of phosgene is that it may cause only mild transient irritation of the mucous membranes of the eyes and respiratory tract at concentrations which can nevertheless cause delayed and fatal damage to lung tissue, the symptoms of which may not begin until 30 minutes to 48 hours later. In having a latent asymptomatic period following exposure, the gas resembles nitrogen dioxide, but the mechanism of its toxicity is unknown.

Exposure is usually confined to the chemical industry where it is used in many organic syntheses requiring chlorination, such as in the manufacture of isocyanates, polyurethane and polycarbonate resins. Gassing may occur from accidental releases from plant. It may also arise whenever a volatile chlorine compound or its vapour comes into contact with a flame or very hot metal and this could give rise to dangerous exposures in confined spaces; for example, welders in the hold of a ship in Sweden welding steel plates which had been degreased by trichloroethylene all suffered pulmonary oedema. In fires, polystyrene may burn to form phosgene, as well as chlorine.

The odour of phosgene is recognizable at concentrations exceeding 0.5 ppm, above which level it is probably dangerous to inhale the gas for prolonged periods. At exposures above 10–20 ppm for 1–2 minutes severe lung injury can follow, and inhalation of 90 ppm is said to be rapidly fatal. The main feature of phosgene poisoning is massive pulmonary oedema. In most fatal cases, pulmonary oedema reaches a maximum in 12 hours followed by death in 24–48 hours. The trachea and bronchi are usually normal in appearance, which contrasts with chlorine poisoning in...
which there is typically damage to the epithelial lining with desquamation. Exposure to high concentrations may also cause severe conjunctivitis and subsequent turbidity of the cornea. Chronic bronchitis and emphysema have been reported as a consequence of acute exposure. No animal studies are available on the carcinogenicity of phosgene. No information is available on its reproductive toxicity or carcinogenicity in humans. Because it is a highly reactive electrophilic compound it would be expected to bind in biological systems at the point of contact and so systemic absorption of unchanged phosgene by the inhalation or dermal route of exposure is not likely to be significant.

A notable escape of phosgene gas from storage tanks occurred in Hamburg in 1928, leaving at least 11 people dead and 250 casualties.

**Hydrogen halides**

The irritant effect of hydrogen halides arises from the fact that they behave as strong acids in aqueous media, i.e. they dissociate forming high concentrations of hydrogen ions. Hydrochloric acid, hydrofluoric acid, hydrobromic acid and hydroiodic acid all behave as very strong acids and for equal molar concentrations they are expected to behave very similarly in their capacity to release hydrogen ions and cause irritation to the respiratory system. Incidents involving inhalation of high concentrations of hydrogen chloride in the workplace can lead to reactive airways dysfunction syndrome; it seems plausible that high levels of exposure to hydrogen bromide and hydrogen iodide would have similar consequences.

**HYDROGEN CHLORIDE (HCl)**

[CAS No. 7647-01-0]

**Exposure limit:**

- LTEL (8 h TWA) 1 ppm (2 mg/m³)
- STEL (15 min) 5 ppm (7.6 mg/m³)

**Relative density:** 1.27

Hydrogen chloride is a colourless to light yellow gas which has a sharp, suffocating odour perceptible at 0.8 ppm. It is highly soluble in water and will produce a mist containing hydrochloric acid in moist air. Occupational exposure will therefore usually be to a mixture of gas and aerosol. It has a wide range of uses in the chemical industry. In parallel with chlorine consumption anhydrous HCl is used in the synthesis of vinyl chloride and other chlorinated hydrocarbons, and in steel pickling. Hydrogen chloride is also formed in the exhaust gases of many types of missile.

A NOAEL for irritant or potentially inflammatory effects on the lower respiratory tract and outer eye is a concentration in the air of 1 ppm. The maximum levels of exposure that can be sustained over several hours are 10–50 ppm, although partial tolerance does occur. A lethal level in air is often quoted as 500–1000 ppm for short exposures, but this is probably an overestimate of toxicity. The gas is highly irritant to the eye, causing conjunctival irritation and superficial corneal damage; on contact with the skin, it will dissolve in the perspiration and produce epidermal inflammation. Repeated elevated exposures to the mist may cause ulceration of the nasal septum. Inhalation can cause choking, coughing, laryngeal oedema and non-cardiogenic pulmonary oedema depending upon the severity of exposure. Chronic, elevated exposures to the mist can give rise to the discolouration and erosion of teeth, particularly the incisors. It is some 30 times less irritant to the respiratory tract than chlorine and major incidents involving the public have not been recorded.

Hydrogen chloride was one of the first gases to have its factory emissions controlled by legislation with the passing of the Alkali Acts in 1863. The alkali industry of the nineteenth century manufactured sodium sulphate which was used in glass making and to produce alkalis, such as sodium carbonate and sodium hydroxide. The Leblanc process was based upon the reaction of common salt with sulphuric acid, and the unwanted byproduct hydrogen chloride was discharged into the air around the factories where it blighted vegetation over wide areas. Hydrogen chloride is one of the most common gases emitted by volcanoes and it readily dissolves in rainwater to form acid rain. The gas is also formed in voluminous white clouds when liquid lava flows into sea water.

Hydrogen chloride is emitted from a variety of industrial sources including incinerators and coal-burning power plants. It is not one of the major ambient air pollutants. It undergoes rapid dry deposition from the air and low ambient air levels do not seem to pose a direct health risk. Subjects with asthma do not appear to respond with adverse respiratory effects on exercising while breathing air containing less than 2 ppm hydrogen chloride. Limited experimental and epidemiological studies do not provide any evidence that the gas is a human carcinogen. There are concerns that co-exposure to hydrogen chloride and formaldehyde may enhance the known carcinogenicity of formaldehyde possibly by the formation of bis(chloromethyl) ether (BCME), a human and animal lung carcinogen, but the amounts of this carcinogen formed by this mechanism are probably too low to be significant.

There are no studies on the potential effects of the gas on human reproduction.

**Compounds which hydrolyse to hydrochloric acid**

The following gases are highly soluble in water and hydrolyse to hydrochloric acid; the treatment of overexposure is the same as hydrogen chloride and for irritant gases in general (see under Principles of first aid and treatment in gassing incidents, p. 262).
BORON TRICHLORIDE (BCl3)

[CAS No. 10294-34-5]
Exposure limit: not established
Relative density: 4.1

Boron dichloride is a colourless gas which will form a mist in moist air to give hydrochloric acid and boric acid. It has a sharp odour and is non-flammable. It is used in metal refining and as a catalyst.

DICHLOROSILANE (SiH2Cl2)

[CAS No. 4109-96-0]
Exposure limit: not established
Relative density: 3.5

Dichlorosilane is colourless and produces a mist in moist air. It is used in the semiconductor industry for the deposition of silicon.

NITROSYL CHLORIDE (NOCl)

[CAS No. 2696-92-6]
Exposure limit: not established
Relative density: 2.3

Nitrosyl chloride is a reddish brown, non-flammable, highly irritant gas. It is used in diazo reactions and other organic preparations. It reacts rapidly with water to form hydrogen chloride and nitrogen oxides which makes it a highly dangerous irritant gas with both immediate and delayed effects on mucous membranes and lungs.

Other hydrogen halides

Both of these gases are more corrosive than hydrogen chloride.

HYDROGEN BROMIDE (HBr)

[CAS No. 10035-10-6]
Exposure limit:
   STEL (15 min) 3 ppm (10 mg/m³)
Relative density: 3.5

Hydrogen bromide is a colourless, fuming, corrosive and non-flammable gas with a strong acidic odour. It is used as a chemical reagent in the manufacture of inorganic bromides, in organic synthesis, in the processing of ores and as an alkylating catalyst.

It is usually met in solution as aqueous hydrobromic acid to a strength of 48 per cent HBr.

Because of its high solubility, the major irritant effects of acute exposure are confined to the eyes (conjunctivae) and the upper respiratory tract. Knowledge on the effects of the gas in humans is sparse. Evidence from animal studies suggests that its effects are similar in character to, but less severe than, those seen in exposure to a similar concentration of hydrogen chloride. A NOAEL based on this comparison is 2 ppm. Exposure to 2–6 ppm for several minutes causes nasal and throat irritation, but no eye irritation.

Other severe exposures to hydrogen bromide have been rarely reported. These have been as a result of inadvertent pyrolysis of fire extinguisher compounds and home fumigant agents containing methyl bromide.

No studies on the carcinogenicity of hydrogen bromide are available.

HYDROGEN IODIDE (HI)

[CAS No. 10034-85-2]
Exposure limit: not established
Relative density: 4.5

Hydrogen iodide is a colourless, corrosive, very dense, fuming gas and the most unstable of the hydrogen halides. It is used as a reducing agent and in the preparation of iodies. The anhydrous hydrogen iodide produces aqueous hydroiodic acid when dissolved in water, which is a strong acid that is corrosive and reacts strongly with bases.

Human data on the effects of hydrogen iodide are too sparse and so a notional NOAEL for irritation of the respiratory tract is based on the other hydrogen halide gases, which is 1 ppm.

Fluorine and hydrogen fluoride

FLUORINE (F2)

[CAS No. 7782-41-4]
Exposure limit:
   LTEL not available
   STEL (15 min) 11 ppm (1.6 mg/m²)
Relative density: 1.31

Fluorine is a pale yellow acrid gas which is highly reactive and rarely exists in the elemental state in nature. It is more toxic than hydrogen fluoride. Its effects on the eyes and respiratory tract resemble hydrogen fluoride, but gaseous fluoride is capable of reacting with the skin to induce severe thermal or chemical burns depending upon the duration of exposure.

The element fluorine is widely distributed in the environment, being present in virtually all rocks, normal soils, surface waters, seawater and air. Low concentrations of fluoride in drinking water (about 1 ppm) are beneficial in preventing dental caries, but excessive ingestion or inhalation of fluoride over prolonged periods causes fluorosis in humans and livestock. Since 1974, chlorofluorocarbons (CFCs or ‘freons’) have been implicated in stratospheric ozone depletion. Hydrofluorocarbons (HFCs) are less destructive of ozone, but they and CFCs are ‘greenhouse’ gases.
HYDROGEN FLUORIDE (HF)

[CAS No. 7664-39-3]

Exposure limit:

- LTEL 1.8 ppm (1.5 mg/m³)
- STEL (15 min) 3 ppm (2.5 mg/m³)

Relative density: 1.86

Hydrogen fluoride, or anhydrous hydrofluoric acid, is a colourless, corrosive liquid which boils at 19.4°C and reacts in moist air to form a mist. Its main uses are in the manufacture of fluorocarbons, the etching and polishing of glass and as a fluoridating agent in organic and inorganic reactions; it is handled in the form of gaseous hydrogen fluoride or as an aqueous solution of hydrofluoric acid which on contact with the skin can cause severe burns.

Industrial exposure to fluoride may also arise in mining and use of fluoride-containing materials. Fluorspar (CaF₂) is mined in many countries (in Derbyshire, England, local deposits are known as 'Blue John') and is used throughout the world as a flux in high temperature smelting and refining processes for the production of metals and alloys. It is reacted with concentrated sulphuric acid to produce hydrogen fluoride. Cryolite (3NaF AIF₃) used to be mined in Greenland until deposits became exhausted and is now produced by chemical synthesis instead: it is used in the manufacture of aluminium. Fluorapatite (CaF₂·₃Ca₃(PO₄)₂) is present in rock phosphate which is mined in vast quantities in the production of phosphate fertilizers, phosphoric acid and phosphorus.

Exposure to hydrogen fluoride and silicon tetrafluoride, as well as fluoride particles, may occur in a wide range of processes. Silicon tetrafluoride is also produced when hydrofluoric acid is used to etch glass, and in water this toxic gas hydrolyses to form fluosilicic acid (H₂SiF₆) which is the agent most commonly used to fluoridate water. Processes with the potential to create large fluoride emissions include: phosphate fertilizer production, which involves the crushing and drying of phosphate rock; the manufacture of bricks, tiles, pottery and cement products when fluoride is released during the firing of clays containing fluoride; glass enamel and glass fibre production; metal casting; steel and petroleum refining; coal combustion; and aluminium production. Calcium fluoride and other inorganic fluorides are used as fluxing agents in arc welding. In uranium processing plants, isotopes of uranium are separated using the extremely corrosive solid uranium hexafluoride; emissions of fluoride compounds are usually negligible, but a cloud of hydrogen fluoride was released from a uranium plant in Gore, Oklahoma, in 1985, killing one worker and affecting numerous others.

In 1989, an accidental release of about 24 tonnes of hydrogen fluoride occurred over a 48-hour period at a petroleum plant in Texas; 94 local residents were hospitalized and many others suffered from the irritant effects of the gas 'fog'.

Acute health effects of hydrogen fluoride and fluorides

In industrial exposures to gaseous and particulate fluoride, absorption of fluoride is mainly through the respiratory tract. Of fluoride in the body, 99 per cent is found in the skeleton since fluoride is not retained in soft tissue and is not metabolized. There is rapid renal excretion of an acutely absorbed dose so that about half is lost in the urine in a few hours. Only a very small amount is excreted in sweat or in the faeces. Occupational fluoride exposure has not been shown to cause liver or kidney injury and evidence is inadequate to implicate hydrogen fluoride and fluoride-derived gases as carcinogens or teratogens. The maximum concentration of hydrogen fluoride in air tolerated by humans for one minute is about 120 ppm when it causes smarting of the skin, conjunctivitis and irritation of the respiratory tract. The gas has a sour taste. At 60 ppm, there are no skin symptoms but irritation of the eyes and nose with discomfort in the pharynx and trachea is present. A level of 30 ppm can be tolerated for several minutes. In magnitude of acute toxicity, studies of human volunteers and experimental animals suggest that the halide gases hydrogen fluoride, hydrogen chloride and hydrogen bromide are of the same order; their high water solubility ensures a rapid absorption in the nose and upper respiratory tract.

Inadvertent inhalation of high levels of hydrogen fluoride can cause rapid death from intense inflammation of the respiratory tract and gross haemorrhagic pulmonary oedema. Inhalation of hydrogen fluoride and fluoride and most fluorine-derived gases may cause coughing, choking and chills lasting 12 hours after exposure. After an asymptomatic period of one or two days, pulmonary oedema may develop followed by regression over a period of 10–30 days. Advice to patients who have been in gassing accidents involving fluorine gases should therefore be cautious and should include the need for admission to hospital for 24–48 hours’ observation.

The NOAEL for irritant effects on the face, eye and respiratory airways is 1 ppm.

Chronic fluoride toxicity – osteofluorosis

Osteofluorosis was first recognized as an occupational disease in Danish cryolite workers in 1932, since when cases have been reported in aluminium production, magnesium foundries, fluorspar processing and superphosphate manufacture. The accumulation of fluoride in the skeletal tissues is associated with pathological bone formation. The condition appears to be identical to endemic skeletal fluorosis found in parts of the world where drinking water contains fluoride in excess of 5–10 ppm and which was first described several years after the report of the first case of occupational fluorosis was published.

The disease is detected by osteosclerotic changes in spongy and other bones on the radiograph. There may be no symptoms even in the presence of radiological changes,
or back stiffness and vague joint pains are reported in the absence of such changes. Initially, there may be increased density of vertebral and pelvic bones but as the disease advances the bone contours and trabeculae become uneven and blurred. The bones of the extremities show irregular periosteal thickening with calcification of ligaments and muscular attachments. The cortex of the long bones is thick and dense and the medullary cavity is diminished. Radiological thickening of the bone may cause confusion with Paget’s disease or osteoblastic metastases. In severe cases, exostoses and osteophytes develop and calcification of ligaments, tendons and muscle insertions may lead to fusion of the spine and the development of a ‘poker back’ which clinically resembles ankylosing spondylitis.

Diagnosis is based upon the radiological findings and a history of prolonged fluoride exposure, together with raised urinary fluoride levels. Urinary excretion may remain high for several years after long-term heavy industrial exposure. There is evidence that the condition at least partially regresses if occupational exposure ceases, unless exposure has been prolonged in a patient suffering from poor nutrition.

The daily limit that may be ingested without risk of developing the skeletal fluorosis is 4–5 mg of fluoride,\textsuperscript{100} and in areas of endemic fluorosis, the level of ingestion often exceeds 8 mg daily. In industrial situations, absorption higher than 20–25 mg daily used to occur due to the inhalation of fluoride dust and gases. The current eight-hour time-weighted average work exposure limit for gaseous and particulate fluorides (as fluorine) is 1.5 mg/m\textsuperscript{3}, which is intended to protect workers against developing fluorosis.\textsuperscript{107} Inorganic fluoride exposure at 3.4 mg/m\textsuperscript{3} has resulted in an increase in bone density in workers. Persistent urinary concentrations of fluorides above 5–7 ppm are quoted in the literature as reflecting unsafe exposure, while the urinary biological exposure limits published by the American Conference of Governmental Industrial Hygienists (ACGIH) are 18 mol/mmol creatinine pre-shift and 60 mol/mmol creatinine post-shift.

Plasma fluoride levels correlate with concentrations of inhaled hydrogen fluoride, but they are not used for routine monitoring.\textsuperscript{104}

Workers exposed to fluorides are not at risk of developing dental fluorosis as the mottling occurs when enamel is being laid; beyond 12–14 years of age, a person’s permanent teeth can no longer be mottled, whatever the fluoride intake. Roholm, however, described three different family cases of dental fluorosis arising in the children of female cryolite workers in which the exposure to fluoride was believed to have been through the mother’s breast milk.\textsuperscript{106}

The manifestations of dental fluorosis range from chalky white flecks on the teeth in mild forms to brown discolouration and pitting in the severe cases (Figure 39.9). There are many parts of the world dependent on groundwater supplies for drinking which are contaminated by fluorides in geological strata. Developing, particularly permanent, teeth are extremely sensitive to fluorides during their formation.

**Pot room asthma in aluminium production**

Aluminium is produced by the reduction of alumina (Al\textsubscript{2}O\textsubscript{3}) which is obtained from bauxite, an ore produced mainly in South America and Australia. Since 1936, reports of asthmatic symptoms in pot room workers engaged in the manufacture of aluminium have suggested that respiratory irritants in the working atmosphere (hydrogen fluoride, sulphur dioxide and fluoride particles) may cause asthma or chronic obstructive pulmonary disease. Despite numerous studies, the relation between exposure agents and disease is not resolved, but exposure to irritant gases, such as hydrogen fluoride, can cause a bronchial inflammatory reaction and a reactive airway dysfunction syndrome.\textsuperscript{108}

![Figure 39.9](image_url) Dental fluorosis in a fisherman brought up on the volcanic islands of the Azores. Until recently, his village water supply came from a spring fed by groundwater contaminated with fluoride (>5 ppm).
The manufacture of carbon anodes in the carbon plant is associated with the release of polycyclic aromatic hydrocarbons from coal tar pitch volatiles and substantial exposure to these in the past has been found to be associated with an excess risk of lung cancer in several epidemiological studies. Gaseous and particulate fluoride are given off in the two reduction processes.

Exposure of susceptible individuals to the pot room atmosphere may provoke bronchial hyper-reactivity or precipitate symptoms in those with subclinical asthma, but the mechanism is probably irritant rather than allergic. The syndrome tends to persist in some individuals even after stopping exposure. A study of Norwegian pot room workers over six years of follow up found an increased decline in FEV₁.

### Occupational systemic poisoning by fluorides

Acute systemic toxicity may arise from the ingestion of fluoride salts, e.g. sodium fluoride, or from absorption of fluoride in hydrofluoric acid burns. There is no single cause of death in fluoride poisoning. Fluoride causes enzyme inhibition involving vital functions, such as the origin and transmission of nerve impulses. Calcium complex formation, with a rapid fall in plasma calcium, may interfere with blood clotting and cell membrane permeability. Deaths associated with profound hypocalcaemia, hypermagnesaemia and hyperkalaemia have all been reported. In addition, there may be specific organ injury involving cell damage and necrosis. Terminally, there is a shock-like syndrome in which tetany is a prominent characteristic. There is no specific antidote, but the slow infusion of intravenous calcium gluconate may be life-saving.

Accidental exposure of the skin to hydrofluoric acid solutions can cause severe, deep tissue injury. The treatment is beyond the scope of this chapter, but it relies on immediate removal of contaminated clothing, thorough washing of the skin with water and rigorous topical application of 2.5 per cent calcium gluconate gel which should always be available for use at locations where workers may be exposed. In hospital, subcutaneous injections of 5 per cent calcium gluconate solutions may be necessary. Systemic effects from skin burns may be fatal; in one patient, as little as 2.5 per cent of the body surface area was affected.

The first-aid procedures in the event of exposure to hydrofluoric acid are shown in Table 39.5.

### Other gases which hydrolyse to hydrofluoric acid

The following gases hydrolyse to hydrofluoric acid. Their effects and treatment of overexposure are as for hydrogen fluoride.

**BORON TRIFLUORIDE (BF₃)**

- **[CAS No. 7637-07-2]**
- **Exposure limits:** not available
- **Relative density:** 2.4

Boron trifluoride is colourless and forms a mist in moist air to give hydrogen fluoride and boric acid. It is highly corrosive and has severe irritant effects on body tissues. It has a sharp odour and is non-flammable. It is used mainly as a catalyst in many chemical processes.

**CHLORINE TRIFLUORIDE (ClF₃)**

- **[CAS No. 7790-91-2]**
- **Exposure limits:** not available
- **Relative density:** 3.2

Chlorine trifluoride is extremely reactive. The utmost care must be taken in ensuring that no contact with living tissue

**Table 39.5** Recommendations on first-aid procedures for hydrofluoric acid poisoning.

Source: Health and Safety Executive.
is possible. It is used for specialized purposes, such as rocket propellants and fluorinating agents.

**CARBONYL FLUORIDE (COF)**

[CAS No. 353-50-4]

*Exposure limit:* not established  
*Relative density:* 2.29

Carbonyl fluoride is a colourless, pungent gas used mainly for the preparation of organic fluorine compounds. It is also produced during the thermal decomposition of polytetrafluoroethylene (PTFE).

**PERCHLORYL FLUORIDE (ClO₃F)**

[CAS No. 7616-94-6]

*Exposure limits:*

STEL (15 min) 6 ppm (26 mg/m³)  
*Relative density:* 3.6

Perchloryl fluoride is a colourless, stable, non-flammable, sweet-smelling gas. It is a strong oxidizing agent used in fluorination processes and for rocket fuels.

**PHOSPHORUS PENTAFLUORIDE (PF₅)**

[CAS No. 7647-19-0]

*Exposure limit:* not established  
*Relative density:* 4.5

Phosphorus pentafluoride is a colourless gas with a sharp odour. It produces a mist in contact with moist air. With large quantities of water it will ultimately yield phosphoric acid. It is used in laboratory and experimental work.

**PHOSPHORUS TRIFLUORIDE (PF₃)**

[CAS No. 7783-55-3]

*Exposure limit:* not established  
*Relative density:* 3.0

Phosphorus trifluoride is a colourless gas. It is odourless at concentrations which can cause toxic effects. It is used in specialized small chemical processes for the fluorination of some metals. The gas is highly toxic, but only slowly hydrolyses to hydrogen fluoride.

**SILICON TETRAFLUORIDE (SiF₄)**

[CAS No. 7783-61-1]

*Exposure limit:* not established  
*Relative density:* 3.6

Silicon tetrafluoride is a colourless non-flammable gas with an overwhelming odour, and produces a dense white mist in air. It is used to manufacture fluosilicic acid (H₂SiF₆) and thence cryolite and aluminium fluoride. Fluosilicic acid has the same general effect as hydrogen fluoride and the treatment is the same.

**SULPHUR TETRAFLUORIDE (SF₄)**

[CAS No. 7783-60-0]

*Exposure limits:* not available  
*Relative density:* 3.8

Sulphur tetrafluoride is a very reactive, colourless and corrosive gas with a sharp odour. It is rapidly hydrolysed to hydrogen fluoride and thionyl fluoride, which in turn is slowly hydrolysed further into hydrogen fluoride and sulphur dioxide. It is used to batch produce fluorinated compounds by replacing oxygen with fluorine.

**TETRAFLUOROHYDRAZINE (N₂F₃)**

[CAS No. 10036-47-2]

*Exposure limit:* not established  
*Relative density:* 3.7

Tetrafluorohydrazine is a colourless gas with a musty odour and which slowly hydrolyses to hydrazine and hydrogen fluoride. Hydrazine is suspected of being a potential carcinogen in man. Tetrafluorohydrazine is used for the preparation of specialized fluorides.

**SULPHUR HEXAFLUORIDE (SF₆)**

[CAS No. 2551-62-4]

*Exposure limit:*

LTEL (8-h TWA) 1000 ppm (6070 mg/m³)  
STEL (15 min) 1250 ppm (7590 mg/m³)  
*Relative density:* 5.1

This is an inert, heavy, colourless and odourless gas used by the electrical supply industry to insulate high voltage circuit breakers and cables. It is also frequently added to emissions to track the spread of pollution. The gas may also be used in loudspeakers and gas-filled cushions in the soles of trainer shoes. It is harmless except in a confined space where it displaces air, but electric sparking in the presence of oxygen will produce the irritant breakdown products sulphur oxyfluoride, sulphur dioxide and sulphuryl fluoride. A group of repair workers were inadvertently exposed to these gases by inhalation and suffered severe
irritant effects. It is one of the most potent greenhouse gases known.

**NITROGEN TRIFLUORIDE (NF₃)**

[CAS No. 7783-54-2]

*Exposure limits: not available*

*Relative density: 2.46*

This gas is used as an oxidizing agent in rocket fuel and in fluorination reactions. Its principal hazard on inhalation is that it readily oxidizes haemoglobin to form methaemoglobin.

**SULPHURIYL DIFLUORIDE (SO₂F₂)**

[CAS No. 2699-79-8]

*Exposure limits:
  - LTEL (8-h TWA) 5 ppm (21 mg/m³)
  - STEL (15 min) 10 ppm (42 mg/m³)*

*Relative density: 3.7*

Sulphuryl difluoride is a colourless, odourless non-flammable gas with minimal smell. Its main use is as a fumigant. Overexposure has been reported to cause respiratory tract irritation, nausea and vomiting with crampy abdominal pain.

The following gases contain fluorine and are usually relatively inert, but they can undergo pyrolysis to produce respiratory irritants.

**Fluorinated hydrocarbons**

These gases are more widely known by their trade names. They are heavy, colourless, usually non-flammable and are used as refrigerants, specialized solvents and aerosol propellants. The usage of CFCs grew rapidly in the 1950s and 1960s as aerosol spray can propellants and blowing agents for foam insulation and foam packaging containers. CFCs are not biologically reactive and, being insoluble in water, are not removed from the air by rain. In the stratosphere, they undergo photodissociation, the chlorine atom reacting with ozone to form chlorine monoxide (ClO) and oxygen. The destruction of the ozone layer by CFCs has been recognized since 1974, but the dramatic discovery by investigators from the British Antarctic Survey of an ozone hole above Antarctica in 1985 led scientists to confirm that the depletion was due to the increase of CFCs and related halocarbons (especially methyl chloroform-1,1,1-trichloroethane and halons). There are now plans to phase out the worldwide usage of the fully hydrogenated CFCs (see under Gases in the ambient air, p. 265).

Although CFCs chiefly pose an occupational hazard by displacing oxygen in confined spaces, they are not all as innocuous as has been supposed. Most cause narcosis at high concentrations and skin contact with the compounds with low boiling points can cause skin irritation or frostbite. In animal studies mixtures of over 1 per cent (vol.) cause respiratory depression, bronchoconstriction and reduced pulmonary compliance. The pyrolysis products of CFCs include chlorine, hydrogen chloride, hydrogen fluoride and phosgene, and these may be a hazard to firefighters. CFC-22 (chlorodifluoromethane) has been reported to cause cardiac arrhythmias (palpitations) in hospital workers who sprayed tissue with an aerosol preparation in order to ‘speed up’ the work of a cryostat machine, but these adverse effects have not been found in studies of refrigerator repairmen. CFC-113 (Freon-113 or Genetron-113) has been implicated in fatalities from cardiac arrhythmia, asphyxiation or both in those working in confined spaces or in poorly ventilated areas.

The following gases are representative of the group and include some related compounds.

**DICHLORODIFLUOROMETHANE (FREON-12, GENETRON-12)**

(CCl₂F₂)

**CHLOROTRIFLUOROMETHANE (FREON-13, GENETRON-13)**

(CClF₃)

**TETRAFLUOROMETHANE (FREON-14)**

(CF₄)

This substance occurs naturally in significant traces in natural gas and is a potent greenhouse gas, being inert like silicon hexafluoride.

**DICHLOROFLUOROMETHANE (FREON-21)**

(ChCl₂F)

**CHLORODIFLUOROMETHANE (CFC-22; FREON-22)**

(ChClF₂)

*Exposure limit:
  - LTEL (8-h TWA) 1000 ppm (3590 mg/m³)*

**FLUOROFORM (FREON-23)**

(CHF₃)

1,1,2-TRICHLORO-1,2,2-TRIFLUOROETHANE (FREON-113)

(CCl₂FCClF₂)

1, 2-DICHLOROTETRAFLUOROETHANE (FREON-114, GENETRON-114)

(C₂Cl₂F₄)

**HEXAFLUOROETHANE (FREON-116)**

(C₂F₆)

**CHLOROPENTAFLUOROETHANE (GENETRON-115)**

(C₂ClF₅)

1,1-DIFLUOROETHYLENE (GENETRON-1132A)

(H₂C=C(ChClF₂)

1, 1-DIFLUORO-1-CHLOROETHANE (GENETRON-142B)

(H₂C=CCl(CF₃)

**1,2-DIBROMOTETRAFLUOROETHANE**

(FLUOROCARBON-114B₂)

(C₂Br₂F₄)

**1,1,1,2-TETRAFLUOROETHANE**

(HCFC-134A)

*Exposure limit:*

- LTEL 1000 ppm (4240 mg/m³)

This is used as a new ozone-sparing propellant, and has been used in asthma inhalers, for example. No human data
on its health effects are available. At high concentrations in animal studies, delayed fetal development has been found. For a review of the health effects of the fully halogenated chlorofluorocarbons, see Ref. 116.

Substitutes for the phased out chlorofluorocarbons are the partially halogenated hydrochlorofluorocarbons (HCFCs), the most important being 1,1-dichloro-2,2,2-trifluoroethane (HCFC 123) and 1-chloro-1,2,2,2-tetrafluoroethane (HCFC 124). These have only recently become available for commercial and industrial use.117,118 An outbreak of liver disease has recently been reported in workers who received repeated accidental exposure to a mixture of these two compounds.119 They were drivers of an overhead gantry in a secondary smelting depot and were exposed to a leaking air-cooling system in their cabin. Three out of nine workers presented with acute hepatitis, the remainder progressively developed varying degrees of liver abnormalities. Liver biopsy showed hepatocellular necrosis which was prominent in perivenular zone three and focally extending from portal tracts to portal tracts and centrilobular areas. Autoantibodies against human liver cytochrome P4502E1 and P58 protein disulphide isomerase isoform areas. Autoantibodies against human liver cytochrome P4502E1 and P58 protein disulphide isomerase isoform areas.

BROMOTRIFLUOROMETHANE (HALON 1301) (CF₃Br)

[CAS No. 75-63-8]

Exposure limits: not available

STEL (15 min) 1200 ppm (7430 mg/m³)

This gas is commonly used as a fire extinguishant in computer and high technology facilities. A group of workers exposed in an accidental discharge of a halon fire-extinguishing system reported irritation symptoms of the eyes, nose and throat, and light-headedness, but there may also have been exposure to irritant breakdown products of halon 1301 and Freon-22.120

SULPHUR DIOXIDE (SO₂)

[CAS No. 7446-09-5]

Exposure limits:

 LTEL (8-h TWA) 2 ppm (5.3 mg/m³)
 STEL (15 min) 5 ppm (13 mg/m³)

Relative density: 2.26

Ambient air quality standard: 100 ppb (15 min)

Sulphur dioxide is a colourless, highly irritating, non-flammable toxic gas. It is a common pollutant of urban air, wherever fossil fuels are burnt. Being moderately soluble in water, it will dissolve easily in the layer of fluid on the surface of the epithelium of the nasal passages and upper airways. The upper respiratory tract and the large bronchi are the major site of absorption and toxicity of sulphur dioxide, but at high concentrations it behaves like other soluble irritant gases in causing acute lung injury and damage to the front of the eye.121 Survivors of gassing incidents with sulphur dioxide may develop reactive airways dysfunction syndrome.

Sulphur dioxide from anthropogenic sources, such as coal- or oil-fired power stations, is oxidized in the atmosphere to sulphate at a rate of about 1–5 per cent per hour,122 but it can be faster in the presence of catalysts, such as metals or their particulate compounds in a plume. Sulphate is much more soluble than the gas and readily forms fine sulphuric acid aerosols or combines with rainwater and cloud droplets to produce acid rain, often at long distances from the source of the pollution. Acid rain has no direct health impact, but it blights vegetation, acidifies surface waters and corrodes buildings. The major natural sources of sulphur dioxide are volcanic activity, and the oxidation of dimethyl sulphide released from marine organisms.

Occupational exposures to the gas may arise in petroleum processing, wood pulping, food preservation, sulphuric acid production, and in paper mills. The uses of sulphur dioxide include bleaching and refrigeration. Quite high exposures to sulphur dioxide are common in many smelting operations since most ores contain sulphide; it is also a contaminant of the air of non-ferrous metal foundries. Explosions of sulphide dust may occur when blasting in massive sulphide ores, and workers may become exposed to dangerously elevated concentrations of sulphur dioxide in such accidents.123,124 Particulate matter will arise during many industrial processes, as well as in the combustion of fossil fuels, and the respiratory effects of the accompanying particle concentrations may also need to be considered.

Sulphur dioxide concentrations of 3–5 ppm in the air are easily noticeable and at these levels a few sensitive individuals will show a fall in pulmonary function at rest.125 Healthy individuals do not respond to sulphur dioxide below 1 ppm, but may respond on exercise or deep breathing at levels of 1–5 ppm; healthy individuals may show an effect with an increase in airflow resistance when exposed to concentrations of 4–5 ppm or higher for five minutes. Asthma sufferers, on the other hand, are especially sensitive to sulphur dioxide and can respond at rest to short-term concentrations of about 0.4 ppm and very sensitive subjects as low as 0.2 ppm, although no discernible threshold exists. The odour threshold is in excess of 1 ppm and so this criterion does not provide warning of potentially harmful lower levels. In the past, regular exposures in industry to over 30 ppm have been recorded, but marked irritation of the eyes, throat and upper respiratory tract usually occur at concentrations around 10 ppm. The maximum concentration that healthy individuals can endure for a few minutes is 150 ppm,125 a level which can be fatal in the elderly asthma sufferer.126

‘Dark-room disease’ is a term coined for radiographers reporting eye and upper respiratory irritation during the course of working in x-ray film processing under poorly ventilated conditions. Although the precise cause has not been ascertained, a study showed that the main airborne contaminants were sulphur dioxide and acetic acid at concentrations of about 0.1 ppm, as well as detectable glutaraldehyde.127 With the introduction of automated film development and processing, this condition is now rarely encountered.
Much attention has been paid to sulphur dioxide as one of the main pollutants in smogs that occurred in cities in the nineteenth century and the first half of the twentieth century as a result of the widespread burning of coal in homes and factories. In the London smog of 1952, many deaths occurred in London when daily black smoke (particulate matter) concentration exceeded 5000 g/m³ and was associated with very high levels of sulphur dioxide: 4000 g/m³ (1.5 ppm). With changing patterns of energy production, the emissions of the gas have been much reduced. In the United Kingdom, the highest levels’ peak levels may be mainly found 30–40 km downwind of fossil-fuel power stations where the plume may fumigate at ground level. At low concentrations, sulphur dioxide is thought to act on contact with the nose, throat and bronchi by stimulating neural reflexes which cause the smooth muscle of the airways to contract. This causes a reflex cough, irritation and a feeling of chest tightness. Other mechanisms contributing to airway narrowing include the development of mucosal oedema, vascular congestion of the mucosa and increased airways excretions. Although exposure studies have focused on asthma sufferers, it is likely that similar effects may be observed in patients with other chronic lung diseases. The evidence for longer-term effects and whether exposure to sulphur dioxide actually causes lung disease rather than only provoking attacks of asthma, remains conflicting. Pre-employment health screening in workplaces where exposure to sulphur dioxide may be high enough to affect susceptible individuals should aim to advise patients with asthma or other chronic lung disease to seek alternative employment, although the occupational physician should carefully evaluate individual cases. A proportion of the population are, when exposed to inhaled irritants over time, prone to develop mucous gland hyperplasia and chronic obstructive pulmonary disease. Epidemiological studies of smelter and pulp mill workers exposed to sulphur dioxide at regular concentrations of 1–5 ppm or over have shown inconclusive results on measures of respiratory symptoms or chronic reduction in pulmonary function. Because of its irritant properties, sulphur dioxide has been thought possibly to act as a co-carcinogen in the causation of lung cancer. Studies of workers in copper smelters have shown an increased risk in relation to exposure to arsenic, but no independent effect of sulphur dioxide was seen. There is little information available on teratogenic effects, but the gas is not considered to be a human carcinogen. ‘Smelter disease’ has been recognized in workers replacing pipes in sulphuric acid manufacturing plants. Characterized by dyspnoea, diarrhoea, colicky pain, muscle pain and dermatitis, it was attributed to sulphur dioxide in the past, but it is due to mercury fume exposure when burning through the pipes containing sludge.

Sodium metabisulphite is widely used in the food and beverage industry and in the fishing industry as a preservative. It may have an irritant effect on the airways through a mechanism leading to the release of sulphur dioxide when it is dissolved in water.

**SULPHUR TRIOXIDE (ANHYDRIDE OF SULPHURIC ACID) (SO₃)**

[CAS No. 7446-11-9]

Oleum (‘fuming sulphuric acid’) is a complex mixture of sulphuric acid and sulphur trioxide. Sulphur trioxide can exist as a gas, liquid or solid, and is used primarily as a sulphonating agent, for example in the manufacture of detergents, dyestuffs, drugs and insecticides. Dense clouds of sulphuric acid mist are formed when sulphur trioxide comes into contact with moisture in the air.

**Sulphuric and other inorganic acid mists**

Erosion of the enamel of the teeth has been reported with occupational exposure to sulphuric and other strong inorganic acid mists (nitric, hydrochloric and phosphoric acids). They are irritating to mucous epithelia and provoke respiratory symptoms and changes in pulmonary function and, at high concentrations, death. Acid mists may also cause pulmonary irritation by adhering to fine particles. There is sufficient evidence that occupational exposure to strong inorganic mists containing sulphuric acid is carcinogenic; laryngeal and lung cancer have been implicated in certain strong acid processes.

An interesting incident demonstrating the impact of factory emissions containing concentrated sulphuric acid aerosols occurred in Japan between 1960 and 1969 when asthmatic symptoms were reported in about 600 individuals living within 5 km of a titanium dioxide plant during this period.

**AMMONIA (NH₃)**

[CAS No. 7664-41-7]

**Exposure limits:**

- STEL (15 min) 35 ppm (25 mg/m³)
- LTEL (8-h TWA) 25 ppm (18 mg/m³)

**Relative density:** 0.59

**Flammability limits in air:** 15–28 per cent (vol.)

Anhydrous ammonia is a colourless gas with a distinctive pungent odour. It is extremely soluble in water, forming a caustic alkaline solution of ammonium hydroxide. Ammonia is one of the most widely used industrial gases, as a catalyst and reagent, and has been used for many years as a refrigerant and in the manufacture of fertilizers. Although the gas is lighter than air, it can behave paradoxically, as in an accidental release from storage in liquid form under pressure by undergoing rapid cooling to form a dense cloud that hogs the ground. Most people will recognize the odour of ammonia at 30–50 ppm. At or above 50 ppm, the gas is irritant to the eyes and mucous membranes of the respiratory tract, although partial tolerance does develop. Being readily hydroscopic, it is absorbed by the mucous coating of the upper respiratory tract. Human data are sparse, but the only clearly established effect arising from exposure to low concentrations...
(<200 ppm) in humans is irritation of the skin, eyes and upper respiratory tract. There is no evidence that ammonia is genotoxic, carcinogenic or reprotoxic. Exposure to concentrations up to 500 ppm for a few minutes can be tolerated by healthy adults, but at this level there is cough, hoarseness and tightness of the throat, as well as marked eye irritation and conjunctivitis. At estimated levels of between 5000 and 10000 ppm, ammonia is likely to damage the lower respiratory tract and be life-threatening, and concentrations in excess of 10000 ppm may be rapidly fatal.\textsuperscript{134,135} At life-threatening levels, the gas causes chemical burns of the nose, mouth and throat which become red and raw, and corneal burns. The tracheal epithelium and bronchi may become denuded of epithelium. Pulmonary oedema by itself or with subsequent bronchopneumonia is the main cause of death, but fatalities can also be caused by the very rapid onset of acute laryngeal oedema which initially can manifest itself by hoarseness and dyspnoea.\textsuperscript{136,137}

The strongly irritant nature of ammonia has led to the oft-repeated view that laryngeal spasm is a frequent cause of death in gassing accidents, but it is more likely to be due to rapid onset of laryngeal oedema. Although spasm of the glottis could persist long enough to induce asphyxia, the spasm would normally relax during unconsciousness and then breathing would recommence.

Apart from respiratory tract irritation, injury to the eyes at high concentrations can be severe. Irrigation of the eyes should be instituted immediately after exposure to prevent rapid absorption of ammonia by the eye. Ophthalmic sequelae include corneal opacities, cataract and glaucoma. A jet of anhydrous ammonia on to the moist skin can cause second-degree burns, as will splashes of liquid ammonia. The literature reports a case of severe gastritis continuing for months after a gassing accident.\textsuperscript{137}

There is good evidence that some individuals who have survived an acute gassing incident may go on to develop permanent respiratory disability with complications such as progressive airway obstruction, diminishing diffusion capacity (low transfer factor), bronchiolitis obliterans, bronchiectasis, and continuing cough and sputum.

In contrast, exposure to ammonia in pig farmers is around a few ppm. Respiratory symptoms are common in these workers. However, exposure to dust, disinfectants and endotoxins may contribute to the respiratory irritants in the air of livestock confinement buildings.\textsuperscript{44,138}

**Alkyl amine gases**

The following aliphatic amine gases are used widely in industrial processes and pharmaceutical manufacturing:

**MONOMETHYLAMINE (CH$_3$NH$_2$)**

**DIMETHYLAMINE (CH$_3$$_2$NH)**

[CAS No. 124-40-3]

**Exposure limits:**

<table>
<thead>
<tr>
<th>STEL (15 min)</th>
<th>6 ppm (11 mg/m$^3$)</th>
</tr>
</thead>
<tbody>
<tr>
<td>LTEL (8-h TWA)</td>
<td>2 ppm (3.8 mg/m$^3$)</td>
</tr>
</tbody>
</table>

**TRIMETHYLAMINE (CH$_3$)$_2$N**

[CAS No. 75-50-3]

**Exposure limits:** not available

They are flammable, highly soluble, alkaline, colourless gases which have a fishy odour at low concentrations and an ammoniacal odour at higher concentrations. They are all denser than air and act as irritants to the eyes, nose, throat, respiratory tract and skin. Trimethylamine (TMA) is a major component of the odour produced by decaying fish. In fish odour syndrome, an uncommon inherited autosomal recessive condition, the oxidation of trimethylamine in the body is impaired. Unoxidized trimethylamine is increased in urine, breath, sweat and other secretions, causing the fish smell.\textsuperscript{139}

**OZONE (O$_3$)**

[CAS No. 10028-15-6]

**Exposure limits:**

| STEL (15 min) | 0.2 ppm (0.40 mg/m$^3$) |

**Relative density:** 1.66

Ozone is a faintly bluish gas with a characteristic pungent odour. Because it is irritant to mucous membranes and as it is only moderately soluble in water, it readily penetrates to the small airways and alveoli, even with brief exposure, and at elevated concentrations causes pulmonary oedema. Exposure to moderately elevated levels of ozone causes a measurable fall in FEV$_1$ and FVC (forced vital capacity) associated with symptoms in susceptible adults, and children. These changes are compatible with an inflammatory bronchiolitis causing reflex inhibition of respiration. They are related to the duration of exposure and to exercise and have been recorded at concentrations as low as 0.08 ppm over periods of 6.6 hours.\textsuperscript{140} There is no evidence that asthma sufferers or subjects with chronic obstructive pulmonary disease are more sensitive to ozone than others. Distinct irritation to the eyes and respiratory tract occurs at 0.5 ppm and prolonged exposure to this concentration is reported to cause pulmonary oedema or could increase susceptibility to respiratory infections (bacterial and viral). Even brief exposure to 1 ppm is inadvisable as it may cause severe cough and malaise. The lethal level is not known precisely but inhalation of 50 ppm for 30 minutes is regarded as a potentially fatal exposure.

Ozone is used in industry as an oxidizing agent in chemical reactions, for water fumigation and for the bleaching of synthetic and natural fibres, oils, paper and flour. It is also generated by electrical storms and by discharges in electrical equipment, for example during processes involving arc welding or emission of ultraviolet radiation. In offices with poor ventilation electrostatic photocopiers which utilize the action of high intensity discharge lamps, and laser printers, particularly older models,
may produce sufficient ozone to cause symptoms such as headache and eye and throat irritation in some workers. Laser printers have ozone filters and it is important that the machines are regularly serviced according to the manufacturer’s instructions.

The mechanism of ozone in the lung has been one of the most extensively studied. The cells most susceptible to damage are type 1 cells which line the alveoli and form part of the barrier for gaseous exchange between the air and the blood. With their loss and exposure of the basement membrane, stimulation of inflammatory cascades and increased fluid leak from the capillaries occur, together with an increase in macrophages, neutrophils and alveolar surface protein in the interstitial and alveolar spaces. This is accompanied by the release of surfactant and other secretions by the epithelial type 2 cells, which like the Clara cells, normally produce surfactant which prevents alveolar collapse and helps to keep the alveoli ‘dry’. Biochemical changes induced in the lung by inhaled oxidants of free radical nature, such as ozone and nitrogen oxides are complex and not understood, but include lipid peroxidation. Both the upper and lower respiratory tract have a considerable range of protective antioxidants, with intracellular reduced glutathione (GSH) being one of the major ones of the lower respiratory tract. Clara cells have a major role in chemical detoxification by being a major site for the metabolism of inhaled and systemically administered chemicals by means of GSH, NADPH and P-450 monooxygenases; they also provide the bulk of the antioxidant molecules of the liquid lining of the airways.

Much attention has been focused on ozone as the major oxidant in photochemical smog. In terms of producing inflammation of the respiratory tract, ozone is the most toxic of the common air pollutants. Ozone may also increase bronchial responsiveness to allergens in atopic asthmatic subjects and the response to other bronchoconstrictor pollutants, such as sulphuric acid or sulphur dioxide. The UK Department of Health has advised that those healthy or asthmatic individuals who are particularly sensitive to ozone should limit heavy exercise in the open air in the afternoon, the time of day when ozone levels reach a peak during periods of poor air quality, if peak hourly levels are likely to exceed 0.1 ppm.

There is no information in humans on whether long-term exposure to levels of ozone at the current occupational exposure standard (0.2 ppm) can cause chronic pulmonary health effects or adverse reproductive effects. In practice, most industrial exposures tend to be brief and related to attending specific processes; hence only a STEL has been established. Monitoring methods should be in place to detect leaks so that ozonators can be shut down if abnormal operating conditions prevail. Leak detection by nose is not satisfactory because even slight leaks cause the sensation of smell to be numbed.

---

**Nitrogen oxides**

**NITRIC OXIDE (NO)**

[CAS No. 10102-43-9]

Exposure limits: under review

Relative density: 1.04

Certain conditions, e.g. septic shock, result in enhanced endogenous synthesis of nitric oxide via induction of a nitric oxide synthase in endothelial and vascular smooth muscle cells, leading to vasodilatation and hypotension. A 40 ppm NO/air inspired mixture acts as a highly selective pulmonary vasodilator and reduces pulmonary hypertension. Its therapeutic properties are under study in patients requiring assisted ventilation, as in adult respiratory distress syndrome. Endogenous nitric oxide production probably accounts for most of the methaemoglobin in the blood of normal subjects. At 40 ppm nitric oxide, the increase in methaemoglobin is small and clinically insignificant, but at over 100 ppm methaemoglobinemia and pulmonary oedema are the principal hazards of the gas. Much of the toxicity is accounted for by the formation of nitrogen dioxide, which is not a vasodilator.

Relative density: 2.62

Nitric oxide is a colourless and odourless gas which rapidly oxidizes in air to nitrogen dioxide, a reddish-brown gas with a pungent odour apparent to most people at about 0.5 ppm. Both are found in nitrous fumes produced by fuming nitric acid, but nitric oxide is non-irritant, while nitrogen dioxide is the more hazardous. Nitrogen dioxide is non-flammable and hydrolyses in water to form nitrous and nitric acid. Nitric oxide and nitrogen dioxide are formed in the combustion of fossil fuels or from biomass burning, the amount depending upon the nitrogen content of the fuel and the combustion temperature. Some fuels, such as natural gas, contain negligible amounts of nitrogen, but nitrogen oxides are also formed during the combustion of all fuels in the regions of peak flame temperature. In the United Kingdom, some 50 per cent of the atmospheric nitrogen dioxide is produced by motor vehicles and some 25 per cent by power stations. The most significant indoor source of nitrogen dioxide is cooking with gas. Like ozone, nitrogen dioxide is an oxidant gas with free radical properties and these may be responsible for its injurious effects on the pulmonary parenchyma by damaging cell membranes and proteins, although the gas is considerably less irritant than ozone. The formation of nitrous and nitric acid in dissolved nitrogen dioxide may also injure the
airways. Individuals with mild asthma are more sensitive than unaffected people to exposure to nitrogen dioxide. At relatively high concentrations, the gas causes acute inflammation of the airways. Nitrogen dioxide reduces mucociliary clearance and in animal studies has been shown to affect the immune cells of the airways and increase susceptibility to bacterial and viral respiratory infections.141,142

In the indoor environment, the burning of natural gas as a cooking fuel in homes is an important source of nitrogen dioxide as are paraffin space heaters: indoor air concentrations may readily exceed those outside the home. An unvented gas cooker may typically provide peak levels of 200–400 ppb in a kitchen.

In industry, nitrogen dioxide is released as a byproduct whenever nitric acid acts on metals or on organic materials, such as in the nitration of cotton or other cellulose, and in the manufacture of many chemicals. Certain welding operations also produce nitrogen dioxide. Fermentation of silage will produce high concentrations of gas within two days of silo filling and exposure to farmers entering the confined silo space may give rise to acute fatalities or the respiratory effects of exposure to nitrogen dioxide known as ‘silo fillers’ disease’. The hazard from oxides of nitrogen in silos was first reported from the United States where farmers commonly silage maize stalks.143,144 Under certain growth conditions, for example drought or in soils with elevated nitrates, the content of nitrate in the grass or maize stalks used for silage may be increased enough to release an abundance of nitrous acid during fermentation which then breaks down into oxides of nitrogen. Warning signs to farmers are dead birds or rodents and a yellow-brown haze around the silage surface. Elevated carbon dioxide and reduced oxygen concentrations may also occur at the same time. Similar reactions can arise if silage grass is treated with ammonium salts. To prevent the build up of gases, silos should have adequate mechanical ventilation. Nitro-explosive fumes contain oxides of nitrogen, and when dynamite or gun cotton burn quietly instead of detonating, nearly the whole of the nitrogen is given off as nitric oxide instead of free nitrogen. Thus, numerous inhalation accidents have occurred in mining and tunnelling from the imperfect detonation of nitro-explosives, or from dynamite catching fire in poorly ventilated spaces. Armed services personnel may also be exposed to the fumes in gun-pits, armoured vehicles, ships’ magazines and turrets.

Increased airways resistance has been measured in healthy human volunteers exposed to two-hour concentrations as low as 2.5 ppm of nitrogen dioxide. Asthma sufferers may respond at concentrations as low as 0.3 ppm when exercising and exposure may enhance their response to common allergens.145 The main danger of nitrogen dioxide is that it is only a mild upper respiratory tract irritant so that exposure to up to 50 ppm may produce no immediate symptoms to warn of its potential hazard. However, exposure to 4–25 ppm may result in severe cough, haemoptysis and chest pain. Exposure for less than an hour to 100–150 ppm can result in fatal pulmonary oedema arising between 3 and 72 hours later, with the initial irritant effects comprising throat irritation, cough, headaches, tightness in the chest and sweating, all of which may pass off within 30 minutes. Thus, people who are believed to have received significant exposure should be admitted to hospital and placed under observation for 48 hours. At more elevated concentrations, a few breaths can produce severe and immediate hypoxaemia which may be fatal. In less severe cases, the delayed symptoms will be dyspnoea, chest pain with haemoptysis, and headache followed by an uneventful recovery in most patients, although the cough may last several weeks.

Apollo astronauts were accidentally exposed in an incident to an average of 250 ppm of nitrogen dioxide for 4 minutes before splashdown. They developed chest symptoms and evidence of pneumonia over the next day.

Poisoning by oxides of nitrogen is a prescribed disease.

The initial treatment of nitrogen dioxide poisoning is as for non-cardiac pulmonary oedema induced by irritant gases. However, with this gas a second episode of pulmonary oedema may occur, and following apparent recovery bronchiolitis obliterans (see above under Bronchiolitis obliterans, p. 263) may develop after an asymptomatic period that can last up to six weeks.146

Nitrogen dioxide exposure should always be considered in workers who have suffered an acute onset of pulmonary symptoms with haemoptysis associated with minimal evidence of preceding respiratory irritation. Such incidents have also involved ice hockey players and spectators due to nitrogen dioxide emitted by malfunctioning combustion engines in ice surfacing machines that use propane.147 Symptoms attributed to high levels of nitrogen dioxide have been reported in blast furnace workers when the slag is under cooling conditions (cold blast furnace syndrome).

Methaemoglobin determinations should be routinely performed: in an accident involving the deaths of three men entering a silo that had been filled with corn the previous day post-mortem blood samples showed a methaemoglobinemia in the range of 38–44 per cent in the three men.148

Information on the effects of chronic low-level occupational exposures is currently inadequate. A meta-analysis of epidemiological studies of the effects of exposure to nitrogen dioxide in the indoor air from domestic gas cookers on respiratory disease in children was inconclusive.140 Nitrogen dioxide is not considered to be carcinogenic or teratogenic.141

HYDROGEN SULPHIDE (H₂S)

Relative density: 1.19

Flammability limits: 4.3–46 per cent (vol.)
Hydrogen sulphide is a colourless gas which burns in air with a pale blue flame and is moderately soluble in water. It is rapidly converted to sulphur dioxide in the atmosphere by a reaction with hydroxyl groups and carbonyl sulphide. In the body, the sulphide ion is oxidized to thiosulphate and sulphate in the liver and kidneys and is mostly eliminated in the urine. The toxic effects of the gas are caused through the inhibition of cytochrome oxidase and through a direct depressant effect on the respiratory centre of the brain. At high concentrations, hydrogen sulphide is very poisonous, but recent research has found that at low levels it normally behaves in the body as a cell messenger emitted in red blood cells. Hydrogen sulphide poisoning is a frequently met hazard in the oil, gas and petrochemical industries where the risks of exposure are well known. Less well recognized are the dangers from the release of hydrogen sulphide as a result of the fermentation of proteinous material, e.g. the decay of ‘trash’ fish in boat holds and on farms which store slurry and liquid manure. It may also be found in dangerous concentrations in the vicinity of fumaroles and the craters of volcanoes, as well as in geothermal and hot spring areas (Figure 39.10). Occupations associated with hydrogen sulphide exposure include carbon disulphide production, viscous rayon production, sewer and tunnel work and mining, petroleum production or processing, rubber vulcanizing, pulp industry, sulphuric acid production, tanning and glue manufacture. Its characteristic smell of rotten eggs is normally readily detectable below 1 ppm: the threshold of detection of the gas is 0.02 ppm and the rotten egg smell is detectable at levels several times higher. However, the sense of smell to hydrogen sulphide is soon lost at over 20 ppm and so the worker may have little, if any, warning of the presence of the gas at dangerous concentrations. Inhalation of concentrations of 10 ppm hydrogen sulphide has no effect on pulmonary function in exercising healthy subjects and levels of 20 ppm can be tolerated for some hours without harm (Figure 39.10), and there is no cumulative action. Hydrogen sulphide is an irritant to the upper airways, but asthma sufferers do not appear to so readily respond to low levels of hydrogen sulphide as they may do to sulphur dioxide. An exposure study of asthma patients who required regular medication, but excluding patients with severe asthma, found that an effect on airways resistance (but not FEV1 or FVC) was discernible in two of ten subjects exposed to a concentration at 2 ppm, a level which is regarded as the lowest observed adverse effect level. On volcanoes, scientists can be totally unaware of hydrogen sulphide because its smell may be undetectable, even at low levels, in mixtures of fumarolic gases for reasons which are not clear. As with other toxic gases, a safe system of work that includes air monitoring is essential. While the toxic hazard of hydrogen sulphide depends on the duration of exposure as well as its concentration, levels above 500 ppm should be regarded as very dangerous and immediate evacuation from a contaminated atmosphere should begin well below this level. The symptoms of acute intoxication (>1000 ppm) are rapid breathing and distress, with nausea and vomiting, and these may be rapidly followed by loss of consciousness usually in association with cessation of breathing. Loss of consciousness without warning can occur on sudden exposure to a high concentration of hydrogen sulphide (>2000 ppm) after only one or two breaths (‘knock down’) and there is a high probability of death unless emergency resuscitation is commenced. Hydrogen sulphide is also a pulmonary irritant and brief exposures above 500 ppm may cause acute non-cardiogenic pulmonary oedema; this potentially fatal complication can occasionally occur with prolonged exposures at concentrations exceeding 250 ppm. Eye irritation has been reported in workers exposed to 10–20 ppm hydrogen sulphide for six to seven hours. Exposure at concentrations greater than 50 ppm for one hour or more may severely damage eye tissues. Hydrogen sulphide keratoconjunctivitis is usually a feature of subacute intoxication by the gas that may arise after prolonged exposure.
exposure above 50–60 ppm, the symptoms being related to blepharitis and irritant conjunctivitis with lacrimation and photophobia. Sensations of grittiness or pain in the eye are associated with superficial punctate corneal erosions. Usually, the eyes recover within 24 hours following removal from exposure, or after treatment with chloramphenicol eye ointment, but corneal ulceration has been recorded.

With prompt first aid and hospital treatment, the overall fatality rate from hydrogen sulphide poisoning with loss of consciousness is low and recovery is normally complete. However, in a small minority of patients, neurological sequelae may be found after an episode of unconsciousness. There is no specific treatment for hydrogen sulphide poisoning and the use of nitrite therapy is controversial. There is no specific finding at autopsy. Blood sulphide concentrations can be measured in fatal and non-fatal poisonings using an ion-selective electrode method, but blood and urine thiosulphate are believed to be more reliable by most laboratories, although experience remains limited. As sulphahemoglobin is not formed in vivo by hydrogen sulphide, sulphahemoglobinemia is not evidence of exposure to the gas.

Evaluating the long-term effects of hydrogen sulphide poisoning is complicated when case reports often lack good information on exposure levels, in particular, the presence or absence of other gases, such as ammonia and carbon monoxide, which may be present due to fermentation processes. There is also a dearth of good follow-up studies. Reports of interstitial fibrosis and chronic disability following pulmonary oedema (pneumonitis) (pneumonitis) are uncommon. Clinical experience and animal experiments suggest that neurological damage due to hydrogen sulphide poisoning is similar to hypoxic brain damage from any other cause, and case reports of delayed sequelae in carbon monoxide poisoning are rare. However, there is a group of patients occupationally exposed to hydrogen sulphide who present with non-specific symptoms, such as hypersusceptibility to gas smells and other strong odours, fatigue, lack of energy, poor memory, irritability, decreased libido and disturbances of equilibrium. There may even be signs of vestibular dysfunctioning on clinical investigation. Ahlborg concluded that the majority of these patients have suffered repeated episodes of intoxication without loss of consciousness. They may also fall into the category of those patients who develop non-specific symptoms following chemical exposure incidents. There is insufficient evidence in the literature to justify the entity of cumulative or chronic hydrogen sulphide intoxication at prolonged exposures at 50–100 ppm, and such levels above the occupational exposure standard should not be regularly encountered anyway in modern industry.

Chronic exposures to low levels in the environment, such as in geothermal areas, as well as at workplaces, have not been shown to be harmful, although its unpleasant smell can be a considerable nuisance. The New Zealand city of Rotorua sits on a geothermal field, and the air is polluted by low levels of hydrogen sulphide, but there is an absence of scientific data on which to base opinions on the carcinogenicity, teratogenicity or reproductive effects of the gas in this or other locations. The World Health Organization has issued a guideline concentration limit in ambient air of 7 μg/m³ (30-minute averaging period), based on odour annoyance. Natural gas may contain as much as 50 per cent hydrogen sulphide that must be removed through refining. In 1950, an escape of hydrogen sulphide from a refining plant into the local neighbourhood occurred in Poza Rica, Mexico, resulting in 320 hospitalized persons and 22 deaths.

Malodorous sulphur compounds

Hydrogen sulphide and methyl mercaptan are present in the breath of individuals with halitosis as a result of proteolytic activity by microorganisms residing on the tongue and teeth. Both substances, together with dimethyl sulphide and dimethyl disulphide are the principal air pollutants emitted by pulp mills. For safety reasons, odorants are added to natural domestic gas, namely diethyl sulphide, tertiary butyl mercaptan, ethyl mercaptan and methyl ethyl sulphide. Evidence for health effects of low level exposure to reduced sulphur compounds in the ambient air rests in studies of communities in the vicinity of sulphate paper mills in Finland, where concentrations of total reduced sulphur compounds in excess of 40 mg/m³ (one-hour or daily means) have been associated with daily reported symptoms of headache, depression, tiredness and nausea. Dimethyl sulphide is allegedly the principal component of foetor hepaticus.

CARBONYL SULPHIDE (COS)

[CAS No. 463-58-1]

Exposure limit: not established
Relative density: 2.1
Flammability range: 12–29 per cent (vol.)

The most abundant sulphur species in the atmosphere is carbonyl sulphide, being naturally produced from soil decomposition, wetlands and marshes, etc. The gas is often encountered with hydrogen sulphide in processes involving the destructive distillation of coal and the purification of petroleum. It is a colourless gas with an odour of rotten eggs that decomposes in moist air to carbon dioxide and hydrogen sulphide. The gas is less irritant to the lungs than hydrogen sulphide and probably acts in the same way on the central nervous system to cause respiratory paralysis.

SILANE (SiH₄)

[CAS No. 7803-62-5]

Exposure limits:
- LTEL (8-h TWA) 0.5 ppm (0.67 mg/m³)
- STEL (15 min) 1 ppm (1.3 mg/m³)
Relative density: 1.1

Silane is a colourless gas with a repulsive odour and even at low concentrations is spontaneously flammable in air at
room temperature. When silane burns in pipelines carrying the gas, silicon oxide dust is formed. The main use of silane is in the semiconductor industry as a source of high purity silicon where, because of its fire hazard, it has to be used under special control technology with the result that human exposure has tended to be minimal. There is little information on the effects of human exposure, but as it will form silicic acid in the presence of moisture, it is assumed that silane will have an irritant effect on the eyes, mucous membranes and respiratory tract.

**METHYL MERCAPTAN (METHANETHIOL) (CH₃SH)**

[CAS No. 74-93-1]

*Exposure limits:* not available

*Relative density:* 1.7

*Flammability limits:* 3.9–21.8 per cent

Methyl mercaptan (methanethiol) is colourless and flammable with a very foul odour detectable at very low concentrations. It is reported to have similar toxic properties to hydrogen sulphide, being capable of causing central respiratory paralysis and pulmonary oedema. In a rare case of death by overexposure, acute severe haemolytic anaemia and methaemoglobinemia were found in the comatose victim, although this effect was probably unique to the patient who, in addition, suffered from glucose-6-phosphate dehydrogenase deficiency.¹⁶⁶

**HYDROGEN SELENIDE (H₂Se)**

[CAS No. 7783-07-5]

*Exposure limits:* not available

*Relative density:* 2.8

Hydrogen selenide is an irritant gas capable of causing pulmonary oedema. In one reported case of acute poisoning, the effects were acute severe cough and wheeze which were followed by a lasting obstructive lung disorder.¹⁶⁷ Effects of chronic selenium exposure include extreme lassitude and fatigueability, garlic odour on the breath, tremor, excess perspiration, abdominal pain and vomiting, and a metallic taste in the mouth. The gas is used in the preparation of selenides and is important as a doping gas in the semiconductor industry, but routine biological monitoring for selenium is not undertaken.

**IRRITANT OR OTHER GASES WITH SYSTEMIC TOXIC EFFECTS**

**ARSENIC (AsH₃)**

[CAS No. 778442-1]

*Exposure limit:*

  LTEL (8-h TWA) 0.05 ppm (0.16 mg/m³)

*Relative density:* 2.69

Arsine is a colourless, non-irritating gas with a garlicky odour and is moderately soluble in water. Apart from its use in the manufacture of semiconductors in the micro-electronics industry, its evolution is almost always accidental.¹⁶⁸ It can be produced by the action of water on a metallic arsenide, and an ore contaminated with arsenic will liberate arsine when treated with acid. Poisoning may arise in metal smelting and extraction, but exposure may also occur in galvanizing, soldering, etching and lead plating, as well as in the disposal of toxic waste containing arsenic or arsenides.

The gas may lead to incidents in the most unexpected ways. In a classical incident off the British coast involving the Asiafreighter, a cylinder of arsine stored in the ship’s hold leaked through a cylinder valve: four crew members who inspected the hold were inadvertently exposed to the gas and suffered severe poisoning, but exchange transfusion was life-saving, the diagnosis having been made by a physician-toxicologist over the telephone.¹⁶⁹ The occupational and general physician should be alert to arsine poisoning and its characteristic features. The gas is a powerful haemolytic agent and its effects are usually fatal if exposure is severe enough to cause anuria, unless the diagnosis is made quickly and exchange transfusion is employed as a mainstay of treatment.

The presenting symptoms are nausea, vomiting and headache which can arise 2–24 hours after a casual exposure to arsine which may have lasted only 1–2 minutes. There may be no olfactory or other warning of the presence of the gas. Exposure to only 3–10 ppm of arsine in air can produce symptoms after several hours of exposure and 25–50 ppm for 30 minutes is potentially lethal in humans. Early on, the victim may pass dark red urine, and the combination of haemoglobinuria (without intact red blood cells in the urine), jaundice and abdominal pain should alert one to the diagnosis. The abdominal pain and jaundice typically arise in 24–48 hours; and anuric or oliguric renal failure sets in by 72 hours.

Other causes of haemoglobinuria to be considered in the differential diagnosis are leptospirosis, malaria and paroxysmal nocturnal haemoglobinuria. Other chemical agents capable of causing haemoglobinuria include potassium chloride, pyrogallic acid and stibine gas.

Diagnosis is made on the history of exposure and the finding of elevated urinary arsenic.

Because acute poisoning produces rapid and fulminant haemolysis, many body organs, particularly the kidney, are at risk from the sludging of red cell debris within the microcirculation, hypoxia and the direct effect of arsine, but the mechanisms involved are not fully understood. There is reticulocytosis and leukocytosis with an elevated plasma haemoglobin, and methaemoglobin may form in the plasma and urine. Renal failure from severe tubular necrosis is the main clinical complication and requires treatment with exchange transfusion to remove the arsine adequately.¹⁷⁰ In mild cases of haemoglobinuria, forced diuresis is recommended. Recovery from the acute tubular necrosis may be followed by the development of chronic renal failure with glomerular sclerosis, atrophic tubules and interstitial fibrosis. A wide spectrum of clinical
manifestations may arise including damage to the liver, myocardium, nervous system and bone marrow.

A chronic form of poisoning from low-level exposure to arsine has been described in workers engaged in the cyanide extraction of gold and in zinc smelting. This gave rise to severe anaemia, mildly elevated serum bilirubin and raised urinary arsenic.\textsuperscript{168}

\textbf{STIBINE (SbH\textsubscript{3})}

[\textit{CAS No. 7803-52-3}]

\textit{Exposure limits: not available}

Stibine is a highly toxic, colourless gas which is formed when an acid reacts with a metal containing antimony as an impurity, or when nascent hydrogen comes into contact with metallic antimony or a soluble antimony compound. The gas is not used in industry and its evolution is unintentional. Exposure may occur in metallurgy or chemical laboratories but, unlike arsine, it has an extremely unpleasant odour. Stibine poisoning is rare in industry. The manifestations of poisoning and the physiological action of the gas resemble arsine, but are less fulminant. Haemolysis, myoglobinuria, haematuria, renal failure, nausea, vomiting and headache have been reported after inhalation. Antimony trioxide is used as a fire retardant in plastics manufacture, and the release of stibine from PVC cot mattresses was considered, and later discounted, as a cause of sudden infant death syndrome. Urine antimony measurements may be used as a guide to overexposure to the gas in workers.

\textbf{GERMANE (GeH\textsubscript{4})}

[\textit{CAS No. 7782-65-2}]

\textit{Exposure limits:}

\begin{itemize}
  \item \textit{LTEL (8-h TWA) 0.2 ppm (0.64 mg/m\textsuperscript{3})}
  \item \textit{STEL (15 min) 0.6 ppm (1.9 mg/m\textsuperscript{3})}
\end{itemize}

\textit{Relative density: 2.6}

Germane is flammable and colourless and has a pungent odour. Unlike its cousin arsine, it is not encountered as an incidental product in ore or scrap processing. It is used to deposit pure germanium in semiconductor manufacturing.

The toxicity of the family appears to be in the order Ge, As, Sb. Although germane produces haemolysis, no industrial poisonings have been reported. By analogy with arsine, any victim of significant exposure should be removed to an intensive care facility and assessment of blood, kidney and cerebral function continued for some days.

\textbf{PHOSPHINE (PH\textsubscript{3})}

[\textit{CAS No. 7803-51-2}]

\textit{Exposure limit:}

\begin{itemize}
  \item \textit{LTEL (8-h TWA) 0.1 ppm (0.14 mg/m\textsuperscript{3})}
  \item \textit{STEL (15 min) 0.2 ppm (0.28 mg/m\textsuperscript{3})}
\end{itemize}

\textit{Relative density: 1.18}

Phosphine or hydrogen phosphide is a colourless, flammable gas which can auto-ignite at ambient temperatures if it contains other phosphorus anhydrides as impurities. Pure phosphine will auto-ignite above 38°C and forms an explosive mixture in air at concentrations greater than 1.8 per cent by volume. The pure gas is considered odourless, but impurities will give it a characteristic smell of dead fish or garlic which may be imperceptible at low, but hazardous, concentrations.\textsuperscript{171}

Phosphine is used as an intermediate in the synthesis of organophosphines and organic phosphonium derivatives. It is widely used in its pure form as a dopant in the manufacture of semiconductors, but it has chiefly gained notoriety through its use as a fumigant against insects and rodents in grain stores, in grain elevators and on board ships. It is an unwanted byproduct in various metallurgical reactions and in the manufacture of acetylene using impure calcium carbide. It may also be generated when water or acids come into contact with metals containing phosphide as a contaminant, such as ferrosilicon and spheroidal graphite iron.

Aluminium phosphide is a common poison used in suicide in India where it is widely used to fumigate stored grains. When consumed, it reacts with hydrochloric acid in the stomach to liberate phosphine, where it can become an unsuspecting hazard to pathologists performing autopsies as the gas will escape when the stomach is opened. Phosphine may arise transiently in the anaerobic degradation of phosphorus-containing matter, as in marsh gas, but is otherwise rare in nature.

Aluminium or magnesium phosphide pellets are inserted into the cargo of wheat on board ships for fumigation purposes. The moisture causes a chemical reaction which releases phosphine and leaves a harmless residue of aluminium hydroxide. Peak concentrations will arise in a sealed hold during a voyage and it is necessary that the gas is dissipated by opening the hatches to the air for at least 24 hours before the cargo is discharged. Acute poisoning incidents used to be reported with grain cargoes if the gas escaped into living or working areas of the ship.\textsuperscript{172} If the cargo is too dry, the gas is liberated after the hold is opened when the phosphide pellets come into contact with moist air: workers in the mill processing of the discharged cargo can then be affected.

Initial symptoms of exposure to low concentrations of the phosphine include headache, weakness, fainting, pain in the chest, cough, chest tightness and difficulty in breathing. With prolonged exposure, nausea, vomiting and diarrhoea may occur. The main hazard is pulmonary oedema which usually occurs within 24 hours, but may be delayed for up to two days. Central nervous system signs and symptoms, progressing to convulsions, coma and death, have been reported; so too, have gastrointestinal symptoms such as nausea, vomiting, diarrhoea and severe epigastric pain.\textsuperscript{171} Unlike arsine, phosphine does not cause haemolysis, but a case of purpura ascribed to phosphine poisoning is known.\textsuperscript{169} However, some sources of exposure to phosphine may also lead to exposure to arsine whose haemolytic effects should therefore be sought. Chronic poisoning does not appear to have been recorded.
The reported maximum concentration that can be tolerated for several hours is 7 ppm. A level of 2000 ppm is regarded as rapidly fatal and the maximum exposure that can be tolerated for 30–60 minutes without serious effects is 100–200 ppm. Recovery from phosphine poisoning is usually complete.\textsuperscript{171} The evidence for genotoxic effects of phosphine in humans is inconclusive.\textsuperscript{173}

**METHYL BROMIDE (BROMOMETHANE) (CH\textsubscript{3}Br)**

[CAS No. 74-83-9]

**Exposure limits:**
- LTEL (8-h TWA) 5 ppm (20 mg/m\textsuperscript{3})
- STEL (15 min) 15 ppm (59 mg/m\textsuperscript{3})

**Relative density:** 3.36

**Flammability limits:** 10–16 per cent (but practically non-flammable)

Methyl bromide (bromomethane) is a colourless, odourless and relatively insoluble gas, but it is said to have a faintly detectable sweet odour at high concentrations. The gas has been widely used as a fumigant, but it is being phased out. It is highly toxic against mammals, insects, mites and pathogenic organisms in soil and compost.\textsuperscript{174} Thus, it has been used to fumigate soil in compost under gas-proof sheets; fruit in ships’ holds or freight containers; and in aircraft and special fumigation chambers. Fire extinguishers containing methyl bromide are no longer manufactured.

Methyl bromide is the most abundant gaseous bromine species in the atmosphere, being emitted from a wide range of natural as well as industrial sources. Atom for atom, bromine is about 50 times more effective than chlorine in destroying stratospheric ozone, and hence countries are moving to cease production and importation of methyl bromide, although it is proving difficult to find substitutes for some specialized applications.

Sporadic cases of acute poisoning may still occur but, because of its severe toxicity and low warning properties, only qualified operators are normally permitted to undertake fumigant work with this gas and they are well versed in the dangers and protective measures.

Occupational exposure is by inhalation or skin absorption. Although the hazards are well known, serious exposure incidents continue to occur due to lapses in the standard protective measures laid down for working with this gas. At low but dangerous concentrations, it has no irritating effects, thus dangerous exposure may occur without adequate warning, with onset of symptoms usually delayed from 30 minutes up to 48 hours later. Symptoms of mild exposure can come on within a few hours and include headache, eye and nose irritation, cough, nausea and malaise. At high exposures, the gas typically causes injury to the central nervous system as well as the lungs, producing headache, nausea, vomiting, pulmonary oedema (up to 30 hours after exposure), tremors and convulsions followed by coma; the convulsions may not respond to standard anticonvulsant therapy. Health effects may also arise from chronic exposure to lesser concentrations, resulting in nervous system involvement with manifestations such as numbness (especially of the feet), visual disturbance (including optic atrophy), mental confusion, psychiatric disturbances and tremor.\textsuperscript{174} Exposure above 25 ppm is dangerous and acute central nervous system symptoms with possible permanent effects on the vision, hearing and balance are reported to occur above 120 ppm. Concentrations greater than 250 ppm are associated with pulmonary oedema, coma and convulsions. Exposure of the skin to high concentrations of vapour or liquid produces erythema with blister formation and severe burns, particularly if the gas or liquid is trapped under clothing. Blisters are usually large and surrounded by areas of redness and swelling; they may take a long time to heal. Severe inflammation of the eyes induced by the vapour may lead to conjunctivitis and temporary blindness.

First-aiders must not use mouth-to-mouth resuscitation. Treatment of acute poisoning should concentrate on controlling the convulsions and, if there is no response to drug therapy, muscular paralysis and positive pressure ventilation should be considered early on. The toxic mechanism is unknown and no specific antidotes are recognized, but the administration of dimercaprol and glutathione have been suggested.\textsuperscript{174–176} Regular users of methyl bromide should notify the local hospital of the hazard and appropriate treatment measures. Biological monitoring should be undertaken by measuring serum bromide levels. According to the UK Health and Safety Executive, a level of serum bromide of 0.18 mmol/L (1.45 mg/dL) or more suggests occupational exposure, and above 0.35 mmol/L (2.8 mg/dL, equivalent to a concentration of 28 ppm methyl bromide in air) symptoms may arise, but dietary intake of bromide should also be excluded as a cause of increased levels.\textsuperscript{177} The toxic symptoms of methyl bromide are not directly related to the levels of circulating bromide and so the results must be interpreted with caution.

Methyl bromide is a mutagenic agent and is mutagenic in short-term tests, but it is not carcinogenic in rodents.\textsuperscript{178} Poisoning by methyl bromide is a prescribed disease.

**METHYL CHLORIDE (CHLOROMETHANE) (CH\textsubscript{3}Cl)**

[CAS No. 74-87-3]

**Exposure limits:**
- LTEL (8-h TWA) 50 ppm (105 mg/m\textsuperscript{3})
- STEL (15 min) 100 ppm (210 mg/m\textsuperscript{3})

**Relative density:** 1.78

**Flammability limits:** 10.7–17.4 per cent

Methyl chloride is a colourless, flammable and sweet-smelling gas which is widely used in the chemical industry, for example to produce methyl silicone polymers and resins, as a methylating agent in the production of butyl rubber and tetramethyl lead and as a blowing agent for polystyrene foams. The gas is a natural source of chlorine.
in the atmosphere, being released from the oceans and biomass burning.

The effects of methyl chloride and methyl iodide are similar to methyl bromide in that their primary target organs are the brain, liver, kidneys and lungs. All three are mutagens and potential carcinogens, and methyl chloride is a suspect occupational teratogen. However, the evidence for carcinogenicity or teratogenicity in humans is inadequate.

Because methyl chloride is almost odourless, hazardous levels of exposure may occur with little warning. In mild poisoning, there is a staggering gait, dizziness, headaches, nausea and vomiting resembling acute alcoholism, followed by recovery. In more severe poisoning, symptoms and signs include vertigo, confusion, drowsiness, seizures, ataxia and diplopia; these effects may last for weeks and even months or lead on to coma and death.

METHYL ISOCYANATE (NCOCH₃)

[CAS No. 624-83-9]

Exposure limits: as NCO
- LTEL (8-h TWA) 0.02 mg/m³
- STEL (15 min) 0.07 mg/m³
Relative density: 2

Methyl isocyanate is not a widely used chemical, but it gained worldwide notoriety after its disastrous release from the Union Carbide pesticide plant in Bhopal in India in 1984.179 It was being used in the chemical synthesis of carbaryl pesticides, and had been stored in liquid form in two steel tanks. The cause of the incident is still not known, but at 00:30 on December 3, 1984 an exothermic reaction took place in one of the storage tanks, resulting in the escape over a few hours of 40 tonnes of methyl isocyanate. A dense cloud of methyl isocyanate flowed over an area of the city about 40 km² at a time when there was a temperature inversion and a light wind. It is considered that more than 10 000 people were killed and hundreds of thousands injured in the disaster.

Respiratory involvement was the most common serious health problem, with many victims suffering breathlessness, cough, throat irritation or choking, chest pain and haemoptysis. Death was mostly from bronchial necrosis or pulmonary oedema. Eye reactions were also prominent, and included severe watering, photophobia, lid oedema and corneal ulceration.

A follow-up study of survivors after three years reported an increased risk of eye infections and hyper-responsive phenomena, possibly related to immune disturbance.180 A cross-sectional survey conducted ten years after the gas leak suggested that many survivors had symptoms commensurate with persistent small airways obstruction and with obliterative bronchiolitis.181

There was scarcely any toxicological information available on the effects of methyl isocyanate in humans at the time of the incident. Unfortunately, follow-up studies of the survivors have been too few to adequately document the potential long-term pulmonary changes, as well as the adverse effects to other organs, including teratogenicity.

ETHYLENE OXIDE (CH₂CH₂O)

[CAS No. 75-21-8]

Exposure limit:
- LTEL (8-h TWA) 5 ppm (9.2 mg/m³)
Relative density: 1.49

Flammability limits in air: 3.0–80 per cent (vol.)

The main use of ethylene oxide is as a chemical intermediate in the production of ethylene glycol, polyester fibres and detergents, but it has been used on a much smaller scale since the 1950s as a sterilizing agent for medical supplies and foodstuffs. Most hospital gas sterilizers are automatic general purpose sterilizers and many of these use ethylene oxide, the gas being mixed with dichlorodifluoromethane to reduce the flammability and explosion risk. Exposures in hospitals and production facilities in Europe and North America are today generally well controlled using exhaust systems, and air levels should be routinely monitored using sensor and alarm systems. The odour detection level is at least 500 ppm and is therefore of no value in warning the worker of significant exposure.182

Ethylene oxide is a narcotic and depresses the central nervous system, as well as being a primary irritant of the respiratory tract. Acute exposure to high concentrations leads to nausea, vomiting and headache; also reported are excitement, muscular weakness, sleeplessness and diarrhoea. Four men were exposed to an intermittently leaking sterilizer (around 500 ppm) for between two and eight weeks, and three developed a reversible peripheral neuropathy, and one reversible acute encephalopathy. Irreversible neuropathy and encephalopathy have been described in other operators of leaking sterilizers at similar levels of intermittent exposure.182

The gas condenses to a liquid at 10°C and is infinitely soluble in water. Excessive exposure to the vapour causes irritation of the eyes, while contact of the skin with even dilute solutions may cause erythema, oedema, blistering and necrosis. Allergic contact dermatitis has also been reported.

Ethylene oxide is considered to have potential for causing cancer and adverse reproductive effects in humans. It is a highly reactive epoxide and a direct alkylating agent, as well as being a recognized animal carcinogen associated with leukaemia and brain cancer in rodents. Chromosome aberrations and sister chromatid exchange have been found in studies of exposed workers. Epidemiological studies have not unequivocally demonstrated an association with human cancer, in particular of the haemopoietic system, but it is viewed as a human carcinogen by the International Agency for Research on Cancer (IARC).183,184

Medical surveillance of exposed workers using complete blood count and differential was recommended in the United States (lymphocytosis had been reported in symptomatically exposed workers), but no longer. Ethylene
oxide is a potent sensitizing agent: occupational asthma associated with measurable IgE antibodies to ethylene oxide used to sterilize latex gloves and adsorbed on to the glove powder has been reported in a healthcare worker.\textsuperscript{185}

**HEXAFLUOROACETONE (\(\text{F}_3\text{CCOCOF}_3\))**

[\text{CAS No. 684-16-2}]

*Exposure limit:*

- LTEL (8-h TWA) 0.1 ppm (ACGIH)
- *Relative density:* 5.7
- Flammability limits in air: 0.9–98.0 per cent

Hexafluoroacetone is colourless, non-flammable, fumes in moist air, and has a stale smell. It is very reactive and is used to prepare a variety of chemicals.

It is irritating to mucous membranes and especially to the lung. Chronic exposure has been shown to lead to cumulative effects in the testes, kidney and bone marrow of experimental animals. It is teratogenic in rats.

**DIBORANE (\(\text{B}_2\text{H}_6\))**

[\text{CAS No. 19287-45-7}]

*Exposure limit:*

- LTEL (8-h TWA) 0.1 ppm (0.12 mg/m\(^3\))
- *Relative density:* 0.96
- Flammability limits in air: 0.9–98.0 per cent

As well as a doping agent for semiconductor manufacture, diborane has uses in organic syntheses and in rocket fuel. It is a colourless gas with a sickly sweet odour. The ability to detect the odour is rapidly lost with exposure. It is spontaneously flammable in air, but because its ignition temperature (40–50°C) is above room temperature it may remain for several days in air at room temperature without igniting. Diborane is used as a dopant gas, a catalyst in polymer manufacture, and as a rubber vulcanizer. It is hydrolysed to boric acid in the moisture of the respiratory tract and exposure can cause dizziness, headache, drowsiness, chest tightness, cough and nausea. Severe poisoning with boranes is marked by convulsions and pulmonary oedema. The gas is also irritant to the eyes and skin and should be treated with the same respect as phosgene or chlorine.

The other boron hydrides are pentaborane and decaborane. These are more toxic than diborane and they can be readily absorbed by the skin and conjunctivae, as well as by inhalation. Boranes are neurotoxic.

**NICKEL CARBONYL (TETRACARBONYLNICKEL) (\(\text{Ni(CO)}_4\))**

[\text{CAS No. 13463-39-3}]

*Exposure limit:* as nickel
- LTEL (10 min) 0.1 mg/m\(^3\)
- *Relative density:* at 50°C, 5.95
- *Lower flammability limit in air:* 2 per cent (vol.)

Nickel carbonyl is actually a liquid with a boiling point at 43°C, but its vapour is highly toxic. It has a ‘brick dust’ odour detectable at 1–3 ppm. Nickel carbonyl is prepared by passing carbon monoxide over finely divided nickel. In the Mond process, the gas is used to isolate nickel from its ore. The effects of occupational exposure to nickel carbonyl have only been documented in workers engaged in the Mond process which has also been associated with an elevated incidence of carcinoma of the nasal cavities, lung and pharynx.

Acute inhalation effects of nickel carbonyl fall into two categories, immediate and delayed. The immediate response includes headache, dizziness, nausea, vomiting and dyspnoea, which may resolve within a day in mild cases on removal from exposure. The worker should be kept under observation or admitted to hospital because symptoms of pulmonary oedema may arise 12–120 hours after exposure. The patient becomes febrile and cyanosed with a rapid pulse and develops a leukocytosis. Delirium may precede other central nervous system changes, such as cerebral oedema. Death may follow in 4–11 days after exposure. Exposure to 30 ppm for 30 minutes is said to be potentially lethal in humans.

Nickel carbonyl is rapidly absorbed by the lungs and nickel levels rise in the blood and urine soon after exposure. Measurement of nickel in the blood and urine is an important guide for diagnosis and management. In severe cases, therapy with chelating agents to remove nickel from the body is recommended (e.g. disulfiram), as well as treatment with oxygen and corticosteroids. Concomitant poisoning by carbon monoxide from the Mond process should be excluded by measuring carboxyhaemoglobin.\textsuperscript{186}

Poisoning by nickel carbonyl is a prescribed disease.

### GASES WITH MAINLY ANAESTHETIC ACTION: GENERAL ANAESTHETICS

The inhalational anaesthetics consist of gases and volatile liquids. The first deliberate use of an inhaled gas to produce anaesthesia for the performance of surgical operations was in animals, being carried out by Henry Hill Hickman in 1823 using carbon dioxide, but his work went unrecognized by medical opinion at the time. (Later in the century, carbon dioxide was tried out on humans, but was found to be unsuitable as it induced convulsions at anaesthetic concentrations.) The first general anaesthetic to be used in surgery was diethyl ether in 1846 by William Morton in the Massachusetts General Hospital and later that year in a leg amputation performed by Robert Liston at University College Hospital, London. This agent was subsequently replaced by chloroform as the most widely used inhalational agent following its introduction by Sir James Simpson and John Snow in 1847. Snow was later to achieve fame in public health when he ordered the removal of the Broad Street pump handle in the cholera epidemic of 1854. Joseph Priestley discovered nitrous oxide in 1772 and in 1800 Humphrey Davy had proposed the use of the gas as an anaesthetic: surprisingly, it was not adopted until much
Gases with mainly anaesthetic action

later. Cyclopropane was popular for induction anaesthesia in children until the 1980s.

As for volatile agents, trichloroethylene later became popular in obstetrics, but it has now been discontinued in the United States and in the United Kingdom. Since 1956, the CFC halothane (CF3CHClBr) has been one of the most popular agents. Isoflurane has been used since 1971 and, because about 2 per cent of the gas inhaled is biotransformed compared with 18 per cent of halothane, it is considered safer for patients. Other agents in use are enflurane and the newer agents, desflurane and sevoflurane. Fluorinated anaesthetics undergo metabolic breakdown in the liver to inorganic fluoride with potential for nephrotoxicity, but this is not a consideration for the occupational exposure of anaesthetists. Airway irritation may occur in patients with halogenated anaesthetics particularly when used for inhalation induction of anaesthesia.

Most concern over the health effects of anaesthetic gases has centred on the hazard to the reproductive system in anaesthetists and operating theatre staff. This was first highlighted in 1968 in a report describing a marked increase in spontaneous abortions among a group of female anaesthetists in the former USSR. The combined results of subsequent epidemiological studies in Denmark, the United States and the United Kingdom seemed at first to confirm this finding and in addition raised the possible risk of congenital abnormalities in pregnant women and in the offspring of male anaesthetists. In 1976, the UK Department of Health released a circular advising the use of scavenging systems in operating theatres. By 1980, the considered opinion was that spontaneous abortions in operating room staff were likely to be linked with exposure to inhalational agents. However, in the mid-1980s detailed evaluation of the evidence available then did not show support for any of the risks raised. The current prudent view is that exposure to anaesthetic gases should be kept to a minimum and active or passive scavenging should be incorporated into operating theatre design (Figure 39.11). A meta-analysis of the epidemiological studies based on data in the pre-scavenging era indicated an increased risk of spontaneous abortion. Some of the earlier reports of adverse reproductive outcome may have been related to much higher exposures than occur today. Even now, high levels of nitrous oxide can be achieved in poorly ventilated delivery rooms where a mixture of half nitrous oxide and half oxygen (Entonox, BOC Gases) is used for analgesia. These high levels could impair mood and cognitive functions in staff, but in a study of more typical average time-weighted exposure levels (nitrous oxide 58 ppm and halothane 1.4 ppm average) no changes were found. However, high levels of nitrous oxide may impair fertility in female staff.

Suspicion that the health of anaesthetists is poorer than other medical specialists keeps recurring and studies have suggested a higher risk of suicide, lymphomas and reticuloendothelial tumours, as well as an increased rate of early retirement on grounds of ill health. A mortality study of British anaesthetists found a doubling of deaths from suicide compared with other men in social class 1, but the rate was not significantly different from that among doctors as a whole. It may be speculated that adverse health effects could be related to job factors, such as sustained mental stress, long hours or inadequate time to rest and eat.

Occupational hygiene studies in the UK showed that the geometric mean time-weighted average exposure to nitrous oxide among anaesthetists is 94 ppm in unscavenged theatres compared with 32 ppm in scavenged theatres, the corresponding means for halothane being 1.7 ppm and 0.7 ppm. Active scavenging systems are much more effective than passive ones. A further study by the Health and Safety Executive in 14 veterinary practices showed similar results, although the duration of exposure of veterinarians and nurses was shorter than in hospital operating room

Figure 39.11 Wall gas connections for operating theatre anaesthetic gas machine showing scavenging outlet.
staff; halothane is the most common inhalational agent used in veterinary practice. Dental practices may also operate with inhalational agents for only a few hours a week. A high level of efficient forced general ventilation is important for reducing exposure levels by removing contaminants not handled by scavenging. Leakages readily occur from mask use, and intubation is to be preferred whenever it is clinically feasible.

Occupational exposure standards for anaesthetic gases were introduced in the UK in 1996, and these are equally applicable to manufacturing facilities, as well as hospitals. These are (8-h TWA): halothane 10 ppm (82 mg/m³), enflurane 50 ppm (383 mg/m³) and isoflurane 50 ppm (383 mg/m³). As anaesthetic gases are toxic agents, they all call for consideration under the Control of Substances Hazardous to Health Regulations. In hospitals, compliance with the occupational exposure standards is achievable through balanced supply and extract ventilation with high rates of air change in, for example, delivery rooms and recovery areas, as well as by the use of gas scavenging equipment in operating theatres.

NITROUS OXIDE (N₂O)

[CAS No. 10024-97-2]
Exposure limit:
  LTEL (8-h TWA) 100 ppm (183 mg/m³)
Relative density: 1.5

Nitrous oxide is a stable, toxic gas which has been shown experimentally to interfere with DNA synthesis by inactivating vitamin B₁₂, a coenzyme for methionine synthase activity. It is normally used for short periods, as in intensive care, because it may cause megaloblastic changes in the bone marrow if exposure goes on for longer than 24 hours. Excessive occupational exposure to the gas in dentists has been reported to cause measurable bone marrow changes from depression of vitamin B₁₂ activity. Agranulocytosis and subacute combined degeneration of the spinal cord have also occurred after repeated exposure in patients. Experimental studies of nitrous oxide in animals indicate that at subanaesthetic levels it may reduce fetal weight and growth, but there is no evidence of teratogenicity or mutagenicity. However, a study of female dental assistants suggested that exposure to high levels of unscavenged nitrous oxide may impair fertility as measured by an increased time before conception. Nitrous oxide neuropathy has been reported in abusers of the gas. Abusers may develop addictive behaviour, tolerance and psychological dependence, and anaesthetists are an at-risk group because of their access to the gas. Deaths have occurred in healthcare workers who have tried to obtain a ‘high’ without using supplementary oxygen. (Nitrous oxide abuse has also been reported in the restaurant trade where it is used in power-whipped cream dispensers and as a non-tainting foaming agent for dairy products.) Overall, there is no convincing evidence that exposure to nitrous oxide in the workplace has caused developmental defects in the fetus or any other reproductive health effects, but this lack of evidence should not foster complacency in its usage.

Other common anaesthetically active gases

ACETYLENE (ETHYNE) (C₂H₂)
[CAS No. 74-86-2]
Exposure limit: not established
Relative density: 0.9

Acetylene is a colourless, highly flammable gas. It is regarded as a simple asphyxiant, but marked intoxication will occur at 20 per cent mixture in air. Very pure acetylene has a pleasant sweet smell, but commercial acetylene smells of garlic. It burns at a very high temperature with oxygen, up to approximately 3500°C.

Acetylene is used in the manufacture of many organic chemicals and polymers. Its fierce flame is used for oxyacetylene cutting and welding and wherever there is an application for great heat.

CYCLOPROPANE (C₃H₆)
[CAS No. 79-19-4]
Exposure limit: 400 ppm (ACGIH)
Relative density: 1.4

Cyclopropane is colourless, flammable and smells like ether. It is used for chemical synthesis and was popular as a general anaesthetic, mainly in children.

DIMETHYL ETHER (CH₃OCH₃)
[CAS No. 115-10-6]
Exposure limits:
  LTEL (8-h TWA) 400 ppm (766 mg/m³)
  STEL (15 min) 500 ppm (958 mg/m³)
Relative density: 1.6

Dimethyl ether is colourless, flammable and is used as a refrigerant and as a fuel gas in welding. It has a lesser anaesthetic action than diethyl ether.

METHYL VINYL ETHER (CH₃OCH:CH₂)
[CAS No. 109-92-2]
Exposure limit: not established
Relative density: 2.0

The principal physiological effect of this gas is its anaesthetic action, but it is much less than that produced by dimethyl ether.

2,2-DIMETHYL PROPANE C(CH₃)₄
[CAS No. 463-82-1]
Exposure limit: not established
Relative density: 2.5

The principal physiological effect of this gas is its anaesthetic action, but it is much less than that produced by dimethyl ether.
2,2-Dimethyl propane is a colourless, flammable gas. It is used in the manufacture of synthetic rubber.

**ETHANE (CH\(_3\)CH\(_3\))**

[CAS No. 74-84-0]  
*Exposure limit:* not established  
*Relative density:* 1.0

Ethane is colourless, odourless and flammable. It is regarded as a simple asphyxiant, and is used as a low temperature refrigerant and an anti-knock agent.

**ETHYL CHLORIDE (CHLOROETHANE) (C\(_2\)H\(_5\)Cl)**

[CAS No. 75-00-3]  
*Exposure limits:*  
  - LTEL (8-h TWA) 50 ppm (124 mg/m\(^3\))  
  - STEL (15 min) 750 ppm (1810 mg/m\(^3\))  
*Relative density:* (gas) 2.2

Ethyl chloride is colourless and flammable, with an ethereal odour. It is used as a refrigerant, a local spray anaesthetic and as a specialized solvent. At 40 000 ppm (4 per cent) it produces stupor and eye irritation almost at once.

**ETHYLENE (CH\(_2\)CH\(_2\))**

[CAS No. 74-85-1]  
*Exposure limit:* not established  
*Relative density:* 0.98

Ethylene is a colourless, flammable and sweet-smelling gas which is regarded as a simple asphyxiant. It is used in horticulture for ripening fruit and increasing plant growth rates, and in specialized welding. It is an important feedstock in the production of ethylene oxide and many polymers.

**ISOBUTANE (CH(CH\(_3\))\(_3\))**

[CAS No. 75-28-7]  
*Exposure limit:* not established  
*Relative density:* 2.1

Isobutane is the simplest isoalkane. It is a colourless, flammable gas which is mainly used as an intermediate in the production of aviation fuel and various organic chemicals.

**ISOBUTYLENE ((CH\(_3\))\(_2\)CCH\(_2\))**

[CAS No. 75-28-5]  
*Exposure limit:* not established  
*Relative density:* 1.9

Isobutylenes are colourless, flammable gas used in the manufacture of butyl rubber.

### Liquefied petroleum gases

**N-BUTANE (CH\(_3\)CH\(_2\)CH\(_3\)CH\(_3\))**

[CAS No. 106-97-8]  
*Exposure limits:*  
  - LTEL (8-h TWA) 600 ppm (1450 mg/m\(^3\))  
  - STEL (15 min) 750 ppm (1810 mg/m\(^3\))  
*Relative density:* 2.1  
*Flammability limits:* 1.8–8.4 per cent (vol.)

Butane is a colourless, flammable gas with a mild aromatic odour, widely used in the petrochemical industry and as a fuel.

**PROPANE (CH\(_3\)CH\(_2\)CH\(_3\))**

[CAS No. 744-98-6]  
*Exposure limit:* not established  
*Relative density:* 1.5  
*Flammability limits:* 2.2–9.5 per cent (vol.)

Propane is colourless and flammable. It is widely used as a fuel gas, in welding, as a solvent and as a refrigerant.

**PROPYLENE (CH\(_3\)CHCH\(_2\))**

[CAS No. 115-07-1]  
*Exposure limit:* not established  
*Relative density:* 1.5  
*Flammability limits:* 2.0–11.1 per cent (vol.)

Propylene is a colourless, flammable gas. It is a widely used chemical feedstock. On July 11, 1978 a road tanker carrying liquefied petroleum gas ran into the Los Alfaques camping ground on the east coast of Spain and overturned, with the fuel that remained in liquid form flowing over the campsite. Ignition of the fuel soon occurred forming an open flammable cloud fire. One hundred and two people died on the site, and there were 148 casualties with burns, at least 122 of whom were severe, requiring urgent hospital treatment.

**VINYL BROMIDE (CH\(_2\)CHBr)**

[CAS No. 693-60-2]  
*Exposure limit:* not available.  
*Relative density:* 3.79  
*Flammability limits:* 9–14 per cent (vol.)

Vinyl bromide is a colourless, flammable gas with a pleasant smell. It is a chemical intermediate, a flame retardant and is used to manufacture acrylic fibres. Easily polymerized, it is used as a fire retardant in plastics. It behaves like an anaesthetic gas, inhalation of very high concentrations leading to coma and death. Liquid splashes are irritant to the eyes and skin. The gas is mutagenic and induces liver angiosarcoma and hepatocellular carcinoma in laboratory animals exposed through inhalation; it is regarded as ‘probably carcinogenic to humans’ by the IARC.
The main use of vinyl chloride monomer (VCM) is to manufacture PVC, the most widely used plastic polymer. Production took off after the Second World War. Polymerization is a batch process undertaken in autoclaves. In the past, workers entered the autoclaves after each batch to clean them from inside; unfortunately, VCM was regarded as very safe and many workers failed to use adequate respiratory protection. As a result, very high levels of exposure to VCM occurred until 1974, when the first human cases of angiosarcoma of the liver were reported in these heavily exposed workers.

Health problems associated with these high exposures had begun to be recognized in the mid-1960s. Acro-osteolysis typically affected the terminal phalanges of the hands, giving rise to ‘pseudo-clubbing’, with clinical and radiological appearances which resemble those seen in some patients with hyperparathyroidism. Other bones could also be affected by osteolysis. Scleroderma and Raynaud’s phenomenon were also reported. These three conditions are now considered to be able to arise independently of one another with VCM exposure.

Animal studies were undertaken to reproduce osteolysis experimentally and these unexpectedly led to the discovery that VCM caused angiosarcoma of the liver, with the first report of the tumour in VCM workers emerging from the United States in 1974. Since then, many cases associated with the industry have been reported worldwide. Angiosarcoma of the liver is an extremely rare tumour in the general population, but sporadic cases without obvious causal factors arise in all age groups. Almost all of the occupational tumours have been reported in highly exposed VCM autoclave workers, although many other chemical workers had some contact with VCM before its dangers were known and its usage came under strict control (in 1974 in the United Kingdom and the United States). Hepatic injury from this chemical also produces non-cirrhotic periportal fibrosis and portal hypertension. Workers exposed in the PVC manufacturing industry before 1974 are at potential risk of manifesting these problems.

The adverse effects of VCM are unlikely to be seen arising from present-day working conditions in the United Kingdom and the United States, but an increasing number of workers worldwide are exposed to VCM, many of whom live in countries where exposure is less strictly regulated. Chemical firms should ensure that general practitioners retain a history of exposure to VCM in the individual’s medical record, in case they develop symptoms that could be referable to VCM exposure. There are, however, no valid routine screening tests of use in the early detection of angiosarcoma of the liver or periportal fibrosis, including special imaging. There is presently insufficient evidence to implicate VCM exposure in humans as a causal factor in primary cancers at other sites such as lung and brain.

In the United Kingdom, angiosarcoma of the liver (but not hepatocellular carcinoma), osteolysis, VCM-related Raynaud’s phenomenon and VCM-related scleroderma are all independently prescribed diseases.

Heating plastic packaging film will form thermal degradation products which may be associated with symptoms known as ‘meat wrappers’ asthma’. All heated plastics will generate carbon monoxide, but PVC also gives off hydrogen chloride and plasticizers such as di-octyl phthalate and di-octyl adipate. The polyolefin plastics (polyethylene and polypropylene) can produce formaldehyde and acrolein. The degradation products are normally quickly dispersed and diluted, but attention needs to be paid to the correct operation of manual heating sealing machines to ensure temperature regulation, and the cleanliness and maintenance of the sealing head. Inhalation incidents have been reported in PVC film manufacture if the film is accidentally overheated.

VINYL FLUORIDE (CH₂CHF)

[CAS No. 75-02-5]
Vinyl fluoride, a chemical intermediate, is regarded as ‘probably carcinogenic in humans’ by the IARC.

GEOTHERMAL POWER

The possibility of using hydrothermal energy to produce heat and electricity arises in parts of the world where there is active volcanism or where magma (liquid rock) lying close to the Earth’s surface forms shallow bodies of hot rocks and fluids (Figure 39.12). The world’s first geothermal steam field was built at Larderello, Italy, in 1904 and today the world’s largest, the Geysers, California, produces nearly 2000 megawatts of electricity. In Reykjavik, Iceland, all the hot water needs of the city are provided by geothermal sources.

The occupational and environmental problems of utilizing geothermal power must be assessed separately in different parts of the world as the technology needed to generate electricity from steam turbines using geothermal energy and the toxic compounds arising in geothermal fluids may vary widely. In the steam fields in Utah and California, hydrogen sulphide, ammonia, carbon dioxide, methane and radon-222 are the chief gases emitted. Of these, hydrogen sulphide is the most important, but in fields elsewhere in the world it may be only a minor component. Leaks from geothermal steam wells may expose workers to gases and toxic compounds, such as mercury, arsenic, boron, selenium, lead, cadmium and fluoride. Steam leaving turbines is passed through a condenser and it is the ‘non-condensable’ gases and toxic compounds that
Geothermal power will enter cooling towers and a proportion of these will escape into the air (Figure 39.13). The drift from the cooling tower may waft around and be deposited in the vicinity. Workers may also be exposed to hazardous gases and entrained substances from leaks inside the plant or by working on or near drilling rigs. Carbon dioxide may pose a risk of asphyxiation in confined spaces, and accidental blow-outs of wells can occur.

Figure 39.12 The Icelandic Diatomite Plant at Lake Myvatn uses geothermal steam to dry algal deposits dredged from the lake bottom, and power is fed directly from the nearby Krafla geothermal power plant. Elsewhere in the world, diatomaceous earth (kieselguhr) is obtained by open-cast mining.

Figure 39.13 Steam venting from a geothermal power plant in Tuscany, Italy. Mount Amiata is an extinct volcano where mercury ore was mined until 1980.

Key points

- Inhalation incidents involving gases are still common in industry in all countries.
- Chlorine remains the most common gas stored under pressure and is the most frequent gas cited in major toxic hazard planning.
- Gases, such as carbon monoxide, hydrogen sulphide and nitrogen dioxide can present as occupational hazards in a wide range of settings and a high degree of vigilance is needed.
- Anaesthetic gases are potential health hazards if exposure to healthcare workers is not adequately controlled.
- Workers in emerging economies may still be exposed to the carcinogenic hazards of gases, such as vinyl chloride, and the risk of explosion disasters from the build up of flammable gases in deep mines.

Reactive airways dysfunction syndrome and irritant-induced asthma

JON G AYRES

INTRODUCTION

Exposure to chemicals or gases in the workplace during a spill or leak can lead to acute severe pulmonary injury and at high concentrations to death through alveolar leak and pulmonary oedema, the classic example being silo-filler’s disease due to nitrogen dioxide, or acute pneumonitis/chemical pneumonia. In these cases, the exposure is clear, the effects immediate and often devastating and the long-term prognosis is usually easy to determine. However, such exposures can lead to effects which are less life-threatening and the term ‘reactive airways dysfunction syndrome’ (RADS) was coined by Brooks in 1985 to describe a syndrome of respiratory symptoms occurring after chemical or gas exposure in the workplace.

TERMINOLOGY AND DEFINITIONS

Brooks used the term ‘RADS’ to define an asthma-like state occurring shortly after a high exposure to a chemical or gas, usually in the workplace. He described fairly strict criteria for the definition of RADS describing it as an asthmatic-like state occurring within 24 hours of an acute, very high-dose exposure and which was characterized by the presence of bronchial hyper-responsiveness to methacholine in an individual with no pre-existing lung disease. However, in the early 1990s the issue of persistent (repeated) lower-dose exposure to chemicals or gases resulting in airways disease was raised. As a consequence, in 1995 a consensus statement on asthma in the workplace recommended that the term ‘irritant-induced asthma’ (IIA) could be used in this context embracing both classical RADS and the consequences of lower-dose exposures. This was achieved by relaxation of the Brooks’ RADS criteria to produce the following more comprehensive criteria:

- absence of previous respiratory complaints;
- onset of asthma symptoms within 24 hours of a single exposure to a high concentration of respiratory irritant gas (or by implication a fuming chemical);
- persistence of asthma symptoms for at least three months after exposure;
- symptoms associated with increased bronchial responsiveness and/or the presence of airflow obstruction with reversibility to bronchodilator in the absence of previous lung disease.

This definition covers all forms of IIA, including classical RADS and low-dose exposure to irritants over time. This issue of a changing definition was highlighted in a review of this area where it was recognized that in a number of reported cases authors included multiple acute exposures as causing IIA, some allowing up to a week after exposure for the onset of symptoms to occur, and some allowing lesser degrees of exposure – so-called low-dose RADS or ‘not so sudden IIA’ in their definition of IIA. The possibility of exposures such as those which are recognized to lead to RADS/IIA could cause a stepwise worsening of patients with pre-existing respiratory disease is equally plausible, perhaps even more so, but does not fall under these definitions. However, in the context of considering the health effect of the specific ambient exposures considered here
this should be regarded as possible although difficult to prove particularly where litigation is an issue.

The likelihood that repeated exposure to chemicals or gases might cause more than simple short-term irritancy symptoms and to more established airways disease fits with reports of asthma developing in cleaners and workers exposed to solvents and with the finding that 18 per cent of cases of occupational asthma reported to the SHIELD scheme in the West Midlands were due to irritants such as cleaning agents. A wider European survey also showed similar associations between persistent respiratory symptoms (cough, wheeze and breathlessness) in workers exposed to irritants. In the occupational setting, small but above normal exposures have been reported to result both in accelerated fall in FEV\(_1\) over time and enhanced bronchial responsiveness.

### EPIDEMIOLOGY

#### Prevalence

Because of the variation of definitions over the time since RADS was first described, clear information on the epidemiology is difficult to secure, in particular in terms of prevalence and prognosis. Much of the published literature in this area has been as case reports or short case series which do not allow prevalence data to be defined, although do identify causal agents. Depending upon the diagnostic criteria used, estimates of the prevalence of RADS or IIA range from 2 to 3 per cent to 18 per cent from the UK’s SWORD reporting scheme to 23 per cent for a range of occupational populations, although most estimates lie in the 3–6 per cent range. Even then, there are issues with what population to use as a denominator – the total workforce exposed or the total workforce within that industry, although using those exposed as the true denominator is logistically better when reporting a series and more logical as those unexposed will not have had the chance to develop symptoms. For example, one report of approximately 3000 people exposed to a pesticide spill (metam sodium: monoalkyl dithiocarbamate which part decomposes to methyl isocyanate) showed that 30 individuals (1 per cent of those exposed) fulfilled the criteria for IIA. In this study, the authors included those with exacerbation of pre-existing asthma, which again raises the issue of variation in diagnostic criteria.

#### Causal agents

The most important causal agents are gases, with chlorine the most reported, but including also sulphur dioxide and nitrogen dioxide, a pattern which applies to both RADS and IIA. Between 1989 and 2003 in the United Kingdom, over 330 cases of chlorine exposure causing respiratory symptoms were reported to the SWORD database, mostly as inhalation accidents, but 69 (20 per cent) of those exposed to chlorine were reported to have developed asthma as did 26 (20 per cent) of those exposed to hydrochloric acid. The occupational group in which exposures were most likely to occur was chemical, gas and petroleum operators (10 per cent for chlorine, 8.5 per cent for hydrogen chloride). In some cases, the exposure is not simple, the best example being those individuals developing RADS who were rescue workers at the World Trade Center disaster, where no clear individual causal agent could be implicated, although alkalinity of the aerosol (pH 10) might have played a part. While the majority of cases of RADS and IIA (around 80 per cent) occur in the workplace, a significant number occur in the home or in the wider environment. As most of these events are reported post hoc, it is very rare for measured levels of exposure to have been reported so attempts at dose–response relationships are not possible.

### Risk factors

The most important causal factor is the dose of the agent, as the nearer individuals are to a spill the greater is the risk of developing RADS which was also the key factor in determining the risk of developing RADS after exposure to World Trade Centre dust. Characteristically, males are more represented in the RADS literature with approximate gender equality for IIA, the average age for both being in the late 30s. Atopy does not appear to be a risk factor, although in much of the literature, atopy was not reported which makes generalizations insecure. Whether current cigarette smoking is a risk factor for either RADS or IIA is unclear.

### CLINICAL PICTURE

In someone with RADS, by definition, symptoms should begin within 24 hours of exposure, although in some for whom there is good evidence for causality there is delay in onset of symptoms of a few days. This is likely to be due to acceptance of minor symptoms as ‘normal’ or to the fact that the development of inflammation in some individuals is only at a later stage sufficient to induce symptoms. Symptoms are dominated by breathlessness and cough which are reported in over two-thirds of cases, but wheeze and chest tightness are reported in just under a half. Upper airway irritation, eye irritation and mucus production are seen in fewer cases, usually between 10 and 20 per cent. Clinical signs if present are non-specific with only occasional wheeze being heard in some cases. Lung function in RADS is either normal or shows a mild obstructive pattern, whereas in IIA (when recorded, which is more often the case not reported) lung function is more likely to be normal. In some affected individuals, particularly those in whom cough is the main symptom, good quality lung function can be impossible to obtain, as forced expiration results in coughing before expiration is complete. Bronchodilator reversibility has not often been recorded in
these individuals, although frequently symptomatic relief over short time periods is reported by patients with use of beta-agonist bronchodilators.

Vocal cord dysfunction (VCD) may also be present following single exposures, a diagnosis which is difficult to make. Clinically, individuals complain of wheezy breathlessness or cough, classically inspiratory and often with inspiratory or throat tightness. Dysphonia is a common associated complaint. Diagnosis is made by direct laryngoscopy while inhaling an irritant which the individual knows will cause symptoms, the classical appearance being paradoxical adduction of either the false or true cords (or both). Deformation of the flow volume loop with truncation of the expiratory peak and flattening of the inspiratory limb if found is a helpful finding, although in most cases this test is normal.

Treatment of VCD is based on that used in conventional asthma therapy largely depending on inhaled steroids and relief beta-agonists, but the response is often poor. One study found that patients with RADS showed considerably less improvement when treated with inhaled β₂-agonists alone than did patients with classical sensitization-associated occupational asthma with a latency period. In the reported literature, around one-third of patients are reported to be taking inhaled steroids which would support the view that they may have limited benefit. The role of oral steroids is debatable, although anecdotally they may be of some help; supportive evidence for benefit has been demonstrated in a mouse model.

Treatment of IIA has not been subject to critical assessment, but the condition is often more refractory to conventional asthma treatment much as in classical RADS. Treatment of VCD is also difficult, as inhaled therapy is rarely effective.

PROGNOSIS

In classical RADS, the tendency is for improvement to occur over time, although in many individuals symptoms continue for years. There is much less evidence about what happens with IIA more broadly, although the impression is that this is a much more permanent state of affairs. However, there are as yet no longitudinal studies of outcome in either of these particular groups. Prognosis can be assessed by persistence of symptoms or by changes in measures of bronchial hyper-responsiveness. Overall, duration of symptoms is poorly recorded in the literature often because the case was reported before symptoms had ceased, the reason for publication being the need to report the causal agent before the long-term outlook had become clear. Consequently, attempts to define likely average duration of symptoms or rates of change in symptoms over time for prognostic purposes should be regarded with caution. However, in one follow-up study, normalization of both FEV₁ and PC₂₀ to methacholine was seen in approximately a quarter of subjects two and a half years post-exposure. This makes advice on return to work difficult although it appears that, in contrast to individuals with occupational asthma, patients with RADS do not necessarily develop a recurrence of their symptoms when re-exposed to a low level of the substance that initiated their problem. Consequently, a worker with RADS may be able to return to work if they can tolerate the prevailing exposure levels in their workplace.

PATHOLOGY

Thus, both single high-dose and repeated lower-dose exposures to relevant agents (alone or as complex mixtures) may result in persistent airway symptoms, but whether this is through the same mechanism(s) is not known. Cumulative exposure over years may result in a chronic inflammatory response, but while there is some suggestion that in RADS histologically there is less eosinophilic infiltration and more fibrosis, general such differences are difficult to interpret as the reported literature on the histology of RADS is very limited. Nevertheless, the pattern of relative steroid resistance might suggest a condition which in some individuals may be more akin to the picture of chronic obstructive pulmonary disease or bronchitis than to asthma.

It is possible that specific exposures, such as exposures to chlorine, may induce specific pathological responses. One worker underwent bronchial biopsies on four occasions following exposure to chlorine. The histology revealed initial epithelial desquamation with a fibrinous exudate followed later by proliferation of basal cells, subsequent regeneration of the epithelium leading to collagen deposition in the submucosa and basement membrane thickening, which might explain the attenuated airflow reversibility seen in RADS. Animal models have confirmed these stages but, interestingly, inflammatory cells do not seem to play an essential role. However, this proposed model is not consistently supported in larger studies. There is no information on the histopathology of RADS occurring in rescue workers involved in the World Trade Center disaster.

Key points

- Reactive airways dysfunction syndrome and irritant-induced asthma are linked conditions associated with single high exposures or repeated lower-dose exposures to a range of substances, most commonly such as chlorine and chemicals.
- More than 60 agents have now been implicated in the development of these conditions. In some cases, the acute exposure was to a mixture of substances where the mixture itself rather than any specific single component may have been the driver of effect such as has been suggested for workers exposed during the World Trade Center disaster.
● These conditions are likely to be more common than is usually believed, but information on outcome is limited.
● The prognosis is poorly understood with relatively little information available to advise employees affected by the condition and their employers.
● The response to anti-asthma therapy is disappointing with limited benefit from inhaled steroids, but good short-lived relief from short-acting bronchodilators.

Deliberate use of chemicals in warfare and by terrorists

ROBERT L MAYNARD

INTRODUCTION

The use of chemicals as a means of causing deliberate injury or death has a long history. Until the First World War, chemicals, though often used or considered for use, had had little impact on the outcome of battles. This was because the compounds used lacked toxicity and the means available for distributing them were primitive. Irritant substances, e.g. ethylbromoacetate and chloracetone, were deployed by French forces in 1914 with little effect, but on April 22, 1915 German forces launched the first and perhaps most successful large-scale attack with chemicals yet recorded. The chemical used was chlorine: released from cylinders brought up to the front line and making use of a favourable wind. One hundred and sixty-eight tons of chlorine were discharged from 5730 cylinders along a 6-km front at Ypres. The effect was very significant: the gas was effective for up to 5 km downwind and 15 000 casualties, including 5000 dead, were produced.1 French troops retired in disorder. This attack was allegedly completely unexpected, although Alan Clark throws doubt on this in his work, The donkeys.2 He records that the Bulletin of the French Army (March 30, 1915) and later reports (April 15 and 16) suggested that a gas attack by German forces was being prepared. Such warnings were clearly ignored and unprotected troops were exposed. Never again was a single gas attack so effective: protective equipment and drills were rapidly developed and by the end of the First World War, although phosgene and sulphur mustard were used on an extraordinary scale, there was never any likelihood of gas producing a breakthrough at well-defended locations. The scale of use of chemicals in the First World War is often forgotten: in all, about 113 000 tons of chemicals were used, including 12 000 tons of mustard gas (sulphur mustard). Despite their lack of effectiveness as far as winning battles was concerned, chemicals produced many casualties: up to 400 000 mustard gas casualties in all, with 14 000 British mustard gas casualties produced during the first three months of use of this weapon beginning on June 12, 1917, again at Ypres.

Italian forces used sulphur mustard against unprotected Ethiopian troops in 1936: again this resulted in many casualties. Iraq used sulphur mustard against Kurdish civilians in the 1980s: casualties were treated in a number of European cities, including London; the author was involved in their care.

Organophosphorus compounds (nerve agents) were produced on a large scale in Germany during the Second World War. These compounds were much more toxic than First World War chemical weapons: the LD50 of sarin (GB) being about 0.01 mg/kg i.v. and that of VX about 0.007 mg/kg i.v. However, these weapons were not used despite great urging by senior members of the German Government. No satisfactory explanation for their not being used has been produced. A lack of material is not the explanation: 12 000 tons of Tabun (GA) were produced by Germany. Nerve agents were used by Iraq during the Iran–Iraq war and against Kurdish unprotected civilians at Halabja. As would be expected, this resulted in many deaths. Thereafter, little was heard of these agents until 1995 when sarin (GB) and VX were used by terrorists in Japan. These incidents are considered in detail below.
What lessons can be learned from the above history? It is clear that chemicals have great potential as weapons, that this is known and that a number of groups (nations and terrorists) have sought to use them in this way. It is also clear that chemicals are likely to be most effective against unprotected troops or civilians. That chemicals would be used on a large scale in war seems unlikely, indeed attempts to destroy chemical weapons and to prohibit their use are proceeding rapidly. Those at greatest risk today are probably civilians targeted by terrorist groups and, importantly, those asked to rescue victims and care for them. It is with this aspect of the deliberate use of chemicals to cause injury and death that this chapter deals.

**TERRORISM**

Terrorism is by no means a recently developed activity. Terrorist organizations see themselves as fighting for a cause and, in general, may not feel bound by international agreements regarding the 'normal usages of warfare'. In particular, terrorist groups may show little reluctance regarding attacks on civilians and, indeed, may focus on these rather than on better protected military targets. The range of weapons available to terrorist groups is wide: explosives being the most frequently used. That chemicals have been so little used is difficult to explain: access to chemicals by purchase or theft is not difficult and dispersion of chemicals can be readily managed. Though it may be unprofitable to speculate as to why chemicals have not been much used, it would be decidedly unwise to ignore the possibility that they could be used and to fail to prepare to deal with the consequences of their use. The incidents in Japan are likely to have been noted and perhaps studied by other terrorist organizations. Recent events (early–mid 2007) in Iraq suggest that bulk carriers of chlorine have been targeted by terrorist groups. A completely successful defence against the use of chemicals by terrorists is difficult or perhaps impossible to achieve: this, again, makes preparations for dealing with the consequences of such use importance.

**Chemicals that might prove attractive to terrorists**

It will be understood that all countries which perceive that they may be at significant risk of attack by terrorists will have prepared lists of chemicals that they anticipate might be used. Such lists are, for obvious reasons, classified and no attempt will be made here to predict their contents. However, it is obvious to all, including, presumably, terrorist organizations, that the so-called classical chemical warfare agents might prove attractive and certain toxic industrial chemicals (TIC) might be chosen for use as have been recently reviewed by Marrs* et al.* Only a brief account of classical chemical warfare agents not dealt with in other chapters of this book will be provided here.

**Organophosphorus nerve agents**

Nerve agents comprise a group of highly toxic compounds with the general formula:

\[
\begin{align*}
R_1 & \quad P \quad O \\
R_2 & \quad X
\end{align*}
\]

Sarin (GB) has the formula:

\[
\begin{align*}
\text{CH}_3 & \quad \text{O} \\
\text{CH}_3\text{CHO} & \quad O \\
\text{CH}_3 & \quad F
\end{align*}
\]

and is volatile (vapour pressure at 20°C = 2.10 mmHg).

VX has the formula:

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{O} & \quad P \quad O \\
\text{CH}_3 & \quad S\text{CH}_2\text{CH}_3 \text{N} \\
\text{CH}(\text{CH}_3)_2 & \quad \text{CH}(\text{CH}_3)_2
\end{align*}
\]

and is not volatile (vapour pressure at 20°C = 0.00044 mmHg).

Nerve agents bind to and inhibit, effectively irreversibly, the enzyme acetylcholinesterase and thus cause an accumulation of acetylcholine at central and peripheral sites of transmission of nerve impulses. This leads to increased secretion from glands (salivary, nasal mucosal glands, bronchial glands), bradycardia, contraction of the pupil (miosis) and skeletal muscle twitching. Death is caused by inhibition of the medullary respiratory centres and depolarizing blockade of the diaphragm. Nerve agents may be absorbed by the lung and across the skin: a volunteer at Porton Down died in 1952 after sarin was placed on his forearm under clothing that prevented evaporation. At high concentrations, collapse occurs rapidly and death follows quickly. Low level exposure causes miosis, eye pain, conjunctival injection and headache. Fortunately, antidotes exist: atropine to block the effects of acetylcholine at muscarinic receptors and oximes (e.g. pralidoxime mesylate P25) to reactivate the inhibited acetylcholinesterase. Diazepam is useful in preventing convulsions. These drugs should be given as soon as possible by intravenous or intramuscular injection. Autoinjection devices containing 2 mg of atropine, 500 mg of P25 and 5 mg of a diazepam–lysine conjugate (Avizafone) are commercially available. Assisted ventilation is essential in all severely poisoned casualties. Exposure to nerve agents is unlikely to cause delayed peripheral neuropathy (OPIDN), but the intermediate syndrome may occur and long-lasting effects on the electroencephalogram (EEG) and on memory function have been reported. \(^5\)
Sulphur mustard

'Mustard gas' is a liquid of low volatility (vapour pressure at 20°C = 0.0650 mmHg). The structural formula is:

\[
\text{S} - \text{CH}_2 - \text{CH}_2 - \text{Cl}
\]

It is rather immiscible with water. Exposure to the liquid and to the vapour causes intense, but delayed, eye irritation and skin blistering. BlisterS may contain up to a litre of fluid, but this fluid does not pose a hazard to the patient or to attendants: mustard binds rapidly to proteins. Sulphur mustard has a radiomimetic effect: damaging bone marrow and the airway and gut epithelium. Its lethality is low, but patients require weeks of care to make a full recovery. Eye damage may cause delayed keratitis leading to blindness. No antidote is known and management is supportive. Eye damage can be severe and sticking of the eyelid margins can be a problem. Vaseline to prevent this and saline irrigation are useful. Hoscine (0.25 per cent) drops to relieve spasm of the iris are also helpful. Photophobia may be severe. Ascorbate and citrate eye drops have been recommended. In cases of bone marrow depression advice regarding bone marrow stimulation with colony-stimulating factors should be sought. Skin lesions are slow in healing and flaminez cream can be useful in preventing secondary infections. Caring for a patient exposed to a high concentration of sulphur mustard: temporarily blinded, coughing sloughed respiratory epithelium, with widespread skin blisters and a collapsing bone marrow is a major challenge. Despite this, the death rate in the First World War was <2 per cent. Other classical chemical warfare agents (hydrogen cyanide, chlorine and phosgene, and arsenical compounds) are dealt with in Chapter 8, Gases.

One group of compounds that might prove attractive to terrorists are the so-called riot control agents. Of these CS (sometimes called CS gas though it is usually encountered as a finely divided powder dispersed as an aerosol) is perhaps the best known. Riot control agents are remarkable in that they cause intense and incapacitating eye irritation, but are characterized by remarkably large LD50 values. The intravenous LD50 of CS in the male mouse is 48 mg/kg and yet the TC50 (concentration intolerable to 50 per cent of the population) is 3.6 μg/L. Exposure to the aerosol produces no lasting effects and the acute effects on the eye disappear rapidly on the patient being removed from the source of exposure. Eye damage as a result of spraying directly into the eye can occur.

Japanese experience with nerve agents deployed by terrorists

Okumura and colleagues\(^6\) have provided a disturbing account of the consequences of the release of sarin (GB) by the Aum Shinrikyo cult on the Tokyo subway on March 20, 1995. This account should be read by all interested in this area.\(^6\) Only a brief summary, in note form, is provided here.

- On March 20, five terrorists punctured plastic bags containing an impure preparation of sarin on Tokyo subway trains.
- Twelve people died, 5654 were affected, 999 people were admitted to hospital, 4643 needed treatment (the large numbers are estimates and vary according to source).
- Atropine was used as the major antidote and atropine eye drops proved useful – this had been questioned in earlier accounts.
- Oxime (2-PAM, pralidoxime chloride) was not thought to have been life saving, although it was used.
- Secondary contamination led to medical and paramedical staff being affected.
- A 'field test' for sarin failed to identify or detect the agent.
- Long-term effects, including visual disturbances, eye discomfort, headache, fatigue and vestibulocerebellar disturbance, were reported. Measures of visual evoked potentials (P300 and VEP) and heart rate variability (R–R interval) also showed long-lasting effects. Post-traumatic stress disorder (PTSD) questionnaire scores were high. That medical and paramedical staff were affected by off-gassing of sarin from patients was notable and in some ways surprising. Casualties had been exposed only to vapour (not to liquid) and yet enough was retained on clothing to produce secondary effects. It should also be noted that though the number dying was low, some thousands of people attended hospitals. This overloading of medical facilities is likely to occur as a result of the use of chemicals and to be a serious logistical problem in a terrorist incident. That the medical and paramedical staff coped as well as they did with a frightening and unique challenge can only be a matter for congratulation regarding their training and dedication.

Dealing with a terrorist incident involving the use of chemicals

The key to success is teamwork. Emergency services, medical services and local authorities need to combine to (1) assess risks, (2) plan how to deal with incidents and (3) exercise their plans. Detailed accounts of this have been provided by Baker\(^7\) and by Roberts and Maynard.\(^8\) Here, we focus on patient care, but other issues including provision of appropriate protective equipment and chemical detectors for first responders are also very important. Modelling the dispersion of chemicals is also vital for planning. Real-time modelling of dispersion during an incident is difficult, but may be possible, especially if the area affected has been studied in advance. Much, of course, depends on the nature of the incident. In Tokyo, a
chemical was released in a closed (not outdoor) environment and it is likely that the release, though not instantaneous as would be produced by an explosion, was short-lived. A slow release, for example, from cylinders or a tanker is also possible and this would present a different set of problems.

In approaching chemical casualties a number of golden rules should be noted:

1. Attendants and rescue workers must be protected – if not, they may soon become casualties.
2. Casualties must be decontaminated before admission to hospitals or other facilities where unprotected staff are working.
3. Life supporting care is the first priority.
4. Specific antidotes are few but, if available, should be given as soon as possible.
5. The identity of the chemical producing the casualties may not be known at first and treatment of effects will be needed. For example, lung injuring agents may cause bronchospasm. Management of effects does not, in general, depend on knowing the exact identity of the causative agent.

Decontamination of casualties

Removing a casualty’s clothing may remove 80 per cent of liquids or powder contamination. This, then, is the first step towards decontamination. Water is the key decontaminant. If a little dilute bleach can be added to the water, this will improve decontamination by aiding hydrolysis. The logistical problems of decontaminating a few hundred casualties are formidable and need to be addressed by planning and exercises. Crowd control is critically important and close liaison between the police and resource services is needed. It should be noted that in Tokyo the majority of subjects made their own way to hospital undecontaminated. In many countries, mobile decontamination units have been developed and facilities for showering and reclothing in clean garments are provided. Preventing hypothermia is obviously important and some facilities provide warmed water. Decontamination of collapsed patients presents special problems: at its simplest a ‘bucket and sponge’ approach is satisfactory. Decontamination using solid decontaminants, such as fullers’ earth, is now not generally recommended.

Separating the contaminated (or potentially contaminated) from the decontaminated is important. In many countries, the incident area is divided into ‘hot’, ‘warm’ and ‘cold’ zones. In the hot zone, there is a risk of primary contamination by the released chemical or chemicals; only well-protected staff can enter this area. In the warm zone, the risk to staff is from contaminated patients: the level of protection needed by staff will be less than in the hot zone. In the cold zone, only decontaminated patients are allowed and here the risk to staff is small and only normal clinical measures, e.g. gloves, are needed. Maintaining the integrity of these zones is clearly important.

Medical care at the scene

The organization of medical care at the scene of a chemical incident is a hotly debated topic. Some authorities recommend dispatching a medical team to the scene with a consultant in intensive care to take charge of casualty management. Others argue that holding medical staff at hospitals and allowing paramedics to take the lead at the scene is more appropriate. The former approach is adopted in Paris, the latter in London. Whichever staff are present at the scene, they must be trained in the rapid identification of the effects of chemicals. It is important to note that the incident may not be known to involve chemicals and recognizable effects may provide the first clue to this. Having an experienced clinical toxicologist at the scene would clearly help. However, such trained medical staff are few and form a resource that should be carefully deployed. Sending medical staff into the hot zone is also debated: the level of protective equipment sometimes recommended may significantly reduce the diagnostic skills of even senior doctors and closed circuit breathing apparatus plus an impermeable protective suit may make such tasks as intubation and establishing an intravenous line difficult. This leads to the question of what level of protection needs to be worn. If the nature of an incident is unknown, there is likely to be a tendency to overprotect staff.

What drugs can be given in the hot zone?

It has already been noted that there are very few effective antidotes of proven value in chemical poisoning. This is sometimes forgotten and it is imagined that medical staff at the scene of an incident will have a battery of effective drugs with which to treat casualties.

In fact, the effects of only two chemicals that might be used by terrorists can be treated by means of antidotes. Casualties exposed to nerve agents causing collapse and impairment of respiration should be treated at once with atropine and oxime. Delay can be fatal and provision of autoinjection devices that can be used to give an intramuscular injection through clothing is important. This should be done as soon as the diagnosis is made. A patient with breathing difficulties, who has small pupils and who is salivating or twitching needs atropine and oxime at once. The second cause of poisoning that calls for rapid antidote therapy is cyanide. Exposure to hydrogen cyanide is rapidly fatal and the likelihood that rescuers will reach patients at risk of dying sufficiently quickly to give an antidote is low. Whether Kelocyanor® or the combination of sodium nitrite and sodium thiosulphate is used, the antidote must be given intravenously. This presents difficulties in the hot zone. Cyanide casualties who survive exposure and who are breathing spontaneously on being brought out into the fresh air do not need antidote therapy: this is unlike the case of nerve agent poisoning where antidote therapy is needed for some time. It is important to stress again that
support for ventilation and the provision of oxygen is critically important for patients with breathing difficulties. Oxygen can be provided and masks attached to low-weight cylinders, with special heads and valves, allow a number of patients to be treated simultaneously. Light ventilators are also available: the ComPac ventilator (Smiths Medical International, St Paul, MN, USA) is a good example of a battery-driven portable device that can supply air filtered through a respirator canister. Oxygen-enriched air can also be provided by portable ventilators connected to light-weight oxygen cylinders.

Much of the thinking outlined above comes from the military field and important differences between the military (battlefield) and civilian (terrorist incident) scenario should be noted. Military doctors do not deal with babies and children or with old or perhaps already ill subjects. Planning should include these groups: dose schedules for babies and children need to be developed and such obvious things as the length of the needle of autoinjection devices are easily overlooked. Treating seriously ill casualties in a contaminated environment is a great challenge and there is a strong case for moving casualties to a more satisfactory environment as soon as possible.

**OCCUPATIONAL HEALTH ISSUES**

Staff from the emergency services, as well as doctors and paramedical staff may be placed at significant risk at the scene of a terrorist incident. The following hazards need to be considered:

- Physical stress imposed by rescue work. Wearing protective equipment imposes a significant physiological penalty in terms of heat stress, dehydration and exhaustion. Staff should be rotated through difficult conditions and adequate periods for rest and recovery should be provided. Staff undertaking such work should be physically fit.
- Exposure to chemicals may occur and casualties among healthcare workers and rescue workers should be expected. Training in the use of protective equipment is vitally important: the duration of safe use of such equipment should be noted and each person’s time in protective equipment should be monitored. The operational period possible in closed circuit breathing apparatus may be short. Protective equipment must be checked for damage before use. Removing contaminated protective clothing is potentially dangerous and drills to allow this to be done safely should be developed.
- Healthcare workers and rescue staff are likely to be exposed to intense mental stress. This should be monitored. Staff may suffer from post-traumatic stress disorder and advice should be taken regarding professional counselling.

**Key points**

- The use of chemicals by terrorists is a very real threat in many countries today.
- A terrorist incident involving the use of chemicals will present formidable difficulties for medical and paramedical staff, including occupational physicians. The key to success under such conditions is planning and training. This needs to be rigorous and repeated.
- Cadres of specially trained staff working to established protocols are important and research needs to be done to develop both better therapies and procedures. In many countries, this research is underway.
- Measures to prevent the chemical contamination of healthcare workers and rescuers are essential.
- Terrorist incidents are very stressful for all responders, and staff may suffer from post-traumatic stress disorder and require specific support.

Organic chemicals

INTRODUCTION

Organic chemicals are a vast group of widely different entities. They differ in their inherent acute, long-term and organ toxicity, as well as reproductive toxicity, carcinogenicity and sensitizing and irritant properties. They are traditionally divided, by their chemical nature, into groups such as alcohols, carboxylic acids, ethers, etc. While this classification may be useful, many organic chemicals contain more than one active group and could thus be listed under many headings in such listings, and more importantly, may show characteristics of different groups. Most chemicals also have several different synonyms, the identification of which is not always straightforward. A unique identification system is provided by the Chemical Abstracts Service (CAS) registry numbers. Often, it is easiest to find information on a specific chemical by searching databases using the CAS number. Therefore, the CAS numbers have been given in this chapter.

It is a formidable task to characterize, even crudely, the hazardous characteristics of all these different individual chemicals. Several approaches have tried to solve the problem by structure–activity analyses, but at present, such approaches cannot be considered reliable. Even if at some time in the future, we have all the statutory animal and in vitro tests done on every chemical that is produced on a large scale – as the European Union legislation on Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) intends to do – we still have the nagging uncertainty of the reliability of our models, notably of the species to species extrapolation, and also the even larger number of chemicals that are produced at small amounts, but to which people are still exposed.

This chapter can provide only a superficial perspective on the world of organic chemicals. The individual chemicals presented here in detail have been selected on the basis of their widespread use or known existence as workplace contaminants, and since they are known to exert toxicological hazards capable of causing occupational diseases. Some chemicals, which have been important occupational toxicants in the past but have, thanks to different national or international bans and restrictions, lost their position as commonly used industrial chemicals are presented in the text only briefly. These include carcinogenic 2-naphthylamine and benzidine. Even if some chemicals are not covered in this text, it does not mean that they may not be toxicologically important. Since our knowledge is advancing and new chemicals are constantly being introduced, new hazardous chemicals or new health hazards of ‘old’ chemicals may become evident. It is therefore of utmost importance for an occupational physician not to consider texts as representing the final word on chemically induced health hazards, but instead, to keep his mind and eyes open, and to be aware of new findings on the effects of all chemicals.
HYDROCARBONS

Aliphatic hydrocarbons

Hydrocarbons are substances consisting of carbon and hydrogen. They are divided into aliphatic and aromatic hydrocarbons, aromatic hydrocarbons being based on specific ring structure. Aliphatic hydrocarbons can exist as open-chain compounds, such as \( n \)-hexane, or as cyclic compounds, such as cyclohexane. Aliphatic hydrocarbons may form branched isomers, like 2-methylhexane, which is also called isohexane. Examples of aliphatic hydrocarbons are given in Table 42.1.

The simplest aliphatic hydrocarbons are methane, ethane, propane and butane. These are saturated hydrocarbons belonging to the group of alkanes, which are also known as paraffins. They have a molecular formula of \( C_nH_{2n+2} \). In the case of methane, \( n = 1 \), ethane, \( n = 2 \), etc. Methane is a principal component of natural gas, and it is also formed in the decay of organic matter. It can act as a simple asphyxiant. Propane and butane are widely used as domestic and industrial fuels and in aerosol propellants, and are extremely flammable gases. As the number of carbons in the carbon chain of alkanes increases, so does the boiling point. While the lightest alkanes are gases, alkanes heavier than butane exist as liquids at room temperature. Alkanes with their boiling points are presented in Table 42.2.

Alkenes are a group of compounds with a carbon–carbon double bond in their hydrocarbon chain. The simplest alkene is ethene, which is commonly known as ethylene.

CNS, central nervous system.
ethylenes. Alkenes have a molecular formula of \( C_nH_{2n} \). Ethylene is followed by propene (propylene) and butenes (1-butene, 2-butene and isobutylene). Like corresponding alkanes, ethylene, propylene and butenes are highly flammable gases. With increasing chain length, the boiling points of alkenes increase.

In contrast to alkenes, dienes contain two carbon–carbon double bonds in their hydrocarbon chain. Rubber is a natural polymer of isoprene (2-methyl-1,3-butadiene). 1,3-butadiene is a compound used in the manufacture of synthetic rubbers like styrene-butadiene rubber and polybutadiene rubber.

Alkynes contain a carbon–carbon triple bond in their hydrocarbon chain. They have a general molecular formula of \( C_nH_{2n-2} \). The simplest alkyne is acetylene, which is commonly used as a welding gas. Like alkanes and alkenes, the first compounds in this series are highly flammable gases at room temperature, whereas higher homologues are liquids. Acetylene has a low toxicity, but it may act as a simple asphyxiant by lowering the oxygen content of the air in confined spaces.

Generally, many aliphatic hydrocarbons may cause acute central nervous system depression at high exposure levels. Some of them, like methane and acetylene, work as simple asphyxiants. In occupational medicine, the most important compounds in this group are \( n \)-hexane and 1,3-butadiene, which are discussed in detail below.

### \( n \)-HEXANE

\[ \text{H}_3\text{C} \quad \text{CH}_3 \]

\( n \)-Hexane is a volatile, colourless liquid with a characteristic disagreeable odour and a high vapour pressure. It is produced from the refining of crude oil, and has been used in special glues, for example in shoe-making, as a solvent in certain processes and as a laboratory chemical. Gasoline contains small amounts of \( n \)-hexane. Exposure to \( n \)-hexane in workplaces occurs primarily via inhalation.

#### Clinical effects and epidemiology

\( n \)-Hexane is not irritating and its acute toxicity is low. Acutely it may result in central nervous system (CNS) depression at exposure levels of approximately 1000–5000 ppm (3500–17 000 mg/m\(^3\)). (In this chapter, the ppm to mg/m\(^3\) conversion is performed assuming a temperature of 20°C and an atmospheric pressure of 101.3 kPa, used in most European countries.) Its main hazards are, however, related to long-term exposure resulting in neurotoxicity. \( n \)-Hexane has been shown to induce peripheral neuropathy in humans, which was first observed in the shoe-manufacturing industry in Japan and Italy. In an early epidemiological study carried out in sandal manufacturing in the 1960s, 93 cases of polyneuropathy (both sensory and sensorimotor neuropathy) were diagnosed out of 296 examined workers. Exposure levels were said to range from 500 to 2500 ppm (1700–9000 mg/m\(^3\)). Common signs and symptoms of \( n \)-hexane polyneuropathy include numbness in the distal portions of the extremities, muscle weakness, hypoactive reflexes, coldness, reddishness and roughness of the skin. Numbness in the feet and hands are the first symptoms to appear, followed by weakness in the lower legs and feet. The severity of the symptoms depends on the exposure: occupational exposure to 500 ppm (1700 mg/m\(^3\)) may result in overt neuropathy, whereas subclinical reductions in nerve conduction velocities may be observed after a few years of exposure at air levels of \(<100\) ppm \((<350\) mg/m\(^3\)) \(^2\)-\(^4\).

Muscle wasting and atrophy have been reported in individuals with severe \( n \)-hexane neurotoxicity, although CNS symptoms may not be present. In EMG examination, abnormalities in conduction velocity, distal latency and action potential amplitudes have been reported. \(^4\) The findings may be subclinical. Biopsies of peripheral nerves may show demyelination and infiltration of leukocytes. After cessation of exposure, gradual improvement may be seen. A follow-up study\(^5\) of shoe manufacture workers diagnosed in the past with \( n \)-hexane polyneuropathy showed some improvement in motor nerve conduction velocities and distal latencies one year after the cessation of exposure. However, sensory nerve conduction velocities and distal latencies, while improved from those at diagnosis, were still statistically significantly worse than in controls. The neurotoxicity of \( n \)-hexane is caused by one of its metabolites, 2,5-hexanedione, which is formed by P450-mediated oxidation of \( n \)-hexane via metabolic interaction. \(^4\) The mechanism of action of \( n \)-hexane polyneuropathy may involve formation of lysine adducts and cross-linking, resulting in neurofilament accumulation, axonal swelling and ultimate axonal degeneration. \(^4\)

Methyl ethyl ketone (MEK) and methyl iso-butylketone (MiBK) have been shown to enhance the neurotoxicity of \( n \)-hexane via metabolic interaction. \(^5\) It has also been suggested that acetone potentiates \( n \)-hexane neurotoxicity by decreasing the body clearance of 2,5-hexanedione. \(^6\)
Metabolism and monitoring

n-Hexane is metabolized by mixed function oxidases in the liver to a number of metabolites including the neurotoxicant 2,5-hexanedione. Most of the absorbed n-hexane is excreted as metabolites in urine, with 2,5-hexanedione as the major metabolite. n-Hexane exposure can therefore be monitored by measuring 2,5-hexanedione in the urine.

Management and diagnosis

Diagnosis of n-hexane neuropathy is based on typical symptoms, neurophysiological examination (ENMG) and the assessment of exposure. Other possible causes of polyneuropathy, e.g. long-term alcohol abuse, diabetes, neurotoxic drugs, vitamin B1, B6 and B12 deficiencies, and inflammatory, infectious or malignant diseases causing polyneuropathy, must be excluded. Biological monitoring can be used in the assessment of current exposure and the management of n-hexane-related health risks.

1,3-BUTADIENE

[CAS No. 106-99-0]

\[
\begin{align*}
  &\text{CH}_2 \\
  &\text{H}_2\text{C} \\
  &\text{H}_2\text{C} \\
  &\text{CH}_2
\end{align*}
\]

1,3-Butadiene is a colourless gas, with a mild aromatic odour and an odour threshold between 0.4 and 1.7 ppm (1 and 4 mg/m³). The main industrial uses of 1,3-butadiene include the manufacture of synthetic rubbers, such as styrene-butadiene rubber (SBR) and polybutadiene rubber, manufacture of thermoplastic resins like acrylonitrile-butadiene-styrene (ABS), and manufacture of styrene-butadiene latex. It is also used as a chemical intermediate, e.g. in the production of the nylon precursor hexamethylene-dimethylenediamine. The industrial use of butadiene occurs in closed systems. However, 1,3-butadiene is also found in cigarette smoke and in the combustion products of fossil fuels, and hence it is one of the impurities found in urban air.

Clinical effects and epidemiology

1,3-Butadiene has low acute toxicity. The main hazard related to butadiene is its carcinogenicity. Inhaled butadiene is metabolized in the body to active epoxide metabolites (1,2-epoxy-3-butene, 1,2,3,4-diepoxybutane and the monoepoxide diol), which are responsible for its carcinogenic effects. The International Agency for Research on Cancer (IARC) has classified 1,3-butadiene as a known human carcinogen (group 1) on the basis of sufficient epidemiological and toxicological evidence.

The most convincing evidence on butadiene carcinogenicity in humans comes from the large cohort studies of styrene-butadiene rubber manufacturing workers in the United States and Canada, which show a relationship between estimated cumulative butadiene exposure and leukaemia. This relationship remained after correction for other confounding exposures, i.e styrene and dimethyldithiocarbamate. Although there are uncertainties related to dose–response relationships of butadiene-induced cancer, there is some indication of the role of peak exposures in the development of leukaemia. Peak exposure intensities of \( \geq 100 \text{ ppm} \) (230 mg/m³) may be of importance in causing an increased cancer risk.

Based on animal tests, butadiene may cause harm to the developing fetus. Therefore, exposure during pregnancy should be avoided.

Metabolism and monitoring

The first step in 1,3-butadiene metabolism is the formation of epoxybutene (Figure 42.1). Further metabolism of epoxybutene can, however, proceed by a number of different pathways, with possible conjugation with glutathione, hydrolysis to monoepoxide diol, or further epoxidation to diepoxybutane. There are considerable species differences in the metabolism of butadiene, shown by diepoxybutane levels in the mouse exceeding those in the rat by up to 160-fold in some tissues at equivalent butadiene exposure levels. This may explain the species differences in the carcinogenicity of butadiene. In humans, butadiene is metabolized to epoxybutene with subsequent hydrolysis to monoepoxy diol. There are no data on the formation of diepoxybutene in humans in vivo. However, considerable individual variation in the metabolism of butadiene has been observed, which raises the possibility that some humans may be quantitatively comparable to the mouse in terms of the production of diepoxybutene. Human low-level 1,3-butadiene exposure has been monitored by measuring haemoglobin adducts in the blood of exposed workers. This method is, however, mainly used for research purposes.

Management and diagnosis

The management of butadiene-related cancer risks is mainly related to monitoring and controlling exposure to 1,3-butadiene to as low as technically feasible.

There are no unique diagnostic features for butadiene-caused leukaemias (nor indeed for almost all occupational malignancies). If there is a suspicion regarding butadiene as a cause of leukaemia in an individual, consideration should be given to the extent of exposure, and other possible exposures and risk factors for the disease.

Aromatic hydrocarbons

Aromatic hydrocarbons consist of unsaturated cyclic hydrocarbon compounds based on a benzene ring. Thus, benzene is the simplest member of this group. Other important compounds in this group include toluene, xylene and styrene, which have widespread use and well-documented central nervous system toxicity. These substances are discussed in detail below.
Other significant compounds in this group are ethylbenzene, cumene and vinyl toluene. Irritation and central nervous system effects are the main hazards related to these substances. Similar to styrene, ethylbenzene is metabolized to mandelic acid and phenylglyoxylic acid. Urinary mandelic acid can be used for the biomonitoring of ethylbenzene exposure.

**BENZENE**

[CAS No. 71-43-2]

Benzene is a clear colourless liquid with a vapour pressure of 10 kPa at room temperature. Crude oil is the main natural source of benzene. Motor fuel and coal tar also contain benzene. In motor fuel, benzene exists usually at concentrations of 1–5 per cent. Exposure to benzene has occurred especially in the petroleum industry. Benzene is used also as an intermediate for chemical synthesis; it forms the basis for the production of a great variety of aromatic and cycloaliphatic compounds such as ethylbenzene, cumene, cyclohexane, nitrobenzenes, alkylbenzenes, chlorobenzene and maleic anhydride. Only very small quantities are used nowadays as a laboratory reagent or as a solvent. Cigarette smoke also contains benzene.

**Clinical effects and epidemiology**

Occupational exposure to benzene occurs mainly by inhalation, but it is also well absorbed through the skin. Acute (few hours) exposure to benzene at exposure levels of \(>50–150\) ppm (160–500 mg/m\(^3\)) can cause headache, weakness and drowsiness. However, the most relevant health hazard of benzene in occupational settings is related to its long-term toxicity to the haemopoietic system.

**Haematotoxicity**

Benzene has been shown to induce haematotoxic effects varying from depression of white and red blood cell counts to potentially life-threatening aplastic anaemia and leukaemia. Decreases in white and red cell counts have been seen after long-term exposure to levels of \(>10–20\) ppm (30–60 mg/m\(^3\)) of benzene. These effects on blood cell counts have usually been reversible, whereas aplastic anaemia resulting from bone marrow failure may be irreversible. According to recent studies, the most sensitive reaction in humans
to long-term benzene exposure is lymphocytopenia. When compared to controls, statistically lower lymphocyte counts have been reported in workers exposed to benzene levels of 1–31 ppm (3–100 mg/m³).\textsuperscript{15,16}

**Leukaemia**

Benzene is classified by IARC as a group 1 carcinogen\textsuperscript{17} because of its ability to cause leukaemia in humans. Acute myeloid leukaemia (AML) has been shown to be related to benzene exposure. Also an association between benzene exposure and other types of haematological malignancies, such as multiple myeloma and non-Hodgkin’s lymphoma, has been suggested.\textsuperscript{18,19} Leukaemias caused by benzene have often been associated with predisposing myelodysplasia or aplastic anaemia.

Estimates on the exposure–response relationships of benzene-induced cancer vary between different studies, with some studies suggesting significant increases at cumulative exposures of <40 ppm years (e.g. exposure to 1 ppm concentration for 40 years) and some only at dose levels of 200 ppm years.\textsuperscript{20,21} Other studies have suggested the role of high peak exposures.\textsuperscript{22} The latency period for benzene-induced leukaemia may be up to ten years.\textsuperscript{23}

Mechanisms behind benzene haematotoxicity and leukaemia are still unclear, but may include oxidative stress induced by benzene metabolites (especially phenolic metabolites, but also benzene oxide, trans, trans muconaldehyde), which may result in DNA damage in bone marrow cells.\textsuperscript{24} Benzene is regarded as a genotoxic carcinogen since it has been shown to induce chromosomal aberrations and micronuclei in animal tests. However, most of the bacterial tests for gene mutations for benzene have been negative.\textsuperscript{14,25,26} Genetic differences in benzene-metabolizing enzymes (especially CYP2E1) may affect the sensitivity of different individuals to benzene toxicity.

**Metabolism and monitoring**

Once absorbed, benzene is rapidly distributed throughout the body (Figure 42.2). Because of its lipophilicity, lipid-rich tissues have been found to contain the highest levels of benzene.\textsuperscript{26} Benzene is metabolized to a number of metabolites by the cytochrome P450 mixed-function oxidase system. CYP2E1 is one of the most important isoenzymes metabolizing benzene. It has been shown that oxidative metabolism of CYP2E1 is needed for the induction of haematotoxic and genotoxic effects of benzene. Since ethanol is able to induce CYP2E1, alcohol consumption can enhance benzene toxicity.

Excretion of benzene metabolites occurs mainly in the urine, whereas after inhalation unchanged benzene is rapidly

![Figure 42.2](image-url)
eliminated in exhaled air. The main metabolites measured in urine include S-phenyl mercapturic acid, trans, trans-muconic acid, phenol and phenolic metabolites. Trans, trans-muconic acid is commonly used for biological monitoring of benzene exposure, but at low exposure levels diet may interfere with the assessment since sorbic acid present in diet is also metabolized to trans, trans-muconic acid. S-phenyl mercapturic acid is not as sensitive to dietary effects and it has been shown to correlate well with blood benzene levels. Since cigarette smoke contains benzene, smoking is one of the confounding factors in the interpretation of biomonitoring results.

Management and diagnosis
Monitoring and controlling of exposure to levels as low as technically feasible is important in the prevention of benzene-caused cancers. At the dose levels following modern standards for controlling exposure (e.g. to below the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) of 0.5 ppm (1.6 mg/m³)), risks of developing health effects are likely to be very low.

If AML has been diagnosed, the classical circumstances that might support benzene as a potential cause are:23

- occurrence of certain forms of myelodysplastic syndrome;
- defects in chromosome 5 or 7;
- a substantial exposure history with a cumulative dose of at least 40 ppm-years during the preceding ten years;
- a poor response to anti-leukaemic chemotherapy.23

Confounding aetiologic factors include heavy cigarette smoking, previous exposure to chemotherapy or radiation, or certain underlying constitutional disorders, such as Down’s syndrome or pernicious anaemia.23 However, the occurrence of de novo AML and myelodysplasias in the general population increases dramatically with advancing age and these diseases may exhibit similar chromosomal changes as those found in benzene-caused AMLs in younger individuals, even without any specific history of hazardous exposures.23

TOLUENE, XYLENE AND STYRENE

Toluene (CAS No. 108-88-3), xylene (CAS No. 1330-20-7, mixed isomers) and styrene (CAS No. 100-42-5) are well-known and widely used aromatic hydrocarbons with a benzene ring-based structure. Toluene has one methyl group bound to benzene ring, whereas xylene has two methyl groups allowing three different isomers: ortho-, meta- and para-isomers. Styrene has a vinyl group with a double bond bound to benzene ring making it possible to form polymers.

Toluene (methyl benzene) is a volatile, highly flammable liquid with a vapour pressure of 3 kPa at 20°C. It has a sweet benzene-like odour. Toluene is produced by different petroleum conversion processes. The main use of commercial toluene is as an intermediate in the production of other chemicals, but it is also widely used as a solvent in paints, thinners, adhesives, inks and as an extraction solvent in the production of pharmaceutical and other chemical products.28 Significant exposure to toluene may occur in painting, gluing (for example, in car or boat upholstery) or in rotogravure printing.

Xylene (dimethylbenzene) is a colourless liquid with a sweet benzene-like odour. Technical xylene is a mixture of xylene isomers with 4–20 per cent o-xylene, 44–60 per cent m-xylene and 12–20 per cent p-xylene. Some technical grades may also contain ethylbenzene and small amounts of benzene or toluene as an impurity. Xylene has a vapour pressure 0.8 kPa at 20°C. Like toluene, it is produced by petroleum conversion processes. Xylene is used as a solvent in a variety of different applications, but also to a great extent for further separation into the three isomers through distillations and fractionated crystallization. Separated isomers are used for the production of other chemicals, e.g. ortho-xylene is used for the synthesis of phthalic acid anhydride, and para-xylene for the production of dimethyleneterephthalate and terephthalic acid, which are then used for the production of polyethylene terephthalate (PET). All three isomers are also raw materials for the synthesis of vitamins, pharmaceuticals and flavouring agents. Significant exposure to xylene may occur in painting, especially in spray painting with xylene.

Styrene (vinyl benzene) is a colourless to slightly yellow volatile liquid with a sweet and pungent odour. It has a vapour pressure of 0.6 kPa at 20°C. On exposure to light and air styrene polymerizes, but it can also oxidize to form certain aldehydes and ketones. Styrene is mainly produced commercially from crude oil. The main use of styrene is as a precursor to polystyrene, an important synthetic material. It is also used in the production of co-polymers, e.g. acrylonitrile–butadiene–styrene, styrene–acrylonitrile, methyl methacrylate–butadiene–styrene and in the production of styrene–butadiene rubber (SBR) and related latices (e.g. SB latex). In the production of glass-reinforced plastics, styrene is added to unsaturated polyester resins to act as a cross-linking agent and reactive diluent. It also acts as a solvent for the resins. Significant styrene exposure may occur in glass-reinforced plastic plants and in boat manufacturing.

All three compounds are well absorbed by inhalation. Dermal absorption also occurs and it contributes to total systemic exposure.
Clinical effects and epidemiology

Acute effects

The main target organ for these compounds is the central nervous system. In uncontrolled situations, all three compounds can easily form air concentrations resulting in acute central nervous system effects like headache, dizziness, drowsiness and drunkenness. Dose–response relationships on these acute effects are presented in Table 42.3. Accidental high-level exposures have also caused liver and kidney changes.28–30

Solvent-induced, long-term neurotoxicity

Long-term, low-level exposure to solvents may cause chronic neurotoxicity, which may become evident as so-called ‘chronic solvent encephalopathy’ (CSE) or ‘chronic toxic encephalopathy’ (CTE).31 Symptoms related to chronic toxic encephalopathy are unspecific, including fatigue, poor memory, difficulties in concentration, emotional lability and depression.32 Memory is suggested to be the first mental property to be impaired in chronic toxic encephalopathy.32 The most persistent dysfunction in chronic toxic encephalopathy seems to be difficulties in tasks demanding working memory processing, which is a good predictor of the CSE status.33 The memory deficits in CTE may resemble those seen in moderate or severe Parkinson’s disease.33

Other neurobehavioural disorders related to CTE include possible defects in colour vision and visual perception. CSE patients may have impaired colour discrimination ability, despite their eyes and their other visual functions being normal.34 Visual search performance may also be impaired when compared to healthy controls.35

Since occupational exposure to solvents usually involves mixtures of different solvents, it is difficult in epidemiological studies to show associations between a specific solvent exposure and long-term CNS effects. However, rotogravure printers are exposed almost purely to toluene and past exposure levels may have been considerable. There are some studies suggesting an increased risk of organic brain syndrome in these toluene-exposed workers. A higher frequency of organic brain syndrome in subjects exposed to toluene for more than 12 years has been observed.36 In another study,37 toluene-exposed workers had substantially more neurasthenic symptoms and scored lower in psychometric tests. However, in more recent studies no significant effects have been seen in rotogravure printers.38,39 It appears that at low exposure levels in modern industry, the risk of long-term CNS effects from toluene is low.

Workers occupationally exposed to solvent mixtures including xylene have been reported to have neuropsychological and psychological disorders,30 but since xylene is one of several different components of the solvent mixtures, it is difficult to attribute these effects to xylene alone.

Since high styrene exposures have occurred in the glass-reinforced plastics industry, there are many studies evaluating the neuropsychological effects of long-term styrene exposure. In some of these studies, effects on neurological and neuropsychological function have been seen but the results have been variable.29,40 Benignus and co-workers41 conducted a meta-analysis of several studies on styrene exposure and effects on reaction times (simple and choice reaction times: in simple reaction time (SRT), the subject must simply react to a predefined stimulus as quickly as possible, whereas in choice reaction time (CRT), the subject must first select between options before deciding whether to respond or not and how to respond) and colour

</table>
vision (using a colour confusion index that measures the ability to discriminate between colours). According to this analysis, eight years of exposure to 20 ppm (90 mg/m³) of styrene was estimated to produce a 6.5 per cent increase in CRT, whereas no significant effect was observed on SRT. An increase in colour confusion index (CCI) was seen; with similar exposures estimated to cause a 2.23 per cent increase in CCI, which is the same as the expected effect of 1.7 additional years of age in men.

**Aromatic hydrocarbon solvents and ototoxicity**

Organic solvents have also been suggested to induce ototoxicity. A review found the incidence of sensorineural hearing loss to be higher than expected in noise-exposed workers who were also exposed to solvents. Aromatic hydrocarbon solvents are among the best studied occupational toxicants suggested to cause ototoxic effects in humans.

The most convincing data on the ototoxicity of industrial chemicals are those relating to styrene. Exposure to low levels of styrene and noise was studied in a cross-sectional study in Sweden. According to the results, noise exposure (past and current) and urine mandelic acid levels (the biological marker for styrene exposure) were significantly related to the incidence of hearing loss; the odds ratios for hearing loss were 2.44 times greater for each year of age, 1.19 times greater for each dB of current noise exposure, and 1.18 times greater for each mmol of mandelic acid per gram of creatinine. Lower levels of styrene and noise was studied in a cross-sectional study in Sweden. According to the results, occupational toxicants suggested to cause ototoxic effects in humans.

The IARC has classified styrene as a group 2B carcinogen. Since Clara cells are not as abundant in humans as in mice, there has been discussion regarding whether or not these carcinogenic effects seen in mice are relevant in humans.

**Other long-term hazards**

Styrene has caused lung tumours (mainly adenomas) in cancer bioassays in mice. In humans, no clear and consistent epidemiological evidence for the causal link between cancer and exposure to styrene exists. Mutagenicity of styrene is equivocal, although some studies show that styrene may be weakly clastogenic in humans. The possible genotoxicity and carcinogenicity of styrene is considered to be mediated through reactive metabolites, especially styrene 7,8 oxide (SO) and 4-vinylphenol (4-VP). Clara cells in mice bronchioles can metabolize styrene to these active metabolites. Since Clara cells are not as abundant in humans as in mice, there has been discussion regarding whether or not these carcinogenic effects seen in mice are relevant in humans.

The IARC has classified styrene as a group 2B carcinogen. Based on animal studies, all these aromatic solvents may cause developmental toxicity. The effects seen include decreases in birthweight, delayed development and developmental neurotoxicity. In the case of toluene, data on pregnant women sniffing toluene showed lower birthweight and neurological dysfunction in their offspring.

These aromatic solvents have a degreasing effect on the skin of humans, resulting in dermatitis on repeated skin exposure. They are not known to be skin sensitzers.

**Metabolism and monitoring**

**Toluene**

Most of absorbed toluene is metabolized in the liver by the P450 system and excreted in urine (Figure 42.3). Around 20 per cent of absorbed toluene is eliminated in expired air. Toluene is metabolized via benzyl alcohol and benzoaldehyde to benzoic acid, which is then conjugated with glycine and excreted in the urine as hippuric acid. If insufficient glycine is available, the benzoic acid may be conjugated with glucuronic acid to form benzoyleglucuronide. Small amounts of toluene undergo ring hydroxylation to form o-, m- and p-cresol, which are excreted in urine as sulphate or glucuronide conjugates.

Toluene exposure can be monitored by measuring blood toluene levels or hippuric acid levels in urine. Although good correlation between toluene air levels and concentration of hippuric acid in post-shift urine samples have been demonstrated, background levels of hippuric acid formed as a product of endogenous metabolism, and metabolism of substances present in food may decrease the sensitivity of the method. At exposure levels below 100 ppm as eight-hour time-weighted average (TWA) (380 mg/m³), urine hippuric acid cannot be used to separate an exposed person from an unexposed one. In some developing countries, low urinary hippuric acid background levels are found, and so it can be used as a biological marker for toluene exposure even at exposure levels lower than 100 ppm (380 mg/m³).
**Styrene**

Styrene can be metabolized via several different metabolic pathways, which have all been identified both in rodents and in humans, although there are species differences in their relative importance. The most important pathway involves cytochrome P450-mediated oxidation to styrene-7,8-oxide (SO). Specific P450 isoforms involved in the production of SO include CYP2E1, CYP2B6 and CYP2C8 in the liver and CYP2F2/1 and CYP2E1 in the lung. SO is either further conjugated with glutathione to give mercapturic acid or hydrolysed by epoxide hydrolase to phenylglycol, which is further metabolized to mandelic, phenylglyoxylic and hippuric acids. Mandelic acid or combined urine levels of mandelic and phenylglyoxylic acids can be used to monitor styrene exposure (Figure 42.4).

**Xylene**

Absorbed xylenes are excreted mainly as metabolites in urine (Figure 42.5). Metabolism of xylenes in humans includes primarily side-chain oxidation to form methylbenzoic acid, which is subsequently conjugated mainly with glycine and excreted in urine as methylhippuric acid. More than 90 per cent of xylene is transformed to methylhippuric acid and excreted in urine.

Urinary methylhippuric acid has proved to be a robust measure of the amount of xylene taken up in the body and is therefore routinely used in many countries for the biomonitoring of xylene exposure.

**Management and diagnosis**

Chronic nervous system damage including CSE caused by long-term, low-level exposure has aroused significant controversy worldwide. Therefore, the diagnosis and status of chronic solvent encephalopathy as an occupational disease varies in different countries. For example, in Scandinavian countries, chronic solvent encephalopathy is accepted as an occupational disease, with the diagnosis being based on a history of long-term, high-level exposure to solvents, specific signs and symptoms and exclusion of the other possible aetiological factors.

Neurotoxic symptoms of CSE can be screened by questionnaires, including the Q16 questionnaire and Euroquest (EQ). Neuropsychological testing forms the basis of the diagnosis of solvent-caused organic brain disease. In some cases, neuroimaging (magnetic resonance imaging (MRI), single photon emission computed tomography (SPECT)) findings and changes in colour vision tests may support the diagnosis. Other diseases, which may cause similar signs and symptoms, have to be considered in the differential diagnosis. These include clinical depression and other diseases resulting in organic brain disease, such as degenerative brain diseases, cerebrovascular
Hydrocarbons

331
disease, brain injuries, tumours and infections, vitamin B12 deficiency, disturbances in cerebrospinal fluid circulation and effects caused by other toxic agents, for example alcohol and medicines. The progression of CSE usually stops after the cessation of exposure. If clear progression of organic brain disease occurs after the cessation of exposure, other aetiological causes for the disease should be considered.
Polycyclic aromatic hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are formed in incomplete combustion processes. They exist almost always as mixtures of several different compounds, except single compounds such as naphthalene, which has been widely used in moth repellents for clothing.

PAHs consist of two or more fused benzene rings, the simplest being naphthalene, anthracene and naphthacene (Figure 42.6). The most well-known PAH compound is benzo[a]pyrene. Industry, traffic and heating produce PAH compounds in the environment. Thus, all individuals are exposed to PAHs via the environment, from cooking food, and from tobacco smoke.

Industrially important mixtures containing polycyclic aromatic hydrocarbons include coal tar creosote, which is used for wood impregnation (Figure 42.7), coal tar pitch and its distillation products, bitumen used for road paving, heating oils and diesel oils. Bitumen and diesel oil produced from crude oil contain 10–100 times less PAHs than creosote produced from coal tar.

Occupational exposure to PAHs occurs via the inhalation of fumes or aerosols containing PAHs, or via skin contact. Most PAH compounds have low vapour pressure and exist in particulate phase in workplace air, but some lighter PAHs, like naphthalene and phenanthrene, are found almost exclusively in gaseous phase. Occupations in which exposure to PAH mixtures may occur are listed in Table 42.4.

NAPHTHALENE

Naphthalene (CAS 91-20-3) is used as an intermediate for phthalic anhydride production and in the production of azo dyes and naphthalene sulphonic acids. The use of naphthalene as a moth repellent and insecticide has decreased in Europe since the introduction of chlorinated compounds, such as p-dichlorobenzene, but it is still used for the production of moth balls in other countries. Naphthalene is a...

- white solid, which has a vapour pressure (sublimation pressure) of 10 Pa at room temperature. It has a characteristic odour with a very low odour threshold of 0.08 ppm (0.4 mg/m³).

Clinical effects and epidemiology

Non-cancer effects

The acute toxicity of PAHs varies from moderate to low. Systemic toxicity, other than carcinogenicity, is very rare. The only PAH compound known to cause significant acute or systemic toxicity in humans is naphthalene.

Naphthalene causes haemolytic anaemia. It has caused several poisoning accidents when naphthalene-containing moth balls have been eaten. Serious poisonings after dermal or inhalation exposures have been described mainly in small children who have been exposed to naphthalene via moth ball-treated nappies, clothing or blankets.61,62 The lethal oral dose of naphthalene in humans is 5–15 g in adults. The first signs and symptoms of naphthalene poisoning include nausea, vomiting, diarrhoea, dark urine, pallor, fever and abdominal pain. On clinical examination, the liver and spleen may be enlarged and jaundice may be present. On haematology, fragmentation of red blood cells with anisocytosis and poikilocytosis, and reduction in haemoglobin and haematocrit levels are seen. More severe reactions include Heinz body formation, haemoglobinuria and mild methaemoglobinemia. Individuals who are deficient in G-6-PD (glucose 6-phosphate dehydrogenase) are particularly sensitive to haemolytic anaemia produced by naphthalene.63 Occupational exposure has not, however, been reported to cause naphthalene poisoning or haemolytic anaemia.

PAH mixtures, like coal tar pitch and coal tar creosote, have been shown to induce phototoxicity in humans. The symptoms appear when PAH-exposed skin parts are exposed to sunlight. Skin irritation, dermatitis, hyperpigmentation and even blisters may be observed.

In animal tests, different PAHs have been reported to have immunosuppressive effects. The relevance of these effects to human exposures is, however, unclear.

Carcinogenicity of PAHs

The main hazard related to polycyclic aromatic hydrocarbons is their potential mutagenicity and carcinogenicity. The first occupational cancers caused by PAHs were described in 1775 when Sir Percival Pott described scrotal cancers in chimney sweeps exposed to soot. The ability of individual PAHs to induce cancer varies. Since human exposure to PAHs is almost exclusively a mixed exposure, data on the carcinogenicity of the individual PAHs come from animal tests. Although some individual PAHs are extensively tested, there are many PAH compounds for which the toxicological data are very limited. The IARC has recently classified several PAH compounds according to their carcinogenicity; the results of the IARC classification are shown in Table 42.5.

Many PAH compounds have shown mutagenic activity in mutagenicity tests. The mechanism of the carcinogenicity of PAH compounds is considered to be related to the formation of DNA binding species, mainly diol epoxides in the body resulting in mutagenicity.64

Naphthalene has caused nasal cancers in carcinogenicity tests in animals after inhalation exposure. Naphthalene is, however, not genotoxic and it has been suggested that the mechanism of naphthalene-caused nasal cancers is mainly related to local tissue damage. This may, therefore, be relevant for humans only at high exposure levels that cause considerable local nasal irritation.64

The carcinogenicity of several work tasks involving significant PAH exposures has been studied in epidemiological studies. In the case of coal gasification, epidemiological studies have consistently shown an excess of lung cancer associated with gas production.64 Also, most of the epidemiological studies have provided evidence of an excess risk for lung cancer among coke production workers.64,65 Additionally, in the case of aluminium production, an association between cancer and PAH exposure has been demonstrated.64,65 A recent meta-analysis of PAH exposure and lung cancer estimated the risk equivalent to a relative risk of 1.06 for a working lifetime at 1 μg/m³ exposure to benzo[a]pyrene for exposures in the coke ovens, gas works and aluminum industries.65 All these work tasks have been recently evaluated by the IARC and designated as carcinogenicity group 1 (carcinogenic to humans).64,100 Other work tasks evaluated by the IARC and assigned to carcinogenicity group 1 because of the PAH exposure include coal tar distillation, paving and roofing with coal tar pitch, and chimney sweeping.64,100

Creosote has been shown to induce local skin cancers in mice at the site of application.66 In cohort studies of Swedish and Norwegian wood impregnators and in Finnish round-timber workers, increased risks for lip and skin cancers have been observed.66–68 However, epidemiological data on the carcinogenicity of creosote are still

International Agency for Research on Cancer (IARC) classification: Group 1, carcinogenic to humans; group 2A, probably carcinogenic to humans; group 2B, possibly carcinogenic to humans; group 3, not classifiable for its carcinogenicity.

Metabolism and monitoring

PAH compounds are absorbed through the lungs and skin. The metabolism of PAH is complex: parent compounds are converted via intermediate epoxides to phenols, diols and tetrots, which can then be conjugated with sulphuric or glucuronic acids or with glutathione. PAH metabolites and their conjugates are excreted in urine and faeces. Urinary 1-hydroxy-\textit{p}yrene, which is the metabolism product of pyrenol, has been commonly used as a biological marker of exposure to PAH compounds. 1-Naphthol has been used as a marker of naphthalene exposure.

Management and diagnosis

Management of PAH-related cancer risks is mainly related to good industrial hygienic practice and monitoring and controlling of the exposure to PAHs to as low as technically feasible. Special attention should be paid to avoidance of skin exposure. Urinary 1-hydroxy-\textit{p}yrene measurement is especially important when exposure occurs mainly via the skin.

There are no identified special features in PAH-induced cancers. If suspicion on the aetiological role of PAH exposure for the cancer (especially lung or skin cancer) arises, consideration should take account of the extent of the long-term exposure to PAHs, and other possible confounding exposures and aetiological factors that may be responsible for the disease (smoking, sun exposure, etc.).

Hydrocarbon mixtures

There are a number of hydrocarbon mixtures consisting of different aliphatic and aromatic hydrocarbons, the final properties of the mixture depending on its special hydrocarbon composition. Many different hydrocarbon mixtures are produced by distillation of crude oil. These include:\textsuperscript{71}

- Petroleum solvents, which can be divided on the basis of their distillation ranges to:
  - special boiling-point solvents, which are mixtures of C-5 to C-9 normal- and branched-chain paraffins and cycloparaffins with a boiling range of 30–160°C;
  - white spirits, used extensively as industrial solvents, which have longer chain-length (C-7 to C-12) and higher boiling range (150–220°C) and contain various amounts of aromatic compounds; and
  - high boiling point (BP) aromatic solvents (BP 160–300°C) containing more than nine carbon atoms per molecule.
- gasolines, kerosene and other fuel oils (such as diesel fuel, jet fuel)
- lubricant base oils, greases and waxes
- bitumen.

Of the petroleum solvents, white spirits are the most important due to their toxicological properties and widespread use.

The main health hazards related to gasoline include its potential carcinogenicity due to its benzene content and central nervous system depressant properties at high exposure levels.
Kerosene and other fuel oils have also been studied for carcinogenicity, but the results are inconclusive. Certain types of fuel oils may contain significant amounts of polycyclic aromatic hydrocarbons in addition to aliphatic and aromatic hydrocarbons, but the PAH content of, for example, kerosene and diesel fuel is less than 5 per cent. The IARC has determined that residual (heavy) fuel oils and marine diesel fuel are possibly carcinogenic to humans (group 2B). However, evidence on the carcinogenicity of distillate (light) fuel oils or distillate (light) diesel fuels is inconclusive (IARC group 3).

Bitumen (asphalt) is a complex mixture of naphthenic, aliphatic and/or aromatic hydrocarbons and heterocyclic compounds containing sulphur, nitrogen and oxygen. It is mainly used for paving roads. It has been studied extensively for the possible carcinogenicity of its vapours and aerosols formed during paving. These vapours and aerosols also contain polycyclic aromatic hydrocarbons.

**WHITE SPIRITS**

White spirits are colourless liquids with boiling points between 130 and 230°C and vapour pressures between 0.1 and 1.4 kPa at 20°C (Table 42.6). They are mixtures of saturated aliphatic and alicyclic hydrocarbons (mainly C7–C12) and aromatic hydrocarbons (C7–C12). In the past, they have contained benzene, but modern white spirits usually contain very little or no benzene. The most widely used quality of white spirit (white spirit type 1, standard solvent, CAS 8052-41-3) contains 80–85 per cent (by weight) aliphatic and alicyclic alkanes and 15–20 per cent (by weight) aromatic hydrocarbons.

The various types and grades of white spirit are produced from straight-run naphtha and straight-run kerosene, which are refinery streams obtained from the distillation of crude oil. Fractional distillation into appropriate boiling ranges and different kind of treatments are used to obtain the desired type of white spirit. The current trend in western countries is towards increased use of low aromatic white spirits.

Straight-run white spirit (type 0, CAS 64742-88-7) is a white spirit that has not been treated beyond the process of distillation. Types 1, 2 and 3 are further divided into three technical grades defined by flash point: 'low flash' white spirit, 'regular flash' white spirit and 'high flash' white spirit.

White spirits are widely used in paints and varnishes, in cleaning products and as a degreasing and extraction solvent. The main use is in paints and as a paint diluent. The odour threshold of white spirit is quite low; vapours can be detected at air levels of 0.5–5 mg/m³. Exposure to white spirits occurs mainly through inhalation, but absorption through the skin may also occur.

**Clinical effects and epidemiology**

Vapours of white spirit can cause eye and mucous membrane irritation at air levels of 600 mg/m³ (100 ppm). At higher levels, dizziness, drowsiness, headache and nausea may be induced. In controlled volunteer studies, exposure to white spirit for seven hours at 600 mg/m³ or more has resulted in impaired balance and increased reaction times. Skin exposure may result in defatting of the skin from repeated exposure.

According to several studies in painters, white spirits may cause chronic solvent encephalopathy. The clinical picture of the disease is the same as described in the case of aromatic hydrocarbon solvents, with symptoms including fatigue, poor memory, difficulties in concentration, emotional lability and depression. The incidence of symptoms increases with increasing number of years of exposure. Impaired performance in neuropsychological tests may be seen. Chronic solvent encephalopathy induced by white spirits may also be associated with defects in colour vision and visual perception, which has been suggested in studies of patients with a diagnosis of chronic solvent encephalopathy.
In the past, white spirits contained small amounts of benzene. However, nowadays benzene levels are very minimal or negligible. The carcinogenicity of white spirit has not been fully evaluated.

Metabolism and monitoring
Since white spirits are complex mixtures of several different hydrocarbons with varying composition, general metabolic pathways or specific monitoring methods cannot be provided for white spirits.

Management and diagnosis
The diagnosis of chronic solvent-induced encephalopathy follows the principles described above under Toluene, xylene and styrene, p. 327.

ALCOHOLS

Alcohols share the common property of an -OH group in a carbon chain; primary alcohols in the form of R-CH₂OH, secondary alcohols R₁R₂CHOH and tertiary alcohols R₁R₂R₃C-OH. With increasing chain length, the volatility, water solubility and skin penetration capacity of the alcohol decrease. Toxicity per mole absorbed increases with increasing chain length, but methanol is an important exception.

Alcohols are very extensively used as solvents and also as building blocks in organic synthesis.

The acute toxic effects of alcohols, notably of the low-boiling alcohols, such as methanol, ethanol and propanols, is mostly due to the ingestion of large quantities, but adverse effects have also been described after occupational inhalation and dermal exposure. The common and most apparent effect of alcohols on humans, is the effect on the central nervous system.

METHANOL

[CAS No. 67-56-1]

Methanol is a clear, colourless, volatile flammable liquid with a mild alcoholic odour. It is, as measured by production volume, one of the most used organic chemicals. It is used in the production of acetic acid and formaldehyde and as a starting material for the synthesis of methyl-tert-butyl ether (MTBE), which is an octane-enhancing and oxygen-donating additive in automotive gasoline. Methanol has also been used as a gasoline additive.

Clinical effects and epidemiology
After exposure, methanol has an acute depressive effect on central nervous system function. This is followed by a symptom-free latent period lasting usually 12–24 hours, occasionally up to two days. Thereafter, dizziness, headache, nausea, vomiting, gastrointestinal pain, blurred vision and pain and light-sensitivity of the eyes follow. The late symptoms are caused by the accumulation of the toxic metabolite, formic acid, which causes a metabolic acidosis (low blood pH, anion gap, compensatory low arterial pCO₂).

Untreated metabolic acidosis may lead to death. The ocular effects are likely to be induced by inhibition of the cytochrome oxidase by formate.

The damage to the retina may be permanent and varies from slight visual disturbance to complete blindness. In mild cases, visual disturbances may disappear with time.

Epidemics with high mortality have been described from the ingestion of illicitly distilled spirits containing methanol. There are case reports and case series of serious, even fatal methanol poisoning following inhalation, and even dermal exposure.

Limited testing in animals has revealed no carcinogenic effects of methanol in animals. Methanol is not genotoxic. Oral and inhalation exposure (usually at exposure levels >10 000 ppm; 13 000 mg/m³) to methanol induced teratogenesis (usually neural and ocular defects, cleft palate, hydronephrosis, deformed tails and limb (paw and digit) anomalies) in mice. This effect apparently is not mediated by the action of formate.

Metabolism and monitoring
Methanol is oxidized by alcohol dehydrogenase to formaldehyde, and this is further oxidized by aldehyde dehydrogenase to formic acid (Figure 42.8). Formic acid is the actual toxic species: it induces metabolic acidosis, and in humans is cleared slowly, with the half-times generally being between three and ten hours, but cases with a half-time of 77 hours have been reported.

Management and diagnosis
Methanol intoxication should be suspected when a patient with a history of exposure to methanol presents with metabolic acidosis, with or without effects on vision. Diagnosis may be aided by the analysis of methanol and formate in serum. Elevated concentration of formate in serum is not
specific for methanol intoxication (there may have been exposure to formate itself), but it is useful in the monitoring of the efficacy of treatment and also in the assessment of the need for haemodialysis.

The traditional management of methanol poisoning makes use of the fact that the toxicity of methanol is due to the oxidation of methanol to formate: this reaction is blocked by administration of ethanol, which competitively and effectively blocks methanol oxidation. The same effect may be achieved by administration of methylpyrazole (fomepizole). Fomepizole has recently gained popularity over ethanol as the main therapeutic choice, as it is easier to maintain the therapeutic concentration with fomepizole than with ethanol – for which there is a wide variation in the clearance kinetics.  

Formate may be removed from the body by haemodialysis. It has been recommended that haemodialysis should be started if the blood methanol concentration exceeds 50 mg/dL (15.8 mmol/L).  

In addition to the methods chosen to decrease the generation of formate from methanol, the metabolic acidosis has to be corrected by use of sodium bicarbonate. Furthermore, it may be advantageous to facilitate the conversion of formic acid to carbon dioxide by the administration of folic acid.

Occupational exposure to methanol may be assessed through biological monitoring by the analysis of methanol in urine. As an alternative, analysis of urinary formate has also been suggested. However, meaningful interpretation is only possible if the sample is collected in the morning after the exposure (16 hours after the cessation of the exposure) because of accumulation in the body over time.

ETHYLENE GLYCOL

[CAS No. 107-21-1]

HO\(\text{--OH}\)

Ethylene glycol is a clear, colourless, odourless, relatively non-volatile, viscous liquid. It is used primarily in the production of polyesters for fibres and films, and polyethylene terephthalate. It is also used in a broad range of products, including paints, lacquers and resins, adhesives, coolants and hydraulic brake fluids, automotive antifreeze/coolants, and as a component of de-icing fluids for aircraft, runways and taxiways.

Clinical effects and epidemiology

Numerous case reports on ethylene glycol poisoning, several with fatal outcome, have been described after ingestion of ethylene glycol; published minimal lethal doses in humans have ranged from approximately 0.3 to 1.4 g/kg body weight. Signs of toxicity following ingestion are due mainly to effects on the central nervous system: inebriation, lethargy, seizures and coma. These are followed by metabolic acidosis, hyperkalaemia, hypocalcaemia, concomitant with tachycardia and hypertension. Finally, haematuria, renal tubular necrosis and renal failure may develop.

Following inhalation exposure, ethylene glycol toxicity observed in humans has been low, nose and throat irritation being the major findings. Notably, metabolic acidosis and renal effects have not been reported after inhalation exposure. Ethylene glycol is a mild irritant to the eyes and skin. Contact dermatitis has not been reported.

In experimental animals, ethylene glycol is not mutagenic and limited carcinogenicity testing has not shown evidence of carcinogenicity. Ethylene glycol is teratogenic in rats and mice at doses lower than those overtly toxic to the dams.

Metabolism and monitoring

Ethylene glycol is effectively absorbed from the gastrointestinal tract and by inhalation. Dermal absorption is slower and less complete, but has reached 20–30 per cent in six hours in experimental animals. Ethylene glycol is oxidized by alcohol dehydrogenase to glycol aldehyde, and subsequently to glycolic acid, formic acid and oxalic acid (Figure 42.9).

Acidosis and subsequent renal toxicity after high oral doses of ethylene glycol is caused by metabolites of ethylene glycol, notably by oxalic acid, which crystallizes in the kidneys. Cytotoxicity of other metabolites, such as glycoaldehyde, glycolic acid, and glyoxylic and formic acids, may contribute to the renal damage (with the acids contributing to the acidosis).

Management and diagnosis

Ethylene glycol poisoning should be suspected in cases with metabolic acidosis with anion and osmolar gap. A diagnosis may be reached from the analysis of oxalic acid and ethylene glycol in urine or blood.

As the renal toxicity ensues from the action of metabolites, toxicity may be prevented by the inhibition of ethylene

![Figure 42.9](image-url)  
**Figure 42.9** Metabolism of ethylene glycol.  

Alcohols 337
glycol metabolism. The treatment includes correction of the acidosis, hyperkalaemia and hypocalcaemia, treatment of seizures, and inhibition of the metabolism of ethylene glycol with ethanol infusion, or fomepizole. Ethylene glycol and the toxic metabolites may be removed by haemodialysis.95

**ALDEHYDES**

Aldehydes have the common structure R-CHO. They react avidly especially with thiols and amines. Because of the reactivity, many of them are irritants or even corrosive, and in experimental systems, genotoxic and cytotoxic. Also because of the reactivity, they tend to have a short half-life, and their effects are mostly limited to the site of entry. Exposure to liquid aldehydes tends to cause contact eczema by irritation or sensitization.

**FORMALDEHYDE**

[CAS No. 50-00-0]

Formaldehyde is a flammable, colourless and readily polymerized gas at ambient temperature with a pungent, suffocating odour. Formaldehyde solution (formalin) is a clear, colourless liquid with a pungent odour. The most common commercially available form of formalin is a 30–50 per cent aqueous solution containing methanol. Formaldehyde is used mainly as an intermediate in the chemical industry for the production of resins for the wood, paper and textile processing industries and in the synthesis of methylene diaminine, diphenylmethane diisocyanate, hexamethylenetetramine, trimethylol propane, neopentylglycol, pentaerythrilol and acetylenic agents. Aqueous solutions of formaldehyde are employed as germicides, bactericides and fungicides. Tobacco smoke, release from urea-formaldehyde foam insulation, formaldehyde-containing disinfectants and preservatives in consumer products, as well as from engine exhausts are important sources of formaldehyde exposure. Formaldehyde is also a product of intermediary metabolism.96,97

It is quickly metabolized and even at high inhalation exposure levels, elevated concentrations of formaldehyde have not been observed in the blood. Thus, the most likely targets for formaldehyde action are the sites of immediate contact, i.e. the respiratory tract epithelium and the skin.

**Clinical effects and epidemiology**

Irritation of the eyes and respiratory tract by formaldehyde has been observed consistently in clinical studies and epidemiological surveys, usually when the concentration of formaldehyde in the air exceeds approximately 0.1 ppm (0.1 mg/m³). At higher concentrations, formaldehyde may also contribute to the induction of obstructive effects on lung function, which are usually quantitatively minor and reversible.96 The respiratory effects of formaldehyde may be mediated by an immunological mechanism, but respiratory sensitization to formaldehyde is apparently rare.

Dermal exposure to formaldehyde in solution causes skin irritation and can provoke contact eczema through irritation, but also through an immunological mechanism affecting susceptible individuals. Contact dermatitis may be elicited in sensitized individuals following exposure to formaldehyde at concentrations as low as 30 mg/L.98

A large number of epidemiological studies have investigated the possible role of formaldehyde as a causative agent for cancer in different parts of the respiratory tract and of leukaemia. In October 2009, IARC concluded that ‘there is sufficient evidence in humans of an increased incidence of nasopharyngeal carcinomas among formaldehyde-exposed people’, and the epidemiological evidence on leukaemia has become stronger with new studies. For both cancer types, the group 1 classification is supported by strong mechanistic evidence.99,100

Inhalation exposure to formaldehyde induced squamous cell carcinoma in the nasal cavity in rats. Formaldehyde is genotoxic in vitro; it also induced protein–DNA crosslinks and cellular proliferation in respiratory epithelium in experimental animals after inhalation exposure. It is likely that both genotoxicity and cell proliferation contribute to the carcinogenic action of formaldehyde.96,99,100

**Metabolism and monitoring**

Formaldehyde is rapidly absorbed from the respiratory tract and metabolized mainly to formic acid and carbon dioxide. Part of the inhaled formaldehyde undergoes intermediary metabolism. Elevated formaldehyde levels in the plasma or urine have not been demonstrated after inhalation exposure to formaldehyde in humans or experimental animals.

**GLUTARALDEHYDE**

[CAS No. 111-30-8]

Glutaraldehyde is a colourless, oily liquid which crosslinks with proteins and, in aqueous solutions, partially polymerizes to form oligomers. Glutaraldehyde is used as an immersion disinfectant in a 1 or 2 per cent aqueous solution for sterilizing endoscopes and other surgical instruments; as a hardener in x-ray film processing; for the prevention of microbial growth and metal corrosion in circulating water systems, including off-shore operations; as a biocide in the petroleum, pulp and paper industries; and as a preservative in industrial cleaning agents for example, in the food,
beverage and tobacco manufacturing industries, and in retail detergents. It is used to disinfect animal housing and bird cages in the form of sprays and by fogging, and to control microorganisms in fish farming. Aqueous solutions of glutaraldehyde are used to soften leathers and to improve their resistance to water, alkalis and mould. It is also used as a tissue fixative in histology and electron and light microscopy. Glutaraldehyde is allowed as a preservative for cosmetics in Europe, but not in the form of aerosols or sprays.\textsuperscript{101}

**Clinical effects and epidemiology**

Glutaraldehyde is an irritant at high concentrations and is corrosive to the skin, eyes and respiratory membranes. The irritative effect is accentuated by the presence of bicarbonate which is added to the glutaraldehyde solutions in use to improve their efficacy as a disinfectant.

In some patients with glutaraldehyde-induced contact dermatitis, there is a positive reaction in patch testing, indicating an immunological mechanism. Immunological processes may also be involved in the respiratory effects (asthma, rhinitis) of glutaraldehyde.\textsuperscript{102,103}

In experimental animals, glutaraldehyde is positive in genotoxicity studies \textit{in vitro}, but usually negative \textit{in vivo} studies. Exposures causing maternal toxicity induce embryo- and fetotoxicity, but teratogenicity has not been reported.\textsuperscript{101}

**KETONES**

The basic structure of ketones is $R_1R_2C=O$. The most commonly used ketones are acetone, methylethylketone, methyl isobutylketone, cyclohexanone, 4-hydroxy-4-methyl-2-pentanone, isophorone, mesityl oxide and acetophenone. Ketones are very extensively used notably as solvents, as they dissolve organic compounds. Ketones are irritating to the mucous membranes and skin. They induce central nervous system depression. Ketones have no sensitizing potential; they are generally not mutagenic, or toxic to reproduction, and have not been shown to be carcinogenic.

**ACETONE**

[**CAS No. 67-64-1**]

Acetone is the simplest of ketones. It is a clear and colourless liquid with a strong ‘fruity’ odour. Acetone is extensively used as an industrial solvent, and in inks, paints, varnishes and other consumer products. It is a starting material for the synthesis of other ketones, such as isophorone and methyl isobutylketone, and other organic chemicals, for example methyl methacrylate and bisphenol A. Acetone is quite volatile, and thus use of acetone may lead to substantial inhalation exposure.

Acetone is produced endogenously in intermediary metabolism mainly from fatty acid oxidation, and its concentration may be high among patients with uncontrolled diabetes mellitus. Fasting and strenuous exercise also elevate body acetone concentrations.

**Clinical effects and epidemiology**

Acetone has low toxicity. At high concentrations, acetone vapour can cause CNS depression, cardiorespiratory failure and death. Eye and nose irritation have been reported at concentrations $\geq 250$ ppm (600 mg/m$^3$), with headache, dizziness, mood changes and ‘confusion’ at 1000 ppm (2400 mg/m$^3$). Vomiting and fainting have been reported in workers exposed to acetone vapour at concentrations $>12000$ ppm (29000 mg/m$^3$) for approximately four hours. Experimental exposure to 250 ppm (600 mg/m$^3$) of acetone was reported to induce changes in neurobehavioural tests.\textsuperscript{104}

Acetone is negative in mutagenicity tests, only slight developmental effects were observed in rats and mice at exposure levels in excess of 6600 ppm (16 000 mg/m$^3$). No carcinogenicity studies are available on acetone, but it has been used extensively as a negative control in skin painting carcinogenicity studies.

**Metabolism and monitoring**

Acetone is metabolized to acetate and formate; these are intermediate steps in metabolic pathways (e.g. to fatty acids, amino acids and in gluconeogenesis). Acetone is mainly excreted unchanged by exhalation, and as the ultimate step in its catabolism, to carbon dioxide. Small amounts of acetone are also excreted in urine.

Acetone induces the cytochrome P450 2E1 enzymes, and may thus effect the metabolism of chemicals that rely on this pathway (e.g. ethanol, benzene, $N$-nitrosodimethylamine, $N$-nitrosodiethanolamine, haloalkanes).

**METHYLETHYL KETONE**

[**CAS No. 78-93-3**]

Methylethyl ketone (MEK) is a highly flammable, volatile, clear, colourless liquid that is stable under ordinary conditions. The primary use of methylethyl ketone, accounting for approximately 63 per cent of all use in the United States, is as a solvent in protective coatings. It is also used as a solvent in adhesives, printing inks, paint removers, in the production of magnetic tapes, and in dewaxing lubricating oil. Methylethyl ketone is used as a chemical intermediate in several reactions, including condensation, halogenation, ammonolysis and oxidation. Small amounts of methylethyl ketone are used as a sterilizer for surgical instruments,
hypodermic needles, syringes, and dental instruments; as an extraction solvent for hardwood pulping and vegetable oil; and as a solvent in pharmaceutical and cosmetic production. MEK is also found in tobacco smoke and exhaust gases from gasoline engines.

MEK is more irritating than acetone to mucous membranes. It has low acute toxicity, but it potentiates the neurotoxicity of \( n \)-hexane and methyl-\( n \)-butylketone (see under \( n \)-Hexane, p. 323) and the liver and kidney toxicity of carbon tetrachloride and trichloromethane. The mechanism for the latter may be induction of cytochrome P450, although an inducing effect of MEK on this enzyme activity is not observed at low exposure levels. The mechanism could be the same for the potentiation of hexacarbon neurotoxicity, but this has not been clearly demonstrated.

MEK is readily absorbed via the respiratory tract, and metabolized to 2-butanol, 2-hydroxy-2-butanone, and 2,3-butanediol and further to products that are incorporated in intermediary metabolism. Smaller amounts are exhaled unchanged; MEK is also found in urine at low levels.

**METHYL ISOBUTYL KETONE**

[CAS No. 108-10-1]

Methyl isobutyl ketone (MiBK) is a clear liquid with a sweet odour. The primary use of methyl isobutyl ketone is as a solvent in protective coatings. It is also used as a solvent in specialty adhesives, in ink formulations, in dewaxing mineral oil, and in textile coatings and leather finishing. As a process solvent, methyl isobutyl ketone is used in the separation and purification of certain metal ions, such as zirconium from hafnium; in the extraction and purification of antibiotics and other pharmaceuticals; and in the manufacture of insecticides and other pesticides. It is also used in purifying stearic acid, refining tall oil and extracting rosin from softwood, especially pine. It is used as a carrier in riot control sprays, for example CS gas.

Exposures to MEK in the range of 25–50 ppm (260–530 mg/m\(^3\)) have been reported to cause respiratory tract irritation. Inhalation exposure to concentrations in excess of 1000 ppm (11 000 mg/m\(^3\)) causes central nervous system depression.

**METHYL \( n \)-BUTYL KETONE (2-HEXANONE)**

[CAS No. 591-78-6]

Methyl-\( n \)-butyl ketone (MnBK) is a clear, colourless, volatile liquid with a sharp odour. It is metabolized to 2-hexanol, 5-hydroxy-2-hexanone, and then to 2,5-hexanediol. This is the metabolite responsible for hexane neuropathy (see under \( n \)-Hexane, p. 323). Consistent with this finding, many cases of peripheral neuropathy have been reported among workers exposed to 2-hexanone; the disease has also been reproduced in experimental animals.

Hexanone, and also 2,5-hexanediol, have induced adverse testicular effects in rodents.

**ETHERS**

Ethers have the general formula \( R_1-O-R_2 \), the simplest of them being dimethyl and diethyl ethers (\( CH_3OCH_3 \), \( C_2H_5OC_2H_5 \)). Ethers are used as solvents, and intermediates in synthetic processes.

**CHLOROMETHYL METHYLETHELER AND BIS(CHLOROMETHYL)ETHER**

Chloromethylmethylether (CMME) (CAS No. 107-30-2) is a colourless liquid with a characteristic odour. It is a direct-acting alkylating agent and it has been extensively used as a cross-linking agent in ion exchange resins and as an intermediate in chemical syntheses. It is a potent irritant to mucous membranes. In 1968, it was demonstrated to be a potent carcinogen in experimental animals. The impurity bis(chloromethyl)ether (BCME) (CAS No. 542-88-1), which occurred in technical chloromethylmethylether, was an even more potent carcinogen. Bis(chloromethyl)ether can form spontaneously from the reaction of hydrochloric acid with formaldehyde. Several studies, starting in the 1970s, have convincingly demonstrated that exposure to technical chloromethylmethylether – apparently always containing BCME as an impurity at a level of a few per cent – is a very potent carcinogen in humans, causing lung cancer, usually of the microcellular type. IARC concluded in 1987 that bis(chloromethyl)ether and technical chloromethylmethylether are carcinogenic to humans; they induce cancer of the lung. The homologues bis(2-chloroethyl)ether and bis(2-chloro-1-methylethyl)ether were not classifiable as to their carcinogenicity to humans.

**METHYL-\( \text{tert} \)-BUTYLETHELER**

[CAS No. 1634-04-4]

Methyl-\( \text{tert} \)-butylether (MTBE) is a volatile, colourless liquid at room temperature with a terpene-like odour. It is used as an octane enhancer and oxygen provider in gasoline, and to a small extent, as a solvent. Following the introduction of two separate fuel programmes in the...
United States requiring the use of gasoline oxygenates, consumers in some areas complained about headache, eye and nose irritation, cough, nausea, dizziness and disorientation. Epidemiological studies of occupationally and non-occupationally exposed people, and studies of exposed volunteers, have not been able to identify a basis for these complaints.\textsuperscript{118}

Inhalation exposure to methyl-\textit{tert}-butyl ether increased the incidence of hepatocellular adenomas in female mice and that of renal tubular tumours in male rats in a non-dose-related manner. In a gavage study in rats, MTBE increased the incidence of Leydig-cell tumours of the testis in males, and of lymphomas and leukaemias in females. The IARC concluded from these carcinogenicity data that there is limited evidence for the carcinogenicity of MTBE in experimental animals. MTBE does not appear to be genotoxic, and does not induce adverse developmental effects in experimental animals at exposure levels that are not overtly toxic to the dams.\textsuperscript{117,119}

MTBE is oxidatively demethylated to formaldehyde and \textit{t}-butanol (TBA). Formaldehyde is rapidly biotransformed (and has not been measured \textit{in vivo} following MTBE exposures) further to formic acid, \textit{CO}_2, or becomes incorporated into the one-carbon pool. The biotransformation of TBA yields 2-methyl-1,2-propanediol and \(\alpha\)-hydroxyisobutyric acid (Figure 42.10).

Concentration of \textit{t}-butyl alcohol in morning urine specimens (16 hours after the cessation of the exposure) may be used for biomonitoring of MTBE.\textsuperscript{120,121}

tert-\textit{AMYL METHYLEETHER}

[\text{CAS No. 994-05-8}]

\textit{t}-Amyl methyl ether (TAME) is clear, colourless and volatile liquid. Like MTBE, it is used as an octane-enhancer and oxygen donor in gasoline, and as a component of an ether mixture added to gasoline. The proportion of TAME in gasoline may exceed 10 per cent.\textsuperscript{122} The advantage of TAME over MTBE is that it is less volatile, and since it is less water soluble, it is not an equal threat to groundwater. TAME is slightly irritating to the eyes and respiratory tract, and at high concentrations, narcotic. In a 78-week gavage study in rats, with limited data reported, statistically non-significant increases were observed for tumours at several sites, and a significant increase was observed for lymphomas and leukaemias combined.\textsuperscript{123} Noting the non-mutagenicity of TAME, and the uncertainties in the assessment of the only available carcinogenicity study, the European Union decided not to use carcinogenicity as the end point for the risk assessment of TAME.\textsuperscript{122} In developmental toxicity studies in mice, cleft palate was observed in mice at inhalation exposure levels that only induced hepatic enlargement in the dams. In rats, weight reduction of the litters was observed at inhalation exposure levels that also induced maternal weight reduction. Based on these findings, the European Union did not consider there to be sufficient evidence to classify TAME as hazardous to human reproduction.\textsuperscript{122} TAME is metabolized to several metabolites (2-methyl-2,3-butanediol, 2-hydroxy-2-methylbutyric acid and 3-hydroxy-3-methylbutyric acid), after an initial hydrolysis of the ether bond to \textit{t}-amyl alcohol. Concentration of \textit{t}-amyl alcohol in morning urine specimens may be used for biomonitoring.\textsuperscript{120,121}

**Glycol ethers**

Glycol ethers, also called ‘cellosolves’, and chemically more appropriately called ‘alkoxyalcohols’ are condensation products of a glycol, such as ethylene glycol or propylene glycol, and an alcohol, such as methanol, ethanol or propanol. Because of their physicochemical characteristics, notably solubility both in water and in organic solvents, and low vapour pressure, they have found very extensive use as solvents in paints, lacquers, resins and pesticides. Glycol ethers are also present in consumer products, such as perfumes and household chemicals.

---

\textbf{Figure 42.10 Metabolism of methyl-\textit{tert}-butyl ether.}\textsuperscript{119}
Many glycol ethers are readily absorbed through the skin, and as the volatility of glycol ethers is low, in many instances, dermal absorption may be more significant than the respiratory uptake at work. While alkoxyalcohols in general have low acute toxicity, some of them are toxic to reproduction, and some cause haemolysis (Figure 42.11). The first glycol ethers to enter the market were the simplest ones, ethyleneglycol ethers of methanol and ethanol. These, however, proved to be toxic to reproduction, and should by now no longer be used anywhere. They have been replaced by ethers with longer-chain alcohols, such as butanol, and derivatives of propylene glycol rather than ethylene glycol.

In addition to glycol ethers, their acetates (such as methoxyethanol acetate versus methoxyethanol) also have been extensively used. In most cases, the acetates are very readily hydrolysed to the parent glycol ethers by the action of carboxylesterases, and present practically identical toxicity as the parent glycol ethers themselves.

**METHOXYETHANOL (ETHYLENELYCOL MONOMETHYL ETHER)**

![Methoxyethanol and Methoxymethylacetate](image)

Methoxyethanol (CAS No. 109-86-4) and methoxymethylacetate (CAS No. 110-49-6) are stable flammable liquids with a slight odour at normal room temperature and pressure.

2-Methoxyethanol has been used in paints, coatings, inks, varnishes, cleaners, polishes, brake fluids and jet fuels, as a solvent, as a chemical intermediate and as a solvent coupler of mixtures and water-based formulations.

**Clinical effects and epidemiology**

2-Methoxyethanol is of low to moderate acute toxicity following oral, inhalation or dermal exposure. It has low potential for causing skin or eye irritation and has not been shown to be a skin sensitizer. Effects on haematological parameters, notably on red blood cell counts, have been observed in humans occupationally exposed to methoxyethanol/acetate. In addition, available data are suggestive of effects on spermatogenesis in men employed in occupations involving exposure to 2-methoxyethanol. Increased risk of spontaneous abortions has been observed in studies among women exposed to alkoxyethanols. It is not possible to discern the effect of methoxyethanol exposure in these studies.

Haematological effects were observed among men exposed to methoxyethanol at exposures where no effects on sperm counts were observed. These men were apparently not exposed to other alkoxyalcohols or chemicals known to affect the bone marrow. A clear-cut haematotoxic effect was observed in workers exposed to 2-methoxyethanol at a time-weighted average concentration of 36 ppm (113 mg/m³). A recovery towards normal was noted at an exposure level of 2.7 ppm (8.4 mg/m³) and full recovery occurred at 0.55 ppm (1.7 mg/m³).

In laboratory animals, the key adverse health effects following repeated exposure to 2-methoxyethanol are haematological effects, and reproductive and developmental toxicity, including both effects on fertility and teratogenicity. Testicular degeneration and effects on the blood were observed following oral and inhalation exposure of rats to the lowest dose tested. Methoxyethanol is considered toxic to reproduction.

**Metabolism and monitoring**

Methoxyethanol is readily absorbed via the respiratory tract, but also through the skin (Figure 42.12). In occupational settings, the dermal absorption may be the major route of absorption. Methoxyethyl acetate is hydrolysed by esterase activity to methoxyethanol. Methoxyethanol is metabolized by alcohol dehydrogenase and aldehyde dehydrogenase to methoxacetaldehyde and methoxyacetic acid. A minor metabolic pathway leads to ethylene glycol and formic acid (and helps explain oxaluria reported in cases of acute intoxication after large oral doses of methoxyethanol). Methoxacetic acid is apparently the ultimate toxic species both for the haematological and reproductive toxicity. Because of the possibility of extensive dermal absorption, the best estimate of exposure at the workplace is by biological monitoring, i.e. analysis of
methoxyacetic acid in the urine in a post-shift specimen collected towards the end of the working week.130–133

ETHOXYETHANOL (ETHYLENEGLYCOL MONOETHYL ETHER) AND ETHOXYETHYL ACETATE

Ethoxyethanol (CAS No. 110-80-5) and ethoxyethyl acetate (CAS No. 11-15-9) are stable flammable liquids with a slight odour at normal room temperature and pressure. They have been used in paints, coatings, inks, cleaners, polishes, brake fluids and jet fuels, as well as a solvent, chemical intermediate and solvent coupler of mixtures and water-based formulations. Ethoxyethyl acetate is readily hydrolysed to ethoxyethanol, and has practically identical effects at equimolar exposure levels.

Because of the risk to reproduction, ethoxyethanol has been widely abandoned; however, it is not self-evident that its use has completely stopped in different parts of the world.

Clinical effects and epidemiology

While some cases of acute intoxication by ethoxyethanol after ingestion of large doses have been described, ethoxyethanol and its acetate have low acute toxicity in occupational settings. They have low irritant potential, and there are no data to indicate that they cause dermal or respiratory sensitization.

Three studies point to a possibility that ethoxyethanol induces semen abnormalities following occupational exposure.134–136 Two other studies, one of which was performed in workers involved in silk screening with a reasonably pure exposure to ethoxyethanol, indicated that the exposure induced a deficit in erythropoiesis.137,138

While studies in exposed humans are quite limited and often involve mixed exposure with regard to both these endpoints, they are amply supported by studies in experimental animals, which clearly demonstrate that ethoxyethanol causes sperm abnormalities in males and is embryotoxic, fetotoxic and teratogenic in different animal species at exposure levels that are not overtly toxic to the dams – and after both inhalation and dermal exposure.139 Similarly, the effect on haematopoiesis is demonstrated convincingly in experimental animals.139

Figure 42.12  Metabolism of methoxyethanol.126
Metabolism and monitoring

Ethoxyethanol is readily absorbed via the respiratory tract, but also through the skin. In occupational settings, dermal absorption may be the major route of absorption. Ethoxyethyl acetate is hydrolysed by esterase activity to ethoxyethanol. Ethoxyethanol is metabolized by alcohol dehydrogenase and aldehyde dehydrogenase to ethoxyacetaldehyde and ethoxyacetic acid (Figure 42.13). Ethoxyacetic acid is apparently the ultimate toxic species both for haematological and reproductive toxicity. Therefore, and because of the possibility of extensive dermal absorption, the best estimate of exposure at the workplace is by biological monitoring, i.e. analysis of ethoxyacetic acid in a post-shift specimen of urine collected towards the end of the working week.

BUTOXYETHANOL (ETHYLENEGLYCOL MONOBUTYL ETHER)

2-Butoxyethanol (CAS No. 111-76-2) is a colourless liquid with a mild ether-like odour. It is widely used as a solvent in surface coatings (paints and varnishes), paint thinners, printing inks and glass- and surface-cleaning products (including those used in the printing and silk-screening industries), and as a chemical intermediate.

Clinical effects and epidemiology

Statistically significant minor changes in haematocrit and mean corpuscular haemoglobin concentration were observed in a group of people occupationally exposed to average concentrations of 2-butoxyethanol of 0.6 ppm (3 mg/m³). Nasal and eye irritation were observed at exposures between 100 and 180 ppm (500–900 mg/m³) 2-butoxyethanol for two to four hours. When two males and two females were exposed to 2-butoxyethanol at 100 ppm (500 mg/m³) for eight hours, the effects included vomiting and headache, with no clinical signs of haemolysis.

Haemoglobinuria, erythrocytopenia, metabolic acidosis, hypotension, pulmonary oedema, albuminuria and hepatic abnormalities have been reported in individuals who had attempted suicide by ingesting cleaning solutions containing

Figure 42.13 Metabolism of ethoxyethanol.
Effects characteristic of poisoning with ethylene glycol (a metabolite of 2-butoxyethanol in humans) such as coma, metabolic acidosis, and renal function changes have been reported in several cases and in cross-sectional studies. 2-Butoxyethanol is apparently not a skin sensitizer.

Good studies on the carcinogenicity of butoxyethanol in humans are not available. In long-term studies on carcinogenicity, exposure to 2-butoxyethanol induced a dose-related increase in the incidence of haemangiosarcomas of the liver in male mice and a dose-related increase in the incidences of combined forestomach squamous-cell papillomas or carcinomas (mainly papillomas) in female mice. No clear-cut carcinogenic effect was observed in rats. The IARC has included butoxyethanol in group 3, i.e. ‘not classifiable’.

In contrast to methoxy- and ethoxyethanol, there is no indication that butoxyethanol is toxic to reproduction. Tests on genotoxicity are similarly negative; however, the intermediate in butoxyethanol metabolism, butoxyaldehyde, is weakly genotoxic.

**Metabolism and monitoring**

Butoxyethyl acetate (CAS No. 112-07-2) is readily hydrolysed by esterases to butoxyethanol. The main metabolites of butoxyethanol are butoxyaldehyde and butoxyacetic acid, the formation of which is catalysed by alcohol and aldehyde dehydrogenases (Figure 42.14). De-ethylation of butoxyethanol produces ethyleneglycol as a minor metabolite. The haemolytically active species is butoxyacetic acid.

In humans, the generation of butoxyacetic acid from butoxyethanol is slower than in rodents, and in addition, rodent erythrocytes are more sensitive than humans to the haemolytic effect of butoxyacetic acid.

For butoxyethanol, the contribution of dermal absorption to total body exposure has been estimated by different authors to be between 25 and 75 per cent of total absorption. Since butoxyethanol is readily absorbed through the skin, biological monitoring methods have been developed for the assessment of exposure to butoxyethanol. This is performed by the analysis of butoxyacetic acid (the metabolite responsible for the main toxicological effects) in urine.

**METHOXYPROPANOL (PROPYLENEGLYCOL METHYLEETHER)**

[CAS No. 107-98-2 and CAS No. 1589-47-5]
It is a mixture of two isomers, 1-methoxy-2-propanol, also called α-isomer, i.e. secondary alcohol, and 2-methoxy-1-propanol, also called β-isomer, i.e. primary alcohol. This is important, as the two isomers have distinct metabolic differences, and are also toxicologically different. In many countries, limits have been set for the maximal proportion of the β-isomer allowed in the commercial product.

Propyleneglycol methylethers are soluble in water and solvents, are not very volatile, have low irritation capacity, and have no offensive smell. They have found extensive use as solvents for surface coatings, inks, lacquers, paints, resins, dyes, agricultural chemicals, oils and greases. The glycol, PGME is also excreted in urine unchanged. Oxidation cause reproductive toxicity. 2-Methoxy-1-propanol (but β-isomer in PGME is below 0.5 per cent, it is unlikely to

Clinical effects and epidemiology

In experimental inhalation exposure, no irritation or discomfort was observed at concentrations of 100 ppm (370 mg/m³), with slight discomfort reported at 150 ppm (560 mg/m³). No data on reproductive or long-term effects in humans are available.

Inhalation exposure to 1000 ppm PGME for two years induced renal tubular adenomas in male Fischer rats; this was accompanied by renal accumulation of α-2 microglobulin and hyaline-drop degeneration. This phenomenon has been considered to be specific to male rats and thus not fully relevant to humans. No increased incidence of tumours in other tissues of rats or mice were observed.

PGME had no effect on the fertility, did not affect sperm quality in rats, was not embryo- or fetotox in mice, rats or rabbits and did not induce teratogenesis. The β-isomer in contrast was fetotoxic and teratogenic, and decreased testicular and epididymal sperm counts in rats. It has been thought that the difference in the toxicity of the α-isomer and β-isomer is due to the formation of the methoxypropionic acid from the latter, but not from the former (see below). It is the alkoxyacid which apparently is the cause of the reproductive, developmental and even haemotoxotoxic effects of methoxy-, ethoxy- and butoxyethanols, but methoxypropionic acid only caused developmental effects at exposure levels that also were toxic to the dams. It has been proposed that if the content of the β-isomer in PGME is below 0.5 per cent, it is unlikely to cause reproductive toxicity. 2-Methoxy-1-propanol (but not 1-methoxy-2-propanol) is classified as reproductive toxicity category 2 by the European Union.

Metabolism and monitoring

Like ethyleneglycol ether acetates, propyleneglycololylether acetate is rapidly hydrolysed in vivo and in vitro to PGME; the two seem to be toxicologically equivalent. At low exposures, most of inhaled PGME is metabolized to carbon dioxide and exhaled. At increasing doses, PGME is increasingly conjugated with glucuronic acid and sulphate. A smaller fraction is O-demethylated to propylene glycol. PGME is also excreted in urine unchanged. Oxidation to methoxypropionic acid apparently does not take place. The β-isomer is mainly oxidized by alcohol dehydrogenase to methoxypropionic acid. Direct conjugation with glucuronic acid and metabolism to carbon dioxide are minor pathways.

As dermal exposure may significantly contribute to the total exposure, biomonitoring is useful for the assessment of exposure. Analysis of total 1-methoxy-2-propanol in urine is the best validated urinary marker of exposure.

CARBOXYLIC ACIDS AND THEIR DERIVATIVES

Carboxylic acids form a large and heterogeneous group of chemicals, with the generic formula R–COOH. This family includes aliphatic acids, saturated and unsaturated, all of which may be mono- or polycarboxylic, as well as aromatic acids. Carboxylic acids may contain substituents other than carbon, oxygen and hydrogen. Acids containing halogenes have important industrial applications, and many are of occupational health interest.

Carboxylic acids are generally soluble in water; the solubility decreasing with increasing molecular mass. The most conspicuous characteristic of carboxylic acids from the human health point of view is that they are strongly irritating or even corrosive to the mucous membranes and the skin. Systemic adverse effects from carboxylic acids are rare in occupational settings, although serious and fatal intoxications have been described after oral and dermal exposure. The main toxicological feature in such cases is usually metabolic acidosis with its sequelae, such as hyperkalemia and hypocalcaemia. Several case reports have been published describing fatal intoxications due to dermal exposure to monochloroacetic acid [CAS No. 79–11–8]. The poisoning cases have involved epidermal and superficial dermal burns, with disorientation, agitation, cardiac failure, metabolic acidosis, rhabdomyolysis, renal insufficiency and cerebral oedema occurring within a few hours.

FORMIC ACID

[CAS No. 64-18-6]

Formic acid is a colourless, fuming liquid, with a pungent odour. It is used in dyeing and finishing of textiles and paper, treatment of leather, electroplating and brewing, silversing glass, and as an intermediate in the manufacture of many chemicals, as a silage additive and prophylactic in animal feeds.

Clinical effects and epidemiology

Human data on the toxicity of formic acid are limited. Severe burns have been reported after dermal exposure to undiluted formic acid.
Acute poisoning after oral or dermal exposure has resulted in metabolic acidosis, intravascular haemolysis and haemoglobinuria.\textsuperscript{180–185} Many cases of fatal formic acid poisoning after ingestion exposure have been described; a dose of 60 g has invariably led to death.\textsuperscript{182,186} Ocular toxicity, similar to methanol intoxication, has been observed in animals treated with formic acid. In inhalation studies in rats and mice, microscopic examination showed lesions (squamous metaplasia, necrosis, degeneration, inflammation) of the nose, larynx and pharynx at concentrations of 60 ppm (120 mg/m\textsuperscript{3}) and higher. Formic acid is immediately transformed to formate in the body. Formate tested negative in bacterial mutagenicity tests using different Salmonella strains.\textsuperscript{187} Formic acid has apparently not been studied for carcinogenicity in experimental animals. In a limited developmental toxicity study, formic acid was not teratogenic, while methanol, causing similar blood formic acid concentrations, induced brain abnormalities.\textsuperscript{84}

Metabolism and monitoring
Formate is partly metabolized in the one carbon pool and is partially excreted unchanged in the urine. The concentration of formate in urine has been used for the biological monitoring of formate exposure.\textsuperscript{92}

Management and diagnosis
Formate intoxication is rare, and as a distinction from methanol poisoning, it is likely that there are symptoms at the point of entry: skin burns and severe gastric discomfort. Poisoned patients also have metabolic acidosis and usually haemolysis. Vision may be affected. A diagnosis may be made by the analysis of methanol and formate in blood. Elevated blood levels of formate, but not of methanol, suggest formic acid poisoning.

Formate poisoning has been successfully treated with haemodialysis, intravenous bicarbonate, administration of folinic acid to facilitate the incorporation of formate to the one carbon pool, and general supportive measures.\textsuperscript{181,184}

**ESTERS**

Esters are condensation products of an acid and an alcohol, and have a general formula \( R_2\text{COOR}_3 \); the simplest ester being methylformate \( CH_2OOCCH_3 \). Esters comprise a very large group of chemicals, the acid moiety may be an alkane, alkene or an aromatic compound, and similarly, the alcohol part may vary. Small molecular weight esters are soluble in water and readily volatile. With an increasing molecular size, both these characteristics decrease. Esters are extensively used as solvents. They are generally inert, with their most important adverse effects usually being narcotic effects at high concentrations, and eye and airway irritation, also skin irritation, from liquid esters. Other than irritation, toxicity is mostly due to the acid part of the molecule.

**ACRYLIC ACID ESTERS**

Acrylic acid (CAS No. 140-88-5) and methacrylic acid (CAS No. 80-62-6) esters readily polymerize and are used extensively for polymer production.

Methyl methacrylate is commonly used in a mixture with pre-polymerized oligomers to prepare medical and dental prostheses and orthodontic devices that are often finished with the technician’s bare hands to obtain the desired dimensions before final hardening of the product. In this respect, dental uses of the monomer differ from industrial application, which do not generally require manual handling of monomer-containing products. Thus, it is understandable that reports on adverse effects from methyl methacrylate come mainly from its use in dentistry.

**Clinical effects and epidemiology**
Acrylic and methacrylic esters are irritating to the eyes, respiratory tract and the skin.

Methyl methacrylate is well known to cause allergic contact dermatitis, typically at the fingertips, spreading along the nail walls, with painful desquamation.\textsuperscript{188–190} Among dental laboratory technicians, the most common allergens include methyl methacrylate, 2-hydroxyethyl methacrylate and ethylenglycol dimethacrylate.\textsuperscript{191} Sensitization to a large number of other acrylates has also been described in a variety of occupations with skin contact to monomer-containing products. Acrylate derivatives to which sensitization has been demonstrated include methylenmethacrylate, ethylmethacrylate, 2-hydroxyethyl methacrylate, 2-hydroxypropyl methacrylate, \( N,N \)-dimethylaminoethyl methacrylate, glycylid methacrylate, tetrahydrofururyl methacrylate, ethylenglycol dimethacrylate, diethyleneglycol dimethacrylate, triethylene glycol dimethacrylate, polyethylene glycol dimethacrylate, urethane dimethacrylate, ethyl acrylate, hydroxyethyl acrylate, hydroxypropyl acrylate, phenoxeythoxy ethylacrylates, hexanediol diacrylate and trimethylolpropane triacrylate.\textsuperscript{192–197}

In addition to dentistry, occupations with reported cases include manufacture of printed circuit boards,\textsuperscript{198} opticians working with polymethyl(meth)acrylate\textsuperscript{199} and optical fibre manufacture (UV-curable acrylate resin coating).\textsuperscript{200}

Skin exposure to methyl methacrylate (usually in the presence of dermatitis) may lead to neurological damage. In an early study, 17 per cent of a group of dental technicians, their assistants, and students of the Dental Technician Institute in Finland reported current or previous hand dermatitis, and 25 per cent reported other finger symptoms, such as whitening, numbness, coldness or pain.\textsuperscript{201} Slowed distal sensory conduction velocity from digits I, II and III of the right hand, and also of the radial
aspects of the digits II and III of the left hand was observed among the dental technicians. These findings represent mild axonal degeneration on the areas with the closest and most frequent contact with methyl methacrylate.202 Finger paraesthesia may also develop without overt dermatitis.203

Asthma, rhinitis and conjunctivitis have been reported among workers exposed to acrylates, methacrylates and cyanoacrylates. Hypersensitivity pneumonitis has also been observed in methacrylate-exposed dental technicians.204–209 Available epidemiological evidence does not point to a carcinogenic effect of methyl methacrylate.210,211 The IARC has categorized it into group 3 (i.e. not classifiable).

Methyl methacrylate has been tested in rats and mice for carcinogenicity by inhalation; IARC concluded that there is evidence suggesting lack of carcinogenicity.210 For ethyl acrylate, the IARC concluded that there is sufficient evidence of carcinogenicity in animals (group 2B).212 Many acrylates, including methyl methacrylate, are mutagenic to bacteria and/or mammalian cells in vitro, but are mostly negative in genotoxicity tests in vivo. Methyl methacrylate was not toxic to reproduction in experimental animals.210

Metabolism and monitoring

Acrylates are absorbed effectively through the respiratory tract and also the skin. They are metabolized rapidly. For several (meth)acrylate esters, metabolism yields small amounts of thioethers, indicating electrophilic metabolites. No validated biomonitoring methods exist for acrylates.

Management and diagnosis

The main means of diagnosing allergic contact dermatitis is by patch testing. However, the group of acrylates is large and varied, and not all possible allergens are available commercially as test reagents. Therefore, the products to which the patient has been exposed, should also be included in the test series – as is also true for diagnosing most cases of occupational contact dermatitis.192 Challenge tests have been used for the diagnosis of acrylate-induced rhinitis and asthma, when the clinical picture and history do not provide a conclusive diagnosis.204–209 However, caution must be exercised in ensuring that, especially for bronchial provocation tests, these are performed in hospital settings with access to immediate emergency support in the event that a severe allergic reaction results from the challenge. Methyl methacrylate-induced axonal damage may be present in the absence of contact dermatitis. The diagnosis is based on the clinical picture and history; nerve conduction velocity determinations may be considered. Axonal damage in dental personnel is a difficult clinical management problem, because acrylates penetrate standard gloves, and truly effective protective gloves tend to affect manual dexterity. This poses a dilemma in regards to providing occupational medical advice on continuing or changing vocation for affected individuals.

**Amides**

Amides are of the general form R1CONR2R3, the simplest of them being formamide –HCONH2. Dimethylacylamides, such as dimethylformamide, and dimethylacetamide are used extensively. They are miscible in water in all ratios, and are soluble in organic solvents. They are chemically stable, with low vapour pressure, and they are used as solvents, in acrylic and cellulose triacetate fibre production, polyurethane coating, electronics industry, varnishing, surface coating, polyamide coating, absorbents, cleaners, extractants, and in pharmaceuticals and plant protection products.213–216

\[ \text{N,N-dimethylformamide (DMF) is a colourless liquid at room temperature with a faint amine odour. It is extensively used in the chemical industry as a solvent, an intermediate catalyst, and as a paint stripper and additive.214,215,217} \]

Clinical effects and epidemiology

The liver is the target organ for the toxicity of DMF in humans. Symptoms include alcohol intolerance, abdominal pain, nausea, vomiting, diarrhoea, anorexia and jaundice. Objective findings include elevated levels of serum alanine-aminotransferase, aspartate aminotransferase, alkaline phosphatase, gammaglutamyl transferase and bilirubin. Although histopathological changes have not been extensively studied, enlarged Kupffer cells, hepatocellular necrosis and fatty degeneration have been described.213,214

Alcohol intolerance, characterized by flushing of the face, dizziness, nausea and tightness of the chest, has been widely reported among DMF-exposed workers after alcohol consumption, and is apparently an effect that occurs at low exposure levels.213 While it is difficult to establish with any certainty the lowest concentration of DMF at which increases in these subjective symptoms first appear, they have been associated with mean or median levels of 10 ppm (30 mg/m3). In a recent study, some workers reported symptoms upon exposure to concentrations for which the median value was as low as 1.2 ppm (3.6 mg/m3).218

Low sperm motility, but with no variation in sperm morphology or semen volume, was related to urinary concentrations of N-methylformamide (NMF) among workers exposed to DMF in a synthetic leather factory.
in Taiwan. There was no relationship with the airborne concentrations of DMF, and the reasons for this may be dermal absorption from splashes, or to the mediation of the effect by an active metabolite, instead of to the parent compound.219 Although several experimental studies have indicated that DMF may adversely affect sperm quality, these effects have only been seen at exposure levels considerably higher than those inducing hepatic damage. The irritation potency of DMF is low; no consistent information is available on any sensitizing capacity. An early study reported an increased incidence of testicular tumours in men exposed to DMF; later studies have not been able to confirm this finding.213,217

The IARC evaluated data on the carcinogenicity of dimethylformamide in experimental animals, and concluded that based on adequate findings in one study on rats and one using mice, there was evidence suggesting lack of carcinogenicity.217 However, a subsequent study reported that inhalation exposure to dimethylformamide led to an increased incidence of liver adenomas and carcinomas in both rats and mice.220 Dimethylformamide has been extensively studied for genotoxicity in vivo and in vitro, with consistently negative results.215 Fетotoxic and teratogenic effects have been reported in several animal studies at doses that are toxic to the dams, but also in some studies at doses that are not overtly toxic to the dams.221 In the European Union, dimethylformamide has been classified as being toxic to reproduction in category 2.128

Metabolism and monitoring

Dimethylformamide is effectively absorbed by the respiratory and also dermal route. Dermal absorption is significant not only for liquid dimethylformamide, but also for the gaseous form. Dermal exposure may be more important than respiratory exposure in occupational settings.222,223

Dimethylformamide is hydroxylated to N-hydroxy-N,N-dimethylformamide, which is the main metabolite in humans (Figure 42.15). A minor further oxidation pathway, also catalysed by cytochrome P450 2E1, leads through N,N-dimethylformamide (or maybe directly) to a reactive intermediate, probably methyl isocyanate, and further via glutathione conjugation, to N-acetyl-N-methylcarbamoyl)cysteine (AMCC).224,225 This minor pathway, and probably the intermediate methyl isocyanate, is responsible for the liver toxicity of dimethylformamide. This notion is supported by the finding that individuals with heritable lack of glutathione S-transferase T1 are at a considerable higher risk to hepatic damage, when exposed to dimethylformamide at work.226

Because of the likelihood of dermal absorption, biological monitoring of exposure to dimethylformamide is a useful tool for exposure and risk assessment. Most often, N-methylformamide is measured in after-shift urine specimens. In the analytical methods used, because the main metabolite HMMF is converted to N,N-dimethylformamide, the sum of the two metabolites is measured. These metabolites have the advantage in that the precursor of the

Figure 42.15 Metabolic pathways of N,N-dimethylformamide.213
putative toxic metabolite is being measured.\textsuperscript{91} Analysis of N-methylcarbamoylated haemoglobin (lysine or N-terminal valine) in blood has also been proposed as a long-term indicator of exposure to N-methylformamide,\textsuperscript{227–229} but the experience is very limited, and the analytical technique more demanding.

**Prevention**

In keeping with the importance of dermal exposure in the uptake of dimethylformamide at work, it was noted that in synthetic leather production, protection of the skin was more effective than respiratory protection against absorption of dimethylformamide.\textsuperscript{223}

**N,N-DIMETHYLACETAMIDE**

[CAS No. 127-19-5]

\[
\text{HN} = \text{O} \quad \text{O} \quad \text{N} \quad \text{H}
\]

Dimethylacetamide (DMAA) is used in the production of acrylic fibres and polyurethane elastane yarns (Spandex\textsuperscript{TM} or Lycra\textsuperscript{TM}) as the spinning solvent. DMAA may also be used as a solvent for production of x-ray and photographic products, reactor solvent for cosmetic and pharmaceutical intermediates, aramid fibres, polyamide films and polymers, resins and polymers, miscellaneous organic chemicals, and liquid treatment fibres and as a solvent in production of photoresistant stripping compounds.\textsuperscript{216}

**Clinical effects and epidemiology**

The irritation potency of DMAA is low; no consistent information is available on any sensitizing capacity. Like dimethylformamide, the main effect of DMAA in occupationally exposed people, is liver damage.\textsuperscript{216,230–232} Liver damage has generally been observed from elevated levels of enzymes in blood reflecting damage to hepatic function and liver cellular integrity; alcohol intolerance has not been reported.

In experimental animals, fetotoxic and teratogenic effects have been reported in several studies at doses that are toxic to the dams. Fetotoxicity and teratogenicity were also observed in inhalation studies in rats at exposure levels that did not induce hepatic damage, although there was slight decrease in weight gain of the dams,\textsuperscript{233} and also in oral studies in the absence of overt dam toxicity.\textsuperscript{216} In the European Union, dimethylacetamide has been classified as being toxic to reproduction in category 2.\textsuperscript{128} DMAA is consistently negative in genotoxicity studies, and in limited testing for carcinogenicity, no consistent elevation of tumour incidence has been observed.\textsuperscript{216}

**Metabolism and monitoring**

DMAA is extensively absorbed via the cutaneous route even from the vapour phase.\textsuperscript{234,235} It is metabolized mainly to N-methylacetamide, and to a minor extent also to hydroxymethylacetamide, acetamide and S-acetamidomethylmercapturic acid.\textsuperscript{216,235}

**Management and diagnosis**

Because of the likelihood of dermal exposure, biological monitoring of exposure to dimethylacetamide is a useful tool for exposure and risk assessment. N-methylacetamide is usually measured in after-shift urine specimens.\textsuperscript{235–238}

**ACRYLAMIDE AND N-METHYLACRYLAMIDE**

[CAS No. 79-06-1 and CAS No. 1187-59-3]

\[
\text{Acrylamide} \quad \text{N-Methylacrylamide}
\]

Acrylamide is a white crystalline solid which sublimes slowly at room temperature. Its vapour pressure is 0.9 Pa. The main use is in the production of polyacrylamides which are used in waste water treatment, paper and pulp processing and mineral processing. The monomer content of polyacrylamides is usually less than 0.1 per cent. In research laboratories, acrylamide is used to produce polyacrylamide electrophoresis gels used for the separation of nucleic acids.

Acrylamide has been used also as a grouting agent. In the European Union, its production for this purpose ended at the end of the 1990s.\textsuperscript{239} N-methylacrylamide is also a grouting agent, with a potential to regenerate acrylamide.\textsuperscript{239} The extent to which this occurs is not known and may depend on environmental conditions. Also, the use of N-methylacrylamide for grouting has ceased in Western Europe, but in some parts of the world it may still be used.

Since the vapour pressure of acrylamide is low, occupational exposure to acrylamide occurs via the respiratory route mainly when aerosols are generated, or also through the skin.

**Clinical effects and epidemiology**

The main concerns related to acrylamide are its neurotoxicity, carcinogenicity and mutagenicity. Based on animal studies, it is also a reproductive toxicant affecting the fertility of male rats and mice.\textsuperscript{128,239}

Skin irritation, rashes and peeling of the skin have been reported in workers exposed to acrylamide solutions.\textsuperscript{240} In the same study, 38 out of 71 (54 per cent) workers occupationally exposed to aqueous acrylamide monomer in the manufacture of monomeric and polymeric acrylamide reported skin peeling of the hands, and on clinical examination this finding was observed in 16 of the 71 workers (23 per cent).\textsuperscript{240} In the control group, the incidence was 2/51 (4 per cent). Erythema was reported in 23 per cent of exposed workers compared with none in the control group. In animal studies, acrylamide has been clearly positive in...
skin sensitization tests, but in humans skin sensitization appears to be rare.239

**Neurotoxic effects of acrylamide**

There are several studies in animals showing the development of peripheral neuropathy after repeated exposure to acrylamide.239 Also, in occupationally exposed workers, neurotoxic effects have been described.240 In a Chinese factory producing monomeric and polymeric acrylamide, neurotoxic effects were experienced by the workers. Symptoms including numbness of hands and feet, lassitude, sleepiness, muscle weakness, clumsiness of hand, anorexia, unsteady gait and coldness of hands and feet; difficulty in grasping and stumbling and falling were reported significantly more in workers than in a control group. Peeling of the skin and excessive sweating of hands and feet appeared only after a few months of exposure. On clinical examination, signs observed in exposed workers included impairment of vibration sense, pain, diminished touch and altered proprioception. Some workers had muscular atrophy, and diminished or loss of reflexes in the extremities. In electroneuromyographic studies, findings suggestive of partial denervation and axonal degeneration were also seen in some workers who did not have any apparent clinical signs of neurotoxicity.240

In the late 1990s, two incidents of significant occupational and environmental acrylamide exposure occurred in Scandinavia in tunnel construction when N-methyloacrylamide-based grouting agents were used.241,242 The first incident occurred in Hallandsås in 1997 during the construction of a railway tunnel. Due to leakage of the chemical, a nearby creek was also contaminated by acrylamide-methyloacrylamide resulting in fish deaths and neurological symptoms in cows that drank water from the creek. Some of the tunnel construction workers were suspected of being heavily exposed and regular medical examinations, including neurophysiological and dermatological assessment and analysis of acrylamide haemoglobin adducts were performed. The results of this study showed exposure-related signs and symptoms of peripheral nervous system dysfunction. An association of symptoms with acrylamide-haemoglobin adduct levels was demonstrated. More than half of the symptomatic workers showed improvement in the symptoms and signs of peripheral nervous system dysfunction after six months of follow up, and after 12 and 18 months almost all were asymptomatic showing reversibility of the acrylamide neuropathy after cessation of exposure.241 Similar results were also obtained in Norwegian tunnel construction workers showing slight demyelinating and axonal changes in peripheral nerves which were reversible after a year of follow up.242

**Carcinogenicity and mutagenicity**

Data on the carcinogenicity of acrylamide is based on animal experiments showing an increase in the incidence of several types of tumours in different organs.239,243,244 No clear evidence of acrylamide carcinogenicity is available from epidemiological studies in exposed workers, although two most recent updates of epidemiological cohort studies found increased rates of pancreatic cancer, which were, however, not clearly related to increasing exposure levels.245,246 The IARC evaluation is 2A (probably carcinogenic to humans).243 There are substantial data available showing that acrylamide is a genotoxic substance.239,244 It has also been shown to induce heritable genetic damage.

Attempts have been made to estimate the potential carcinogenicity risk of low level acrylamide exposure. One of the most recent estimates is from the Dutch Expert Committee on Occupational Standards (DECONS), which has calculated so-called health-based occupational cancer risk values (HBC-OCRVs) for acrylamide.244 Based on the results of animal studies, the committee estimated that an acrylamide exposure of 0.4 μg/m³ (time-weighted average) for 40 years leads to a cumulative excess cancer incidence of 10⁻⁵ and at 40 μg/m³ to an excess cancer incidence of 10⁻³.

**Metabolism and monitoring**

Once absorbed, acrylamide undergoes a complex metabolism involving direct conjugation with glutathione and the formation of an epoxide intermediate glyciamide.239 The main urinary metabolites include acrylamide-based mercapturic acid N-acetyl-S-(propionamide)-cysteine (APC), glyciamide-based mercapturic acids N-acetyl-S-(carbamoylthyl)-1-cysteine and N-(R,S)-acetyl-S-2-carbamoyl hydroxyethyl-1-cysteine (GAMA).247,248 All of these have been suggested as markers for biological monitoring of acrylamide exposure.247,248 Acrylonitrile exposure and smoking are potential confounding factors in biological monitoring especially when N-acetyl-S-(propionamide)-cysteine (APC) is used as a biomarker.248 Since the excretion of acrylamide into urine is rapid, urine biomarkers represent very recent exposure (Figure 42.16).

Haemoglobin adducts have been used as a biological marker for acrylamide exposure, but the invasive nature of blood sampling and complex analytical methodology limit the routine application of this approach.

**Management and diagnosis**

Diagnosis of acrylamide-induced polyneuropathy is based on typical symptoms, neurophysiological examination and the assessment of exposure. Other possible causes of polyneuropathy, e.g. long-term alcohol abuse, diabetes, neurotoxic drugs, vitamin B₁₂, and B₆ deficiencies, and some inflammatory, infectious or malignant diseases, must be excluded. According to current knowledge, the signs and symptoms of acrylamide-induced neuropathy are at least partially reversible after the cessation of exposure.
Nitriles are organic chemicals with one or more cyanide (-CN) groups bound in a hydrocarbon chain. Common, widely used nitriles include acrylonitrile and acetonitrile. Acrylonitrile is used in the production of nitrile–butadiene rubber, acrylonitrile–butadiene–styrene and styrene–acrylonitrile polymers. Acetonitrile is used as a solvent, laboratory chemical and in the chemical or pharmaceutical industry in the production of other chemicals or pharmaceuticals. Acrylo- and acetonitrile have high vapour pressures and therefore they can lead to significant air concentrations and a risk of inhalation exposure in uncontrolled situations.

Clinical effects and epidemiology

Although some nitriles, for example acrylonitrile and acetonitrile, may release cyanide in the body, the toxicity of nitriles varies. Acrylonitrile is over ten times more toxic than acetonitrile. Symptoms of acrylonitrile or acetonitrile poisoning resemble that of cyanide poisoning, but manifest slower than the symptoms of cyanide poisoning. Initial symptoms of acrylonitrile poisoning occur at air levels of 20–100 ppm (44–220 mg/m³) and include headache, irritation, dizziness, nausea and vomiting. At higher dose levels, symptoms of cyanide poisoning including weakness, convulsions and respiratory failure, may become evident, but these may be delayed by 15 minutes up to several hours after exposure. Liver failure due to acrylonitrile poisoning has also been described.

Based on animal experiments, acrylonitrile is suspected of being carcinogenic to humans. In a rat cancer bioassay, it has caused a range of tumours including those of the central nervous system, ear canal, gastrointestinal tract and mammary glands both by ingestion and by inhalation. Tumours have been reported at non-toxic doses and at periods as early as 7–12 months following onset of exposure. Acrylonitrile is considered as a genotoxic carcinogen. There is no clear epidemiological evidence of the carcinogenicity of acrylonitrile in humans.

Metabolism and monitoring

Acrylonitrile or acetonitrile do not accumulate in the body. Acrylonitrile is metabolized primarily either by conjugation with glutathione to form N-acetyl-S-(2-cyanoethyl)cysteine or oxidation by cytochrome P450 2E1. Oxidative metabolism of acrylonitrile leads to the formation of genotoxic 2-cyanoethylene oxide, which is either
conjugated with glutathione to form cyanide and thionitrate or directly hydrolysed by epoxide hydrolase. Also, acetonitrile metabolism follows an oxidative pathway by cytochrome P450 resulting in the formation of cyanohydrin, which then spontaneously decomposes to hydrogen cyanide and formaldehyde. Elimination occurs via the urine.

Management and diagnosis
Diagnosis of nitrile poisoning is based on history and characteristic symptoms. Treatment of severe nitrile poisoning follows the procedures for the treatment of cyanide poisoning. Administration of oxygen is essential and may suffice for less severe cases of poisoning. Amyl nitrite (0.2 mL ampoule) can be given by inhalation repeatedly (maximum of six times). Because of the slow release of cyanide ions, patients have to be followed up for a sufficiently long time and antidotes may be needed even several hours after the poisoning. Intravenous antidotes which may be used in severe poisoning include hydroxycobalamin, 4-dimethylaminophenol, sodium thiosulphate and dicobalt edetate. However, treatment protocols differ between countries.

Aromatic amines
Aromatic amines are aromatic hydrocarbons in which one or more hydrogen atoms are replaced with an amino (-NH₂) group. It is a large group of compounds with different uses. A common toxicological property of these substances is their ability to cause methaemoglobinaemia. Several aromatic amines are known or suspected carcinogens, typically causing urinary tract carcinomas.

ANILINE
Aniline (Figure 42.17) is the simplest member of this group of compounds. It is a colourless oily liquid with a characteristic amine odour. Its vapour pressure at ambient temperature is 40 Pa. Aniline is used mainly as a chemical intermediate in the production of methylene diaminine (MDA) and in the production of rubber chemicals and dyes. Exposure to aniline in occupational settings may occur by inhalation and by skin exposure. Aniline is well absorbed after oral, dermal and inhalation exposure.

Clinical effects and epidemiology
Critical health hazards related to aniline are its acute toxicity due to the formation of methaemoglobin and its suspected carcinogenicity.

Methaemoglobinaemia
Methaemoglobinaemia is caused by the oxidation of the iron in the haem group of the haemoglobin molecule from the ferrous state to the ferric state resulting in inability of haem to transport oxygen effectively. Normally, methaemoglobin levels are <1 per cent. Spontaneous formation of methaemoglobin is normally counteracted by protective enzyme systems – NADH methaemoglobin reductase, in which cytochrome b reductase plays a major role and NADPH methaemoglobin reductase (minor pathway). Initial symptoms of methaemoglobinaemia can be seen at methaemoglobin levels of approximately 15 per cent. Hereditary deficiencies of cytochrome b5 reductase or inherited abnormal haemoglobin variants (HbM) can result in abnormally high methaemoglobin levels with a higher susceptibility to chemical agents capable of inducing methaemoglobinaemia. Also, some medicines can increase the levels of methaemoglobin. For example, the mechanism for nitrates used as an antidote for cyanide poisoning is through methaemoglobin formation. Methaemoglobin has an affinity for circulating cyanide, and is able to bind to cyanide before it affects cellular respiration.

Signs and symptoms of occupational aniline poisoning were frequently reported in the past when aniline was produced and used in poorly controlled circumstances. Since the first manifestation of aniline poisoning is an intense cyanosis, the victims of poisoning were referred to as ‘blue boys’. Other signs and symptoms characteristic for aniline poisoning include headache, dizziness, nausea, vomiting, chest and abdominal pain, weakness, seizures and cardiac dysrhythmias. Also, photophobia and visual disturbances can be seen. There is an aniline odour on the breath and on the sweat. The urine is dark in colour owing to the presence of haemoglobin. A Heinz-body haemolytic crisis may follow the development of methaemoglobinaemia after two to seven days. Anaemia can follow long-term exposure to aniline (as well as other methaemoglobinaemia-causing agents). The average lethal inhalation dose in humans is reported to be 25 mg/L air or 0.35–1.43 g/kg body weight, whereas 0.4–0.6 mg/L air may be borne without much harm for 0.5–1 hour, but 0.1–0.25 mg/L for several hours produces slight symptoms. In long-term exposure, effects may be seen at even lower exposure levels. The oral no-effect dose of aniline for methaemoglobin formation in an adult man after a single exposure has been estimated to approximate 15 mg/man (about 0.21 mg/kg body weight), the mean oral lethal dose being between 15 and 30 mg.
Other effects

Aniline has been positive in genotoxicity tests measuring the induction of chromosomal aberrations and micronuclei. In animal tests, it has caused spleen carcinomas in rats. In humans, bladder cancer has been suggested after exposure, for example in aniline dye manufacturing, but these are most probably attributable to exposure to chemicals other than aniline. The IARC has categorized aniline as group 3 (not classifiable as to its carcinogenicity to humans).

Metabolism and monitoring

Aniline is metabolized by acetylation and hydroxylation. Acetylation is mediated by N-acetyltransferase and results in the formation of acetylaniline, which may be either deacetylated back to aniline or 4-hydroxylated to 4-hydroxyacetanilide. The glucuronide and sulphate conjugates of 4-hydroxyacetanilide represent the major urinary metabolites of aniline. About 50 per cent of Europeans have genetically lower activity of N-acetyltransferase; these are called ‘slow acetylators’ in contrast to ‘fast acetylators’. In these individuals, the reaction of aniline to acetylare was retarded in favor of formation of phenylhydroxylamine, nitrosobenzene and aminophenol. Since this is the principal route by which aniline produces methaemoglobinaemia, these individuals may be more susceptible to aniline toxicity.

Occupational exposure to aniline can be biomonitored by measuring urinary aniline in post-shift samples.

Management and diagnosis

Treatment of methaemoglobinaemia is based on the administration of oxygen and intravenous administration of methylene blue, which acts as a reducing agent converting oxidized iron in haem from ferric back to its normal ferrous state. The usual recommended initial dose for methylene blue as an antidote is 1–2 mg/kg of 1 per cent solution given intravenously, but additional doses may be needed depending on the speed of clinical response. The total dose administered should not exceed 7 mg/kg. In patients with G6PD deficiency, treatment may cause haemolytic anaemia and will therefore not be effective.

The use of hyperbaric oxygen has also been considered together with other life-supporting measures.

Toluidines

The 0-, 0'-, m'-Toluidines are aromatic amines, in which one hydrogen atom of aniline is substituted with a methyl group. They are mainly used as intermediates in the production of other chemicals. Toluidines are also able to induce methaemoglobinaemia, m-toluidine being the most potent isomer in this respect. The IARC has classified o-toluidine in group 1, as it has caused urinary bladder tumours in workers. p- and m-Toluidine have not been sufficiently tested for their carcinogenic potential to be known.

Benzidine and naphthylamines

Aromatic amines also include substances with two combined aromatic rings. Naphthylamines are based on naphthalene with one hydrogen atom replaced by an amine group. In benzidine, two aromatic structures are linked together (Figure 42.17). 2-Naphthylamine and benzidine have been used in the past, for example in the manufacturing of azo dyes, but because of their carcinogenicity, they have been replaced by less toxic substances and prohibited by law in many countries. Workers exposed to 2-naphthylamine and benzidine have been reported to suffer from an excess of bladder tumours, which were first described at the turn of the twentieth century. Their carcinogenicity was subsequently also confirmed in animal experiments. They are classified as group 1 by the IARC.

In contrast, 1-naphthylamine has not demonstrated carcinogenic activity. A rubber chemical, N-phenyl-2-naphthylamine (CAS No. 90-30-2) is partly dephenylated in the body to 2-naphthylamine and it has therefore been examined for its potential carcinogenicity. It has been found negative in animal mutagenicity and carcinogenicity assays. This is supported by animal data indicating only very small (at maximum 1 per cent) conversion rates to 2-naphthylamine.

4,4-Methylenedianiline (CAS No. 101-77-9)

4,4’-Methylenedianiline (MDA) is used as an intermediate in the production of 4,4’-methylene diphenylisocyanate (see under Isocyanates, p. 364). The target organ for MDA toxicity is the liver. It has been described to cause jaundice after oral, dermal and inhalation exposure. Jaundice caused by MDA was termed ‘Epping jaundice’ after an incident in 1965 in the Epping area in the United Kingdom when 84 people suffered ill effects caused by eating bread baked with flour contaminated by MDA. Regardless of several reports of acute liver disease caused by MDA, no human fatalities have been described. MDA is a skin sensitiser. It has also demonstrated mutagenic activity in animal tests and caused liver and thyroid cancers in animals. The IARC has classified MDA as group 2B.

Chloroanilines and MOCA (4,4’-methylenebis (2-chloroaniline))

If one or more hydrogen atoms in an aromatic amine are substituted by chlorine, different kinds of chloroanilines are formed. 2-Chloroaniline, 3-chloroaniline and 4-chloroaniline are used as intermediates for the production of other chemicals. All these isomers are haematotoxic and can cause methaemoglobinaemia, with 4-chloroaniline causing the most severe effects. 4-Chloroaniline has shown genotoxicity in various systems, and has also shown carcinogenic activity in animal tests, with the induction of unusual and rare tumours of the spleen in male rats. The results of assays for 2- and 3-chloroaniline are inconsistent and indicate weak or no genotoxic effects.
3,4-Dichloroaniline is a chemical in which two hydrogen atoms of aniline are substituted by chlorine. It is used as an intermediate in chemical production. This compound is acutely toxic and causes methaemoglobinemia. It has demonstrated skin-sensitizing properties in guinea pigs, but no case reports on sensitization in humans have been published.272

MOCA (4,4′-methylenebis(2-chloroaniline)) (Figure 42.17) was introduced in the mid-1950s for the production of high-performance polyurethane mouldings. Although its use has decreased, it is still used in some applications in the rubber and plastics industries and in polyurethane production. It is well absorbed by all routes of exposure, and skin exposure may be significant in occupational settings. MOCA has been demonstrated in animal tests as a genotoxic and carcinogenic substance producing tumours in different organs in animals, including transitional-cell carcinomas of the urinary bladder and urethra in dogs.273 Human epidemiological data on the carcinogenicity of MOCA are limited. IARC has classified MOCA as group 1 based on epidemiological and mechanistic (genotoxicity) data.100 MOCA is metabolized to glucuronide and acetyl conjugates and excreted in the urine as a free compound or as glucuronide or acetyl metabolites, the main metabolite in the urine being N-glucuronide MOCA. N-hydroxy-MOCA is the main toxic, DNA reactive, intermediate of MOCA metabolism. MOCA can be biomonitored by measuring total MOCA (free and conjugated MOCA) in the urine.274 DNA adduct analyses, to measure the levels of biologically active MOCA in the body, have been developed but are not in routine use.275

Phenylhydrazine
Phenylhydrazine (CAS No. 100-63-0) is a substance used worldwide mainly as a chemical intermediate in the pharmaceutical, agrochemical and chemical industries. It is composed of a hydrazine (diamine) group attached to a benzene ring. Phenylhydrazine is an acutely toxic chemical. Toxic effects seen mainly in animal tests include methaemoglobin formation, destruction of red blood cells, reduction in erythrocyte count, increased reticulocyte count and the formation of Heinz bodies. There are a number of case reports of skin sensitization to phenylhydrazine and its hydrochloride salt in humans.276 Phenylhydrazine has shown mutagenic activity in genotoxicity tests and it is clearly carcinogenic in mice following oral dosing, inducing tumours of the vascular system.276

Aliphatic amines
Aliphatic amines are organic chemicals with an amino (NH₂) group in an aliphatic hydrocarbon chain. Ethanolamine, diethanolamine and triethanolamine are aliphatic amines (Figure 42.18), which are used in many different applications including production of cosmetics, detergents, soaps, corrosion control inhibitors, and in pharmaceutical applications. They are also widely used in the metal industry in metal-working fluids. They are colourless viscous liquids or crystalline solids with a faint ammonia-like odour and with low vapour pressure at ambient temperatures. Exposure to ethanolamines may occur by all routes of exposure.

Clinical effects and epidemiology
The main hazard related to ethanolamines is their ability to cause sensitization. Occupational skin sensitization due to ethanolamines has been described in the metal industry after contact to ethanolamines in metal-working fluids.277,278 Monoethanolamine seems to be the most common allergen in metal-working fluids. Geier et al.277 tested over 200 metal workers who were suspected of having allergic dermatitis due to metal-working fluids with the current metal-working fluid (MWF) series and 155 with the historical MWF series. The results show that among the current MWF allergens, monoethanolamine ranked highest as a contact allergen with 11.6 per cent positive reactions. Diethanolamine (3.0 per cent) and triethanolamine (1.1 per cent), and diglycolamine (CAS No. 929-06-6) (1.9 per cent) elicited positive reactions far less frequently.

Ethanolamines are also highly irritating and corrosive. Case reports have referred to asthma caused by monoethanolamine,279–281 diethanolamine282 and triethanolamine.281

Metabolism and monitoring
Ethanolamine is metabolized in the liver and excreted in urine as urea, glycine, serine, choline and uric acid.283 Part of the ethanolamine is excreted in urine unmetabolized. Nine to twenty per cent of ethanolamine is excreted via exhaled air. Diethanolamine is excreted predominantly unchanged with a half-life of approximately one week in urine. Ethanolamine and diethanolamine are incorporated
in the body in phospholipids. Triethanolamine is not incorporated in phospholipids and is readily eliminated in urine. Urinary triethanolamine can be used for biological monitoring. However, urinary limit values indicative of safe exposure have not been established.

Management and diagnosis
The management of sensitization caused by ethanolamines is based on prevention of exposure by appropriate protective clothing and gloves, and follow up and prevention of air contamination with ethanolamines. Diagnosis of ethanolamine-caused skin sensitization is based on a history of exposure and patch-testing. Diagnosis of ethanolamine-caused asthma is based on work-related symptoms, serial peak-flow readings, and on an exposure chamber challenge with the suspected agent, if necessary.

Heterocyclic nitrogen compounds
This group of compounds includes substances whose common chemical feature is a ring structure with nitrogen as a part of the ring.

Examples of heterocyclic nitrogen compounds are piperazine, pyrrolidone and its derivatives N-methyl pyrrolidone and N-vinylpyrrolidone. Many piperazine derivatives are successful medicines. Piperazine is used in the pharmaceutical industry and in the manufacture of plastics and resins. Pyrrolidone derivatives are widely used industrial chemicals.

N-METHYLPYRROLIDONE AND N-VINYLPYRROLIDONE

N-Methylpyrrolidone (NMP) is a colourless liquid with a vapour pressure of 39 Pa at 20°C. It is widely used nowadays as a solvent, for example, for extraction purposes in the petrochemical industry, as a remover of graffiti, as a paint stripper, and for stripping and cleaning applications in the microelectronics fabrication industry, as well as a reactive medium in polymeric and non-polymeric chemical reactions. It is also used as a formulating agent in the pharmaceutical industry and in the manufacture of plastics and resins. Pyrrolidone derivatives are widely used industrial chemicals.

N-Vinylpyrrolidone (NVP) is a colourless to light yellow liquid with a relatively low vapour pressure at ambient temperatures (12 Pa at 20°C). It is used in the production of polyvinylpyrrolidone (used for pharmaceuticals, cosmetics and food additives) and co-polymers (used as viscosity improvers in oils and in water-borne paints and adhesives), and as a reactive thinner in UV-cured inks and lacquers and in the manufacture of contact lenses.

In occupational settings, exposure to N-methyl- and N-vinylpyrrolidone can occur through inhalation, especially when aerosols are formed or when heated. Both compounds are also well absorbed through the skin.

Clinical effects and epidemiology
NMP can cause skin irritation and dermatitis. Its use as a cleaner or as a paint stripper has been described to result in redness, swelling, thickening and painful vesicles of the skin. At high air levels, eye irritation and headache have also been reported. Headaches and irritation of the skin, eyes and the upper airways have been reported among graffiti removers exposed to mixtures of NMP and glycol ethers. In animal tests, NMP has caused developmental toxicity resulting in delayed development, malformations and early fetal resorptions after oral exposure. Fetal toxicity has also been observed after inhalation or dermal exposure, but mainly at maternally toxic levels. No epidemiological data on the effects of NMP in humans are available.

N-vinylpyrrolidone can cause respiratory tract irritation when inhaled. It has also caused liver damage in animals at relatively low exposure levels. In long-term inhalation exposure studies in animals, it has resulted in tumour formation in the liver, larynx and nasal cavity at exposure levels close to those experienced at occupational settings. The mechanism of tumour formation is unclear, but in the absence of evidence to the contrary, these tumours must be considered of relevance to humans. The IARC has allocated NVP to group 3.

Metabolism and monitoring
Since NMP is well absorbed through the skin, biological monitoring may be valuable in the assessment of exposure. NMP is hydroxylated to 5-hydroxy-N-methyl-2-pyrrolidone (5-HNMP), which is oxidized to N-methylsuccinimide (MSI) and further hydroxylated to 2-hydroxy-N-methylsuccinimide (2-HMSI). All these metabolites can be found in the urine of exposed workers. 2-Pyrrolidone (2-P) is a urinary metabolite which is probably formed by demethylation of NMP.

5-HNMP in plasma or urine is recommended for biomonitoring of NMP exposure.

No information on the metabolites of N-vinylpyrrolidone in humans is available. According to animal experiments, it is metabolized to polar metabolites and excreted mainly in the urine.

Management
Management of the health risks from NMP and NVP is based on the monitoring and control of exposure. Attention should be paid to dermal exposure.
N-nitrosamines are an extensive group of chemicals, many of which have been demonstrated to be carcinogenic in several animal species, probably by a genotoxic mechanism. There is no reason to think that humans would be resistant to N-nitrosamine-induced cancer, but clear-cut epidemiological proof of the carcinogenicity of N-nitrosamines as a group, or of individual N-nitrosamines in humans, is lacking. The carcinogenic potency in experimental animals of N-nitrosamines varies widely, some being very potent, inducing cancer even after a single dose. Exposure to N-nitrosamines may be occupational, dietary and also endogenous: amines may be nitrosated in the body to yield nitrosamines.

Early studies indicated the presence of volatile N-nitrosocompounds in azo dye production, fish processing, fish meal production, cutting fluid manufacture and use, rubber industry, and leather tanning.\(^{297-299}\) N-nitrosodimethylamine (CAS No. 62-75-9), N-nitrosodiethyamine, N-nitrosopiperidine (CAS No. 100-75-4) and N-nitrosomorpholine (CAS No. 59-89-2) were detected in practically all breathing zone air samples in a rubber vehicle sealing plant.\(^{300}\) Similarly, these plus N-nitrosobutylamine, were detected in more than half of some 700 air samples collected in rubber industries in France.\(^{301}\) As in the American study, the highest concentrations were observed for N-nitrosodimethylamine. N-nitrosodimethylamine and N-nitrosomorpholine were also detected in rubber industries in Germany, Poland, Holland, the United Kingdom and Sweden.\(^{302}\) Low concentrations of N-nitrosodimethylamine, N-nitrosomethylamylamine, N-nitrosodiethyamine, N-nitrosodi-n-propylamine, N-nitrosodisopropylamine, N-nitrosodi-n-butylamine, N-nitrosopiperidine, N-nitrosopyrrolidine and N-nitrosomorpholine were detected in rubber industries in Italy.\(^{303}\) Volatile N-nitrosamines (notably N-dimethylamylamine, N-nitrosomethylamylamine) were detected in the air in eight foundries using the Ashland procedure for core production.\(^{304}\) Varying, even high concentrations of N-nitrosodiethanolamine (CAS No. 1116-54-7) have been detected in metal cutting/machining fluids.\(^{305-309}\)

Clinical effects and epidemiology

N-nitrosodimethylamine ingested at a large dose has caused extensive, even fatal, liver damage but aside from this, there are few data on the toxicity or carcinogenicity of N-nitrosamines in humans. However, exposure to volatile N-nitrosamines in the rubber industry is well documented, and there are several epidemiological studies demonstrating excess cancer. Tobacco smoke contains at least seven N-nitrosamines, which are considered specific for tobacco smoke\(^{310}\) and it is likely that these proven animal carcinogens contribute to the elevated cancer risk among smokers.

N-dimethyl- and N-diethylnitrosamine, and N-nitrosomorpholine cause liver damage in experimental animals. N-nitrosodiethanolamine is relatively non-toxic in experimental animals, and causes only very limited liver damage.\(^{17,311}\)

N-nitrosodimethylamine has induced tumours in some 20 animal species after oral, inhalation and parenteral administration. N-diethylnitrosamine has been tested for carcinogenicity in more than 40 animal species, and caused tumours in all of them. N-nitrosodiethanolamine is a potent carcinogen; it consistently induced liver tumours in rats, and nasal cancer in rats and hamsters. N-nitrosomorpholine induced liver tumours in rats and mice, and tumours of the trachea and nasal cavity in hamsters. N-nitrosopiperidine induced tumours in mice, rats, hamsters and monkeys.\(^{17,311,312}\)

Thus, there is a marked variation in the target organ for carcinogenic effects between different animal species. Although several alkylnitrosamines are hepatotoxic, there is no direct relationship between hepatotoxicity and carcinogenicity.

Metabolism and monitoring

N-nitrosoamines are activated to genotoxic species by dealkylation, catalysed by CYP2E1 (the same isoenzyme oxidizes ethanol), producing a direct-acting carbonium species, which is considered to be the ultimate carcinogen, and which alkylates DNA.

PHENOL AND PHENOL DERIVATIVES

PHENOL

[CAS No. 108-95-2]

Phenol is a colourless to yellow or light pink solid, which absorbs water easily and liquefies. It has an unpleasant odour with an odour threshold of 0–05 ppm (0.2 mg/m\(^3\)). It is a weak acid. Phenol is a widely used industrial chemical. Its main uses are in the production of bisphenol A, phenol resins, alkylphenols, caprolactam, salicylic acid,
nitrophenols, diphenyl ethers, halogen phenols and other chemicals. A small amount serves as a component in cosmetics and medical preparations. It can also be used for the production of paints and lacquers, adhesives, impregnating agents and biocides.

**Clinical effects and epidemiology**

Phenol is a corrosive and acutely toxic chemical. It can cause serious poisoning by skin absorption, inhalation of vapours or by ingestion. Skin contact following spillage of phenolic solutions can lead to rapid absorption, collapse and death within 30 minutes. Death has resulted from the absorption of phenol through a skin area as small as 400 cm². Because of the analgesic properties of phenol, the sensation of pain due to local exposure to phenol may be diminished leading to less awareness of contact with the chemical and thus resulting in higher degrees of local damage. Affected skin areas turn brown and gangrenous. Prolonged exposure may result in deposition of a dark pigment in the skin (ochronosis). Clinical features of phenol poisoning include shock, collapse, coma, convulsions, cyanosis, damage to internal organs and death. Cardiac manifestations including different kinds of arrhythmias are also typical. A recent case report describes a 47-year-old male who had 90 per cent phenol spilled over his left foot and shoe (3 per cent of body surface area). After a 4 1/2-hour exposure, clinical manifestations included confusion, vertigo, faintness, hypotension, ventricular premature beats, atrial fibrillation, dark-green urine, swelling, blue-black discoloration and numbness of the affected area. His peak serum phenol level was 21.6 mg/L, which was considered to be in the fatal range.

**Metabolism and monitoring**

After absorption, phenol is rapidly distributed in body tissues. In the body, it is extensively metabolized to its sulphate and glucuronide conjugates which are excreted in the urine. Exposure to phenol can be assessed by measuring urinary total (free and conjugated) phenol.

**Management and diagnosis**

In the management of phenol-related health risks, special emphasis should be given to accident prevention and avoidance of dermal exposure. If a spillage resulting in skin contact has occurred, aggressive decontamination of the skin is essential. Polyethylene glycol (PEG) and isopropyl alcohol have been shown to be effective in minimizing phenol-induced skin damage. PEG and isopropyl alcohol with water treatment can also significantly reduce systemic phenol absorption.

**Phenol derivatives**

There is a wide variety of phenol derivatives with different toxicological profiles. These include for example chlorophenols, which have been used as biocides and pesticides, cresol (o-, p-, m-cresol) and resorcinol, as well as nonylphenol and bisphenol A. Some phenol derivatives have been shown to produce skin toxicity resulting in vitiligo. These include p-tert-butylphenol and certain catechol derivatives (4-tert-butylcatechol) and hydroquinone.
and hirsutism have been observed in workers employed in the manufacture of 2,4-DCP- and 2,4,5-TCP-based herbicides.\textsuperscript{318,319} However, since chlorophenols may contain other chlorinated compounds, especially 2,3,7,8-tetraclorodibenzo-p-dioxin (TCDD; see under Chlorinated dioxins and furans and related compounds, p. 370) as impurities, it is difficult to attribute these effects specifically to chlorophenols. Acute toxicity of chlorophenols varies between the individual compounds, pentachlorophenol being the most toxic with an estimated lethal oral dose for humans about 30 mg/kg body weight.\textsuperscript{320} It decouples oxidative phosphorylation resulting in a general increase of metabolic activity.

Pentachlorophenol has shown carcinogenic activity in animal tests, causing for example liver tumours in mice. According to the IARC’s evaluation, there is sufficient evidence in experimental animals for the carcinogenicity of pentachlorophenol.\textsuperscript{321} Also 2,4,6-trichlorophenol has shown increased incidences of cancer in carcinogenicity tests in mice. The epidemiological evidence on the carcinogenicity of chlorophenol exposure is limited, although in some studies significant associations with several types of cancer, e.g. with soft-tissue sarcoma and non-Hodgkin’s lymphoma have been suggested.\textsuperscript{322,323} Potential co-exposure to TCDD complicates the interpretation of these studies. IARC has classified combined exposures to polychlorophenols or to their sodium salts as possibly carcinogenic to humans (group 2B).\textsuperscript{321}

Exposure to chlorophenols can be assessed by measuring the levels of chlorophenols in urine.\textsuperscript{324}

**CRESOL AND RESORCINOL**

Of cresol isomers, o-cresol (CAS No. 95-48-7) is widely used as an intermediate in the production of other different chemical products including plastics, resins and pesticides.\textsuperscript{325} Cresols are corrosive substances. p-Cresol has been associated with occupational vitiligo.\textsuperscript{326} Resorcinol (CAS No. 108-46-3) is used in the rubber industry as a chemical intermediate. It has also been used in antiseptics and in keratolytic topical medications in low concentrations. This chemical has caused skin sensitization after medicinal use and also in exposed workers, but in general resorcinol-caused sensitization seems to be rare.\textsuperscript{327} Resorcinol has been associated with thyroid effects, including hypothyroidism and goitre mainly after medicinal use (mainly for treating skin ulcers), but some older studies report these effects also in workers exposed to unknown levels of resorcinol.\textsuperscript{327}

**4-tert-BUTYLPHENOL**

4-tert-Butylphenol (CAS No. 98-54-4) is used as an intermediate for phenol resins and polycarbonate resins. It can also be used as a raw material for construction components and floors in buildings. 4-tert-butylphenol is a well-known cause of vitiligo.\textsuperscript{328} There are several reports on occupational vitiligo in workers from 4-tert-Butylphenol producing factories.\textsuperscript{327}

Vitiligo may become evident a few months to several years after the beginning of exposure. Depigmented patches occur especially at the skin of exposed body sites, such as the hands and forearms, although in some cases it can also be seen at body sites covered by clothing.\textsuperscript{328} Some reports have suggested liver and thyroid effects in exposed workers.

The mechanism by which 4-tert-butylphenol and other phenol derivatives cause occupational vitiligo is still uncertain, but probably relates to their structural similarity with the melanin precursor tyrosine. This structural similarity to tyrosine possibly leads to a tyrosinase-related protein-1-mediated mechanism in which the generation of reactive oxygen species causes melanocyte death (apoptosis).\textsuperscript{328}

**NONYLPHENOL AND BISPHENOL A**

[CAS No. 25154-52-3 and CAS No. 80-05-7]

Bisphenol A is used especially in the production of polycarbonates and epoxy resins. Bisphenol A diglycidyl ether (see below under Epoxides), derived from bisphenol A and epichlorohydrin, is the building block of epoxy resins. Other uses of bisphenol A include the manufacture of phenoplast resins, unsaturated polyester resins, can coatings and PVC.\textsuperscript{329}

Nonylphenol (and branched 4-nonylphenol (CAS No. 84852-15-3)) are used in the production of nonylphenol ethoxylates and in the plastics industry for the production of phenol and formaldehyde resins. Nonylphenol ethoxylates are used nowadays in many different applications, for example in cleaning and washing agents, cosmetics and construction materials, and as additives in paints.\textsuperscript{330}

There are a number of case reports of individuals showing skin sensitization following exposure to epoxy resins derived from bisphenol A. However, it is unclear whether bisphenol A itself or related epoxy resins (see under Bisphenol A diglycidyl ether, p. 361) was the underlying cause of the sensitization.\textsuperscript{329} Bisphenol A in the presence of UV light may elicit skin reactions in humans, and positive results for photosensitization have also been obtained in animal tests.\textsuperscript{329}

Other hazards related to both of these compounds include irritation (bisphenol A) and corrosivity (nonylphenol) and possible reproductive toxicity. In animal tests, both compounds have shown endocrine modulating
(oestrogenic/anti-androgenic) activity, with a potency of 3–6 orders of magnitude less than that of oestradiol. Bisphenol A has caused adverse effects in fertility especially in mice. Also, nonylphenol has caused minor effects, compatible with possible oestrogenic activity, in the reproductive system of offspring in multi-generation studies. The relevance of these findings to humans is unclear.

**EPOXIDES**

An epoxide is a compound containing an oxirane ring, i.e. a ring with an oxygen bridge between two adjacent carbon atoms. Oxirane rings are highly strained and reactive especially towards any nucleophilic chemical structure, such as water, amines, aldehydes, alcohols and carboxylic acids. This reactivity is the basis for the uses of epoxides, and also for their biological effects.

**ETHYLENE OXIDE**

[CAS No. 75-21-8]

At room temperature and normal atmospheric pressure, ethylene oxide is a colourless, highly reactive, and flammable gas with a characteristic ethereal odour. It is mainly used for the synthesis of ethylene glycol (used as anti-freeze), and for the synthesis of polyester resin and solvents. High exposures are encountered in its minor use as a sterilant for hospital supplies, and a fumigant for furs and some food items.

**Clinical effects and epidemiology**

Ethylene oxide is an ocular, respiratory and dermal irritant and a sensitizing agent. Cataracts have been reported after exposure to ethylene oxide. Sensorimotor polyneuropathy has been reported in a few cases of workers exposed to relatively high concentrations.

An important occupational health concern from ethylene oxide exposure is cancer of lymphohaematopoietic origin. In an extensive study on 18 000 employees at 14 industrial facilities where ethylene oxide was used as a sterilant, there was no overall increase in the risk of mortality from non-Hodgkin’s lymphoma or multiple myeloma. However, associations were observed between cumulative exposure and mortality from lymphoid tumours (i.e. non-Hodgkin’s lymphoma, multiple myeloma and chronic lymphocytic leukaemia) in men. Results from other cohort studies of ethylene oxide exposure did not point clearly or consistently to an increased risk for these cancers. An increase in breast cancer has not been consistently reported in other studies; however, an internal analysis in a study of 7500 women showed a significant exposure–response relationship between ethylene oxide exposure and breast cancer incidence. The IARC working group considered the epidemiological evidence on causal association between ethylene oxide exposure and cancer to be ‘limited’.

Mice exposed to ethylene oxide by inhalation showed an increased incidence of alveolar and bronchiolar lung tumours, tumours of the Harderian gland, malignant lymphomas, uterine adenocarcinomas and mammary carcinomas. Rats similarly exposed by inhalation, showed an increased incidence of mononuclear-cell leukaemia, brain tumours, peritoneal mesotheliomas located in the region of the testis and subcutaneous fibromas.

Ethylene oxide induces a dose-related increase in the amount of haemoglobin adducts in humans and rodents and DNA adducts in rodents. It is mutagenic and clastogenic at different phylogenetic levels and it induces heritable translocations in the germ cells of rodents. It also induces a dose-related increase in the frequency of sister chromatid exchange, chromosomal aberrations, and micronucleus formation in lymphocytes of exposed workers.

As an overall evaluation of all the data available, noting especially the consistent results on adduct formation and genotoxicity in exposed humans, the IARC working group classified ethylene oxide as ‘carcinogenic to humans’ (group 1).

Epidemiological studies, while not conclusive, point to an association between exposure to ethylene oxide and spontaneous abortions.

In experimental animals, ethylene oxide is fetotoxic in the presence and absence of maternal toxicity at concentrations higher than those associated with cancer and other non-cancer end points (e.g. neurological effects). It is teratogenic only at very high concentrations (above about 1600 mg/m³).

**Metabolism and monitoring**

Ethylene oxide is rapidly taken up via the lungs, distributed and metabolized to ethylene glycol and to glutathione conjugates. It can also be absorbed through the skin from the gas phase and from aqueous solutions. Ethylene oxide is an alkylating agent that directly reacts with DNA. DNA and haemoglobin adducts have been demonstrated in exposed humans. However, quantitative information on the association of these findings with exposure (or health risks) is very limited. Because of the short half-time of ethylene oxide in blood/exhaled air, the application of these analyses for biomonitoring is problematic.

**PROPYLENE OXIDE AND 1,2-BUTYLENE OXIDE**

[CAS No. 75-56-9 and CAS No. 106-88-7]

Alkane oxiranes with longer chain length (than ethylene oxide) share the irritating propensity of epoxides, but is less...
marked with longer alkyl chains; at the same time, the volatility also decreases. In addition to irritation and a slight narcotic effect, little information is available on the adverse effects of these epoxides in humans. Polyneuropathy, similar to that observed in humans, has been reported in experimental animals after exposure to propylene oxide and butylene oxide.338

Propylene oxide is a colourless, highly volatile liquid at room temperature and normal atmospheric pressure. It is highly flammable. Inhalation exposure to propylene oxide induced nasal tumours in rats and mice, and less consistently tumours in other organs. Propylene oxide administered by oral gavage to rats produced tumours of the forestomach. Propylene oxide was consistently mutagenic in several in vitro test systems, and also induced cytogenetic changes in experimental animals in vivo. Haemoglobin adducts, but not cytogenetic effects or DNA damage, has been reported in exposed humans.339–342

Propylene oxide caused reproductive toxicity (decreased fetal weight and delayed ossification) with no teratogenic effects in rats, only at doses overtly toxic to the dams.343 Epoxibutane is a colourless liquid with a characteristic odour. It induced degenerative changes in the nasal mucosa in rats and mice in two-year inhalation studies. It also induced a low frequency of nasal adenomas in male and female rats, as well as alveolobronchiolar carcinomas in male rats.344 The IARC working group considered these data to provide limited evidence of carcinogenicity in animals, but based on extensive data demonstrating genotoxic activity concluded that epoxibutane is possibly carcinogenic to humans (rather than the 'not classifiable' normally deduced from limited evidence in animals in the absence of epidemiological data).345

EPICHLOROHYDRIN

[CAS No. 106-89-8]

Epichlorohydrin is a colourless liquid, the vapour of which forms explosive mixtures with air. It is strongly irritating to the eyes and the skin; it may penetrate rubber gloves to the extent that it can cause marked dermal irritation of the underlying skin. Obstructive lung damage and increased small airways resistance, in addition to irritant effects, have been reported among workers exposed to epichlorohydrin.346

Epidemiological studies on four small populations exposed to epichlorohydrin gave inconsistent results with regards to lung cancer risk and epichlorohydrin exposure. Epichlorohydrin induced tumours in rats after inhalation and oral exposure, and noting the chemical reactivity of epichlorohydrin and its direct activity in a wide range of genetic tests, IARC classified it under group 2A.347

BISPHENOL A DIGLYCIDYL ETHER

[CAS No. 1675-54-3]

Bisphenol A diglycidyl ether (BADGE) is the building block of epoxy resins; it is synthesized from epichlorohydrin and bisphenol A. Epoxy resins are used extensively for sealing, encapsulating, making castings and pottings, and formulating lightweight foams. Resins are used as binders in the preparation of laminates of paper, polyester cloth, fibreglass cloth and wood sheets. Epoxy resins have outstanding adhesive properties.348 Fully hardened resin has low toxicity; it is the monomers and oligomers with free epoxide groups that are responsible for the different aspects of epoxy resin toxicity.

The key toxic characteristic of BADGE is contact dermatitis (Figure 42.20), which has been amply demonstrated in numerous case reports; it is apparently the most common causative agent for epoxy resin-induced contact dermatitis (Figure 42.20), which has been amply demonstrated in numerous case reports; it is apparently the most common causative agent for epoxy resin-induced contact
dermatitis (other possibilities being reactive diluents, amine hardeners and epoxy acrylates). 349–351 It also elicits sensitization in experimental animals. Cases of contact urticaria have also been described after exposure to BADGE. 352 Carcinogenicity studies with BADGE have given conflicting results, the IARC evaluation being ‘limited evidence in experimental animals’. 353

Workers exposed to BADGE exhibited elevated urinary concentrations of bisphenol A. 354 Bisphenol A has oestrogenic and anti-androgenic characteristics in studies on endocrine disruption. 355,356 It is not clear whether this has significance from the human health point of view. However, in one study, blood concentrations of FSH, but not of LH or testosterone, were lower in workers exposed to BADGE than in referents. 354 BADGE did not give rise to developmental toxicity in standard experimental tests. 353,357

**CYCLIC ACID ANHYDRIDES**

Cyclic acid anhydrides are a group of reactive chemicals, which are used in the manufacture of polyester and alkyd resins and plasticizers and as epoxy resin hardeners. At room temperature, cyclic anhydrides are powders or crystals, and exposure is mostly to dusts. Hot processes, such as hardening of epoxy resins, welding or burning of painted metals, or curing of the paints, may also involve exposure to fumes.

Cyclic acid anhydrides in use, and with similar clinical effects, include phthalic, hexahydrophthalic, methyl hexahydrophthalic, tetrahydrophthalic, methyl tetrahydrophthalic, tetrachlorophthalic and tetrabromophthalic hydrides, as well as trimellitic, maleic, himic, succinic, dodecensulcotic, chlorendic anhydrides and pyromellitic dianhydride (Figure 42.21).

**Clinical effects and epidemiology**

Exposure to cyclic acid anhydrides causes irritation of the skin, eyes and the respiratory tract as an immediate effect after direct contact. Trimellitic anhydride especially is a very potent eye irritant. Irritation is caused by exposure to both dusts and to vapours. 358

Contact dermatitis and a positive result on prick testing has been reported in a worker exposed to dodecensulcotic anhydride, and in another worker exposed to methyl hexahydrophthalic anhydride. Contact urticaria has been reported in a few cases after exposure to chlorendic, phthalic, maleic, methyl tetrahydrophthalic and methylhexahydrophthalic anhydrides. Urticaria usually occurs after direct dermal contact, but also cases induced by inhalation exposure have been reported.

Occupational asthma and rhinitis have been described after exposure to many different cyclic anhydrides. Typically, after an exposure of 1–35 months, the worker develops rhinitis and asthma. The diagnosis has been based on the exposure, symptoms and a cause–effect relationship supported by immunological tests or challenge tests. The disease is apparently an IgE-mediated immediate-type asthma. 359 In patients with asthma related to the anhydrides, induction of specific IgE antibodies to phthalic anhydride, trimellitic, maleic, methyltetrahydrophthalic, tetrachlorophthalic, hexahydrophthalic, methylhexahydrophthalic, himic and chlorendic anhydride has been detected. 360–374 Cross-reactivity between some acid anhydrides has been reported. 360,369,375,376

Specific IgG antibodies against trimellitic anhydride-human serum albumin have been correlated with late-onset occupational asthma due to trimellitic anhydride. 368,377–380

The potency to induce respiratory sensitization varies between different cyclic anhydrides, phthalic and tetrachlorophthalic apparently being less potent than trimellitic, methyltetrahydrophthalic, methylhexahydrophthalic or hexahydrophthalic anhydrides (Table 42.7).

**Metabolism and monitoring**

Cyclic anhydrides are metabolized to the corresponding carboxylic acids. The concentrations of phthalic and methyltetrahydro-, hexahydro- and methylhexahydrophthalic acids in the urine have been reported to be related to the time-weighted average concentrations in the breathing zone air. Their analysis thus offers the possibility for biological monitoring. 381–384 The information, however, at present is limited and reliable prediction of sensitization risk in an individual from urinary carboxylic acid concentrations is not possible.

Anhydrides react with proteins with lysine residues, and the conjugates are a likely mediator of the immunological response. A relationship between the concentration of the protein conjugates, and air-borne exposure to hexahydro- and methylhexahydrophthalic anhydride has also been demonstrated.

**Management and diagnosis**

For some cyclic anhydrides, information is available of concentrations likely to induce sensitization (Table 42.7). Individuals already sensitized are likely to develop symptoms at considerably lower exposures, and it is not likely that people once sensitized will be able to carry out tasks with exposure to anhydrides. Cross-reactivity between different anhydrides has been reported.

Diagnosis is based on exposure, and exposure-related symptoms. Specific IgE and also IgG concentrations in the serum are often elevated among exposed groups; and positive skin prick test results have also been reported. However, no reliable information is available on the sensitivity or specificity of these analyses. Positive challenge tests have been reported, but these tests have been seldom used for investigating effects of cyclic anhydrides. 358,359
Figure 42.21 Examples of cyclic acid anhydrides.
ISOCYANATES

Isocyanates are a varied group of chemicals, with the isocyanate group (N=Ĉ=O) as the common structural element (Table 42.8). They are reactive and can be irritating to the skin and mucous membranes. There are several thousand different diisocyanates, but relatively few are used extensively. Commerically, the most important isocyanates are shown in Table 42.8. Pre-polymerized oligomers of the diisocyanates, which still contain free isocyanate groups, are increasingly being used. Aliphatic isocyanates, such as HDI, are mostly used in paints and coatings (e.g. car paints) due to the excellent resistance to abrasion and superior weathering characteristics, such as gloss and colour retention. Aromatic isocyanates are used as foams, adhesives, sealants, elastomers and binders. Polyurethane foams are a major end use of aromatic isocyanates. Exposure to isocyanates is also possible in tasks which involve heating of polyurethanes or polyurethane-coated products, such as welding, flame cutting, and sawing. Methyl isocyanate (CH₃NCO; CAS No. 624-83-9) is an intermediate in the synthesis of carbamate pesticides; it has also been used in the production of rubbers and adhesives.

Clinical effects and epidemiology

Exposure to isocyanates causes respiratory tract irritation, sensitization and asthma; cases of hypersensitivity pneumonitis have also been described. They also cause skin irritation and contact dermatitis. Diisocyanates are the most common chemical cause of occupational asthma in many countries.

Methyl isocyanate was the cause of the Bhopal incident, where approximately 42 tonnes was accidentally released from an underground storage facility in a densely populated area in India. An estimated 8000 people were killed initially, and another 9000 later. The principal health effects were irritation and corrosion of the respiratory tract. Among the survivors, several studies have reported residual adverse effects on respiratory function.

The concentrations of isocyanates in the air that are likely to induce respiratory sensitization are not known. It is also not clear if it is the time-weighted average concentration or transient high peak levels that are more important. However, a very high frequency of asthma developed in a new wood-treating facility using MDI and MDI pre-polymer, where the plant was designed to minimize worker exposure. Preventive measures included engineering controls and a comprehensive personal protection programme, as the management was aware that diisocyanate-induced asthma had been reported from other wood-processing facilities. The cases occurred despite the preventive measures implemented.

Dermal exposure may contribute significantly to the development of asthma.

While different isocyanates may differ as to their potency to induce asthma, it seems clear that any reactive isocyanate has such potential; the pre-polymerized oligomers included. It is likely that a determinant of the irritation/sensitization potential is the N=C=O group, and a relevant indicator of exposure is the number of N=C=O structures instead of the concentration of the whole chemical in air samples.

In many patients with isocyanate asthma, the symptoms persist even when the exposure is considerably diminished, or stopped completely. Patients with elevated levels of IgE antibodies seem to have a more favourable prognosis with fewer and less severe symptoms on follow up.

Metabolism and monitoring

Isocyanates are mainly absorbed via the respiratory tract, but absorption through the skin is also possible, notably in contact with liquid isocyanates. Isocyanates are readily metabolized to the corresponding amines, which are rapidly excreted in the urine as such, and as acetylated products. Biological monitoring methods, based on the analysis of the amines in post-shift urine have been published for MDI and TDI, but not for the aliphatic isocyanates HDI and IPDI.

Management and diagnosis

Measurement of isocyanates in the air is complicated, especially for the isocyanates that have low volatility. They partition between the gas and the aerosol phase; both phases being capable of causing sensitization and provoking an asthmatic attack in the already sensitized individuals. Thus, the measurement should comprise both the gaseous and aerosol-carried components of the isocyanate(s), and all chemical species containing these groups should be measured.

The diagnosis of isocyanate-induced asthma depends on a history of symptoms and their relationship to exposure. Demonstration of lung function changes at work may be conclusive. Serial peak flow readings taken at and away from work can indicate a pattern of declines in FEV1/FVC (forced expiratory volume in 1 second over forced vital capacity) typical of asthma (Figure 42.22). Analysis of specific IgE has a high specificity, but low sensitivity to detect isocyanate-induced asthma. IgG analysis is neither specific nor sensitive. Inhalation provocation tests may be performed, but should be limited to specialized units usually in hospital settings. Urinary analysis of the amines generated in the metabolism of aromatic isocyanates (TDI, MDI) have been used for biological monitoring.

CHLORINATED HYDROCARBONS

Halogenated hydrocarbons include both aliphatic and aromatic compounds in which one or more hydrogen atoms are replaced by a halogen. Chlorine is the relevant halogen for the compounds in this section.

The most common and toxicologically relevant aliphatic halogenated hydrocarbons are tri- and tetrachloroethenes, methylene chloride, chloroform, carbon tetrachloride and vinyl chloride. In addition to the toxicological hazards described below, they may also generate highly toxic phosgene gas when heated.

TRICHLOROETHENE AND TETRACHLOROETHENE

Trichloroethene (trichloroethylene) is a colourless liquid with a characteristic chloroform-like odour. The odour
threshold lies between 20 and 30 ppm. It has a vapour pressure of 8.6 kPa at 20°C. The main use of trichloroethene is in cleaning of metal parts. According to industry data, 82 per cent of trichloroethene is used for metal degreasing, 9 per cent in adhesives, 6 per cent for consumer uses and 3 per cent for other uses (e.g. extraction, leather preparation, pharmaceuticals). Exposure to trichloroethene in metal cleaning has decreased over the past few years.

Tetrachloroethene (tetrachloroethylene, perchloroethylene) is a colourless liquid with an ethereal odour. It has a vapour pressure of 1.9 kPa at 20°C. The major uses of tetrachloroethene are as a chemical intermediate and as a dry cleaning agent. Other uses include metal cleaning and extraction processes. Exposure to trichloroethene or tetrachloroethene in occupational settings may occur by inhalation or through the skin.

Clinical effects and epidemiology

Acute exposure to high trichloroethene concentrations causes central nervous system (CNS) depression. Concentrations of >5000 ppm cause narcosis and potentially serious arrhythmias including ventricular tachycardia. In controlled volunteer studies, marked changes in visual-motor performance and subjective symptoms like dizziness, light-headedness and lethargy have been observed following acute exposure to trichloroethene for two hours at 1000 ppm, whereas exposure to 300 ppm caused only slight, non-significant changes in tests measuring visual-motor performance. Alcohol potentiates the acute neurotoxicity of trichloroethene. The consumption of alcohol following exposure to trichloroethene may cause ‘degreaser’s flush’. This is a transient redness of the face and neck, often accompanied by chest discomfort and dyspnoea. It only affects a minority of exposed individuals, and the mechanism is uncertain.

Acute inhalation of high concentrations of tetrachloroethene induces CNS depression, dizziness, fatigue, headache, loss of coordination and narcosis, and liver damage with some deaths having been reported. CNS depression and mild respiratory tract irritation may occur at air levels of 690 mg/m³. In addition, subclinical deficits in vision, cognitive and motor function have occurred in a randomized exposure chamber study at 340 mg/m³. Both trichloroethene and tetrachloroethene can irritate the skin and mucous membranes, and cause occupational dermatitis due to their defatting properties. Based on animal data and human experience, they are unlikely to cause skin or respiratory sensitization.

Long-term exposure to trichloroethene or tetrachloroethene has been suggested to cause chronic solvent encephalopathy (see under Toluene, xylene and styrene, p. 327). A cohort of nearly a hundred metal degreasers showed a significantly increased risk of psycho-organic syndrome from solvent exposure characterized by cognitive impairment, personality changes and reduced motivation, vigilance and initiative. In this study, there was an odds ratio of 5.6 (CI, 0.93–34.3) for psycho-organic syndrome in the medium-exposed group and 42.2 (CI, 1.9–66.6) in the most highly exposed group of workers. None of four other potential confounders (arteriosclerotic disease, neurologic/psychiatric disease, alcohol abuse and current solvent exposure) had any significant association with psycho-organic syndrome.

Exposure-related effects on neuropsychological performance have also been observed in dry cleaners exposed to tetrachloroethene. Impairments in visual reproduction, pattern memory and pattern recognition have been seen in dry cleaners with high chronic exposure. These impairments of visually mediated function were consistent with the impairment of visuospatial functions observed in the patients diagnosed earlier with tetrachloroethene encephalopathy. Effects on visuospatial function were consistently found in subjects employed as dry cleaners for an average of 14.6 years and exposed to an estimated tetrachloroethene eight-hour TWA air concentration of 280 mg/m³. Effects of tetrachloroethene on colour vision have also been reported.

In animal experiments, trichloroethene has caused mid-frequency hearing loss in animal tests. Synergistic effects with noise on hearing thresholds have been reported in animals. In humans, specific evidence on the effects of trichloroethene on hearing is lacking. One report suggests ototoxic effects in jet engine repair workers resulting in balance disturbances. However, they may have also been exposed to other neurotoxicants.

The carcinogenicity of trichloroethene has been investigated in a number of long-term animal studies. These studies provide clear evidence on trichloroethene’s carcinogenicity in rodents. It has induced hepatocellular and lung tumours in mice and kidney tumours in rats. Recent epidemiological studies provide support for the carcinogenicity of trichloroethene. Associations between trichloroethene exposure and kidney cancers, liver and biliary tract cancers, and lymphomas have been suggested. Two recent cohort studies show statistically significant associations between kidney cancer and increasing trichloroethene exposure.

Trichloroethene has been shown to have genotoxic potential. However, there are still uncertainties related to mode of action and metabolites responsible for trichloroethene-induced cancers. The available data support the likelihood that toxicity is due to multiple metabolites through several modes of actions. The IARC has classified trichloroethene as class 2A. Some studies have tried to characterize specific mutations related to trichloroethene-induced renal cancers. Currently, however, no specific pattern of mutations in trichloroethene cancers has been identified.

Tetrachloroethene has caused liver and kidney tumours in animal carcinogenicity tests. Epidemiological evidence on the association between occupational exposure to tetrachloroethene and cancer is limited. However, because of the strong animal evidence and the evidence of the
genotoxicity of its main metabolites, the IARC has classified tetrachloroethene as group 2A.\textsuperscript{414,415} 

**Metabolism and monitoring**

Trichloroethene is predominantly cleared from the body after metabolism, accounting for 50–99 per cent of the absorbed dose. The major metabolic pathway for trichloroethene involves the initial conversion of trichloroethylene by cytochrome P450 to a transient epoxide, which subsequently undergoes intramolecular rearrangement to form trichloroacetaldehyde. Trichloroacetaldehyde is hydrolysed to form chloral hydrate, which is converted by alcohol dehydrogenase and chloral hydrate dehydrogenase to trichloroethanol and trichloroacetic acid, respectively. Other minor metabolites, which have been suggested to be of relevance for trichloroethene-induced cancers include dichloroacetic acid (DCA) and S-(1,2-dichlorovinyl)-\textsuperscript{L}-cysteine (DCVC), which may be involved in liver and kidney carcinogenicity of trichloroethene, respectively.\textsuperscript{413} 

Unmetabolized trichloroethene is mostly exhaled, whereas metabolites of trichloroethene are predominantly eliminated in urine. Urine trichloroacetic acid (U-TCA) is commonly used to assess exposure to trichloroethene. Most (98–99 per cent) of absorbed tetrachloroethene is excreted unchanged in exhaled air, regardless of exposure route. The rest is metabolized by two main pathways, cytochrome P450-mediated oxidative route and glutathione-S-transferase (GST)-mediated conjugation. The major metabolite detected in human blood and human urine is trichloroacetic acid (TCA), formed by cytochrome P450-dependent oxidation of tetrachloroethene to epoxide intermediate, but even TCA is formed only in small quantities. The second pathway involves conjugation of tetrachloroethene with glutathione and is associated with generation of reactive metabolites via initial cleavage to S-(1,2,2-trichlorovinyl)-\textsuperscript{L}-cysteine and further degradation of the cysteine conjugate by beta-lyase to a reactive dithioketene and ultimately dichloroacetic acid. Metabolites derived from P450 metabolism, specifically TCA and DCA, have been linked to hepatotoxicity and liver tumorigenesis, whereas reactive metabolites formed through the GSH conjugation pathway have been associated with tetrachloroethene-induced renal toxicity and carcinogenicity.\textsuperscript{416} 

The available data indicate that tetrachloroethene concentrations in blood and exhaled air give a reliable impression of the exposure over the previous several days. Trichloroacetic acid is a less suitable exposure indicator, as it is also the major metabolite of trichloroethene and trichloroethane, which are often present as impurities in tetrachloroethene, or can be used in the same location as tetrachloroethene.\textsuperscript{401} Tetrachloroethene in urine has also been suggested for biomonitoring of tetrachloroethene.\textsuperscript{417} 

**Management and diagnosis**

The diagnosis of chronic solvent-induced encephalopathy follows the principles described under Toluene, xylene and styrene, p. 327.

Management of tri- and tetrachloroethene-related risks is mainly related to monitoring and controlling of exposure to as low as technically feasible.

**METHYLENE CHLORIDE**

\[[CAS No. 75-09-2]\]

\begin{center}
\textbf{Dichloromethane}
\end{center}

Methylene chloride is a clear, highly volatile liquid with a characteristic ether-like odour. It is used because of its good solvent properties in many different applications. One of the most widespread applications is its use as a paint remover. This use is likely to decrease in Europe due to the planned restrictions on methylene chloride use in paint removers. Methylene chloride is well absorbed by inhalation or through the gastrointestinal tract. Absorption through the skin also occurs.

**Clinical effects and epidemiology**

Since methylene chloride is a highly volatile liquid, it can result in high air concentrations especially when it is used in closed spaces. There are several poisoning cases described in the literature, which have been caused by methylene chloride use in confined spaces.\textsuperscript{418} Acute exposure to air levels of 700 mg/m\textsuperscript{3} causes slight central nervous system effects (behavioural disturbances), with more significant effects being seen at concentrations in excess of 2000 mg/m\textsuperscript{3}.\textsuperscript{418} Methylene chloride is metabolized in the body to carbon monoxide resulting in elevated carboxyhaemoglobin (CO-Hb) levels. Exposure to 100 or 530 mg/m\textsuperscript{3} for 7.5 hours leads to CO-Hb levels of 3.4 and 5.3 per cent, respectively, in human volunteers.\textsuperscript{418} Fatal poisonings are considered to be due to the narcotic effects of methylene chloride rather than directly due to carbon monoxide poisoning.\textsuperscript{418–421} Poisoning cases in which methylene chloride has been heated resulting in the formation of phosgene have been also described in the literature.\textsuperscript{422,423} 

Methylene chloride has caused cancer in mice bioassays. According to current knowledge, this effect is related to the specific metabolism of methylene chloride in mice, and the cancer risk in humans is low.\textsuperscript{418} No epidemiological data on the carcinogenicity of methylene chloride in humans are available. IARC classification is that methylene chloride is possibly carcinogenic to humans (2B).\textsuperscript{424} 

**Metabolism and monitoring**

When inhaled, most of the absorbed methylene chloride is exhaled unchanged and the remainder is metabolized to carbon monoxide, carbon dioxide and inorganic chloride.\textsuperscript{418} At lower doses, the main route of metabolism is mediated by cytochrome P450, whereas at high-dose levels (\(\geq 1800\) mg/m\textsuperscript{3}) this route is saturated and the metabolism is transferred to involve glutathione transferase (GST) resulting
vinyl chloride can be monitored by measuring the solvent itself in exhaled air or blood, or by analysis of carbon monoxide in exhaled air, or by measuring carboxyhaemoglobin (CO-Hb) in blood, which is currently the preferred method. Smoking is a significant confounding factor in increasing CO-Hb levels.

**Management and diagnosis**

Because of the high volatility and acute toxicity, methylene chloride should always be handled only in well-ventilated areas. Diagnosis of methylene chloride poisoning is based on a history, symptoms and carboxyhaemoglobin measurement. Treatment is symptomatic including administration of oxygen and follow up of liver, nervous system and renal functions.

**VINYL CHLORIDE**

[CAS No. 75-01-4]

Vinyl chloride is a colourless, flammable gas with a slightly sweet odour and was previously used as an anaesthetic agent. It is now mainly used for the production of polyvinyl chloride (PVC) plastics in closed systems. It is not known to occur naturally, but is present in cigarette smoke. The level of residual vinyl chloride (VC) in polyvinyl chloride has been regulated since the late 1970s in many countries and nowadays the release of VC from the thermal degradation of PVC is either not detectable or is at very low levels.425 Exposure to vinyl chloride occurs mainly by inhalation.

**Clinical effects and epidemiology**

Vinyl chloride has low acute toxicity, but long-term exposure causes severe adverse effects including a specific type of cancer, liver angiosarcoma, in humans. Prior to the mid-1950s, exposure levels in PVC production could easily exceed 1000 ppm and a specific syndrome called ‘vinyl chloride illness’ was described in workers. Symptoms included headache, dizziness, earache, blurred vision, fatigue, nausea, sleeplessness, breathlessness, stomach ache, pain in the liver/spleen area, pain and tingling sensation in the arms and legs, cold sensation in the extremities, loss of appetite, loss of libido and weight loss.425 Specific findings in the skin and bones caused by vinyl chloride included acro-osteolysis accompanied by scleroderma-like changes in the fingers and peripheral circulatory changes resembling Raynaud’s disease. Acro-osteolysis is caused by the decalcification of the terminal phalanges of the hands and feet, which may be reversible after cessation of exposure. Also Raynaud’s disease caused by vinyl chloride may show some improvement after cessation of the exposure.425 In a study426 on 725 workers exposed to significant VC levels, 3 per cent developed acro-osteolysis, 10 per cent Raynaud-type phenomenon and 6 per cent scleroderma-like skin lesions. Genetic susceptibility has been suggested as a possible reason for variability in the clinical picture.

Exposure to VC is also associated with hepatomegaly and/or splenomegaly.425 Early histological lesions in VC workers showed focal hepatocellular hyperplasia and hyperplasia of sinusoidal cells along with hyperplasia of hepatocytes.427 Later effects preceding angiosarcoma include subcapsular fibrosis, progressive portal fibrosis and a borderline increase of intralobular connective tissue, all associated with focal stimulation and proliferation of sinusoidal lining cells and hepatocytes.

The ability of vinyl chloride to cause liver angiosarcoma is well known. A recent meta-analysis of two recently updated multicentre cohorts and six smaller studies evaluated the relationship of cancer mortality and vinyl chloride exposure.428 Six studies suggested an increased risk of liver cancer. For four of these studies, excesses persisted when known cases of angiosarcoma of the liver were excluded. It was noted however, that these results may have been influenced by the underdiagnosis of angiosarcoma. Also increased standardized mortality ratios (SMRs) were suggested for brain cancer, soft tissue sarcomas and lymphatic and haematopoietic neoplasms. Mortality from other neoplasms, including lung cancer, did not appear to be increased according to this meta-analysis. Gennaro and co-workers429 recently published a reanalysis of updated mortality experience among Italian vinyl chloride and PVC workers exposed in a large petrochemical plant in Porto Marghera between July 1950 and July 1985. In this study, elevated risks for liver cancer, including angiosarcoma, haemolymphopoietic system cancers and lung cancer, were observed in exposed workers. The IARC concluded in 2009 that vinyl chloride causes angiosarcoma of the liver and hepatocellular carcinoma.100

The mechanism for liver cancer caused by vinyl chloride has been well studied. Mechanistic events resulting to cancer include:

- metabolic activation to form chloroethylene oxide;
- DNA binding of the chloroethylene oxide to form exocyclic etheno adducts;
- ability of these adducts to cause base mutations; and
- effects of such mutations on proto-oncogenes/tumour suppressor genes at the gene and gene product levels.

Specific mutations associated with vinyl chloride-induced liver tumours include G>A transitions at codon 13 of Ki-ras proto-oncogene and A>T transitions in tumour suppressor protein p53.431 Also serum anti-p53 antibodies have been found in angiosarcoma patients and in some workers with occupational exposure to VC.431

There are some published risk estimates of cancer risk from VC at low exposure levels based on different sets of data.430 According to these estimates, an angiosarcoma
risk of approximately $3 \times 10^{-4}$ for exposure to 1 ppm vinyl chloride over an entire human working lifetime has been suggested.

**Metabolism and monitoring**

Vinyl chloride undergoes rapid oxidative metabolism to yield reactive metabolites, the most reactive being chloroethylene oxide (CEO) and its derivative chloroacetaldehyde (CAA).

CEO is formed by cytochrome P450 isoenzyme CYP2E1 and detoxified by epoxide hydrolase and glutathione-S-transferase.\(^{431}\) Polymorphism of the genes of these xenobiotic metabolizing enzymes may affect the cancer susceptibility of individual exposed workers. According to current knowledge, CEO is the most biologically relevant metabolite and it is likely that VC biotransformation into CEO occurs in the hepatocytes, thus allowing the epoxide to reach and hit the adjacent sinusoidal lining cells that are the target for angiosarcomas. This results in the formation of exocyclic etheno adducts identified in exposed animals and in humans.\(^{430,431}\)

**Management and diagnosis**

At current exposure levels in PVC manufacturing ($\leq 1$ ppm), the risk for cancer is low, but because of the assumed linear dose–response relationship it is not excludable. Liver angiosarcoma is an uncommon tumour type and therefore if the occupational history shows possible vinyl chloride exposure, the possibility of occupational cancer must be considered. Since there is increasingly more information on specific features of VC-induced liver cancers including specific mutations, these may provide some new tools for the differential diagnosis of VC-induced cancers in future. The prognosis of angiosarcoma of the liver is poor.

The risk of non-cancer effects from VC exposure is related to high-dose exposures and these are unlikely to occur from current work processes.

**CHLOROFORM AND CARBON TETRACHLORIDE**

[CAS No. 67-66-3 and CAS No. 56-23-5]

\[\text{Cl} - \text{Cl} \quad \text{Cl} - \text{Cl} \quad \text{Cl} - \text{Cl}\]

Chloroform is a clear, colourless, volatile liquid with a characteristic, ether-like odour. Its main use is in HCFC-22 production. HCFC-22 is used in refrigerant applications (decreasing use) and increasingly as the feedstock for fluoro-polymers, such as polytetrafluoroethylene (PTFE). Earlier use of chloroform as an anaesthetic has been largely discontinued in the western world. Worldwide, chloroform is also used in pesticide formulations, as a solvent for fats, oils, rubber, alkaloids, waxes, gutta-percha (a rubber-like latex from tropical trees used for wire insulation, and for root canal fillings in dentistry) and resins, as a cleansing agent, in fire extinguishers, and in the rubber industry.\(^{432}\)

Carbon tetrachloride is a colourless, volatile liquid with a characteristic sweet odour. It has been used especially in the production of chlorofluorocarbons (CFCs) used widely as refrigerants and propellants, but this use has decreased in recent years due to restrictions on the use of CFC compounds. It has also had many other uses as a grain fumigant, pesticide, solvent, metal degreaser, fire extinguisher and flame retardant, and in the production of paint, ink, plastics, semiconductors and petrol additives, but many of these uses have decreased or stopped.\(^{433}\)

Both substances are well absorbed through the lungs, skin and gastrointestinal tract.

**Clinical effects and epidemiology**

Chloroform has been used in the past to induce and maintain medical anaesthesia. Induction levels were approximately 24–73 g/m\(^3\) and maintenance levels 12–48 g/m\(^3\) air. This practice was discontinued because chloroform anaesthesia caused deaths due to respiratory effects and arrhythmias and cardiac failure. In addition, jaundice and hepatic dysfunction resulting in lethal liver necrosis have been described after chloroform anaesthesia.\(^{432}\) Some reports suggest toxic liver jaundice and hepatitis in workers exposed to varying levels of chloroform for less than six months to four years.\(^{434,435}\) In animal tests, chloroform has caused liver damage and increased kidney weight after repeated inhalation exposure at high doses.\(^{432}\)

The liver and kidney are also target organs for carbon tetrachloride toxicity. Symptoms of acute intoxication after accidental or suicidal high level exposure are independent of the route of intake and include nausea, vomiting, headache, dizziness and dyspnoea. Liver damage appears after 24 hours or more, but kidney damage is evident often only after two to three weeks following the poisoning.\(^{433}\) No association between occupational, long-term low-level exposure to carbon tetrachloride and liver disease has been described.

Both substances have induced cancer in animals. Chloroform has been negative in genotoxicity tests and its carcinogenicity (hepatic and renal cancers) is most likely secondary to hepatotoxicity and nephrotoxicity observed in animal tests at high dose levels.\(^{432}\) In addition, carbon tetrachloride has been mainly negative in genotoxicity tests and hepatomas and hepatocellular carcinomas seen in long-term cancer bioassays in animals have been observed mainly at the dose levels producing liver toxicity.\(^{433}\) No clear epidemiological evidence on their carcinogenicity in humans is available.

**Metabolism and monitoring**

Chloroform is metabolized mainly by CYP2E1. The endproduct of oxidative metabolism by CYP2E1 is carbon dioxide and reactive intermediates include phosgene.
Carbon tetrachloride is metabolized by cytochrome P450 enzymes (CYP2E1 and CYP2B1/2B2), leading to the formation of reactive trichloromethyl and trichloromethylperoxyl radicals, which can further react to form phosgene.\textsuperscript{432,433}

**Management and diagnosis**

Liver and kidney diseases caused by chloroform and carbon tetrachloride are mainly related to high level accidental exposures or anaesthesia (chloroform). The treatment of acute carbon tetrachloride or chloroform poisoning is symptomatic, including follow up of liver and kidney function. N-acetylcysteine and pyridoxine (administered orally) may provide some protection against carbon tetrachloride-caused hepatic injury, if administered early following acute exposure.\textsuperscript{260}

**CHLOROBENZENES**

Chlorobenzenes, like 1,4-dichlorobenzene and hexachlorobenzene, are examples of aromatic halogenated hydrocarbons. 1,4-Dichlorobenzene (CAS No. 106-46-7) is a substance used in the chemical industry for the production of other chemicals, but also in moth repellants, air fresheners and toilet blocks. The main health concern related to 1,4-dichlorobenzene is its ability to cause liver tumours in mice.\textsuperscript{436} The mechanism of this effect is unknown, but appears to be related to high experimental doses.

Hexachlorobenzene (CAS No. 118-74-1) is an environmental contaminant released from a number of sources, including the use of some chlorinated pesticides, incomplete combustion, old waste removal sites and inappropriate manufacture and disposal of waste from the manufacture of chlorinated solvents, chlorinated aromatics and chlorinated pesticides.\textsuperscript{437} Hexachlorobenzene caused poisoning of more than 600 people in Turkey when they consumed bread made from wheat that was contaminated with hexachlorobenzene used as a fungicidal seed dressing in the 1950s. The clinical manifestations were porphyria cutanea tarda with disturbances in porphyrin metabolism, dermatological lesions, hyperpigmentation, hypertrichosis, enlarged liver, thyroid gland and lymph nodes, osteoporosis and arthritis.\textsuperscript{437} Acquired hepatic porphyrias have also been described following exposure to vinyl chloride, some halogenated biphenyls, chlorinated naphthalenes, and organophosphate and organochlorine pesticides. Hexachlorobenzene has been carcinogenic in animal tests producing liver tumours. IARC classified it under group 2B.\textsuperscript{438}

</table>

TEF, toxicity equivalence factor.
molecule in the body, and this is apparently the reason for the unique toxicity of these compounds.

While the most studied group is compounds with chlorine substituents, other halogenated compounds have similar effects. One of the best studied is polybrominated biphenyls (PBBs), previously used as flame retardants. The most toxic of these compounds are listed in Table 42.9, with an estimated relative toxicity for each as assessed by WHO in 1998 and 2005.439

Dioxins cause chloracne, peripheral neuropathy, liver damage, hepatic porphyria and hypercholesterolaemia. Changes in the immune system and glucose metabolism have been described in adults, as well as alterations in thyroid hormone levels, and possible changes in neurobehavioural tests, and infection resistance.440,441

The best information on cancer and dioxins comes from cohorts exposed to dioxin-contaminated herbicides in herbicide production.440 In these cohorts, the risk of cancer at all sites was elevated and showed a relationship with the estimated intensity of the exposure. The cancer types that show the most consistent relationship to dioxin exposure, are cancer of the lung, non-Hodgkin’s lymphoma and soft tissue sarcoma. The best studied dioxin, 2,3,7,8-tetrachlorodibenzodioxin, is clearly a carcinogen in experimental animals. The mechanism of carcinogenicity apparently is tumour promotion through modification of cellular replication and apoptosis. The IARC evaluation is group 1 for 2,3,7,8-TCDD and 2,3,4,7,8-pentachlorodibenzodioxin.100 Recently, the IARC group 1 classification was extended also to 2,3,4,7,8-pentachlorodibenzofuran (CAS No. 51207-31-9) and 3,4,5,3′,4′-pentachlorobiphenyl, which are indicator chemicals for a larger class of dioxin-like chlorinated dibenzofurans and dioxin-like polychlorinated biphenyls.100

From a meta-analysis of studies performed (but not all published), it was concluded that there was an elevated frequency of all malformations among babies born to mothers exposed to Agent Orange (containing dioxins) during the Vietnam war.442 The data are strongest for spina bifida and anencephaly.443 Exposure to TCDD was related to semen quality and serum testosterone levels in exposed men.444,445 In experimental animals, TCDD is toxic to reproduction and to development; the developing fetus seems to be orders of magnitude more sensitive to TCDD than adult animals. The spectrum of malformations induced varies between species.

**POLYCHLORINATED BIPHENYLS**

Polychlorinated biphenyls (PCBs) have been produced commercially since 1929 (Figure 42.23). They have been used in plasticizers, surface coatings, inks, adhesives, flame retardants, pesticide extenders, paints and microencapsulation of dyes for carbonless duplicating paper, as well as dielectric fluids in transformers and capacitors. Many countries have severely restricted or banned the production of PCBs and at present, occupational exposure should be limited to waste disposal. The pyrolysis of PCB mixtures produces hydrogen chloride and polychlorinated dibenzofurans (PCDFs), and pyrolysis of mixtures containing chlorobenzenes also produces polychlorinated dibenzodioxins (PCDDs). Commercial PCBs are mixtures of (theoretically) 209 different isomers and the trade names used include Aroclor, Pyranol, Pyroclor (United States), Phenochlor, Pyrale (France), Clopehn, Elaol (Germany),
Kanechlor, Santotherm (Japan), Fenchlor, Apirolio (Italy) and Sovol (Russia). 441

Clinical effects and epidemiology

Some PCB compounds are structurally close to dioxins and also exhibit dioxin-like toxicity, albeit at a much lower potency than TCDD (see Table 42.9). Heat transfer fluids and dielectric fluids, which have been exposed to heat, are likely to also contain furans/dioxins.

‘Yusho disease’ was the term given to clinical effects of PCBs that occurred following ingestion of rice oil contaminated with Kanechlor 400 (a heat-transfer medium containing PCB). Two well-recognized public health incidents of Yusho disease occurred in southern Japan in 1968, and central Taiwan in 1979. PCDFs and PCQs (polychlorinated quarterphenyls) also detected in the contaminated oil may be largely responsible for the health effects.

In occupational exposure to high concentrations of PCB, skin rashes occurred a few hours after the exposure. Furthermore, itching, burning sensations, irritation of the conjunctivae, pigmentation of the fingers and nails, and chloracne were found after exposure to high PCB concentrations. Chloracne is one of the most prevalent findings among PCB-exposed workers. Liver disturbances are also a constant finding after occupational exposure to high levels of PCB. In addition, immunosuppressive changes, neurological and unspecific psychological or psychosomatic effects, such as headache, dizziness, depression, sleep and memory disturbances, nervousness, fatigue and impotence have been described, although the causal relationship to exposure to PCB is not well established. 446 Reproductive/developmental effects, such as effects on sperm motility, fetal growth rate (lower birthweight, smaller head circumference) and development (shorter gestational age, neuromuscular immaturity), and neurological functions of the offspring (impaired autonomic function, increased number of abnormally weak reflexes, reduced memory capacity, lower IQ scores, and attention deficit) have also been associated with exposure to PCB. 441 However, it is uncertain if these effects are directly caused by PCB.

PCBs have low acute toxicity in experimental animals. In long-term studies, adverse effects have been described, notably on the liver, skin, kidneys, as well as on the immunological and endocrine system. Fetotoxicity has been described at high doses; neurodevelopmental effects have been observed in monkeys at doses that are not toxic to the mother. 441

PCB isomers, notably those with more than 50 per cent chlorination, as well as commercial mixtures of highly chlorinated PCB, consistently induced tumours in experimental animals, 17, 441 apparently through a mechanism that does not involve direct genotoxic action. The IARC evaluation is group 2B for polychlorinated biphenyls; the non-orth-substituted planar, dioxin-like PCB 126, however, was classified as a group 1 carcinogen. 100

Metabolism and monitoring

PCBs are absorbed by ingestion, inhalation and readily by the dermal route. They are metabolized by hydroxylation, but there are marked differences in the rate of metabolism between different congeners. PCBs that are highly chlorinated and lack adjacent non-substituted carbon atoms (e.g. 2,4,6 and 3,5 substituted PCBs) are metabolized only very slowly and accumulate in adipose tissue. 447 The body burden of PCBs may be assessed from the determination of PCB in serum.

Hydrochlorofluorocarbons

In hydrochlorofluorocarbons (HCFC), there is at least one hydrogen atom left unsubstituted in a structure composed of an alkane chain (usually 1–3 carbons); the rest of hydrogen atoms being substituted by chlorine and fluorine. The most commonly encountered HCFCs are chlorodifluoromethane (HCFC 22, CHF2Cl), dichlorotrifluoroethane (HCFC 123, CHCl(CF2)3), chlorotetrafluoroethane (HCFC 124, CHClF(CF3), dichlorofluorooethane (HCFC 141b, CH2(CFCl)2) and chlorodifluoroethane (HCFC 142b, CH2(CF2Cl)2). 448

Partially substituted hydrochlorofluorocarbons were introduced as a substitute for completely substituted chlorofluorocarbons, when the ozone-depleting and global warming potential of the latter led to their ban under the Montreal protocol. (The Montreal protocol on substances that deplete the ozone layer was an international agreement signed under the Vienna convention in 1985 to restrict the use of chlorofluorocarbons and other halogenated chemicals, for environmental protection.) However, even HCFC have some ozone-depleting and global warming properties, and the amendments of the Montreal protocol dictate restriction and ultimate phasing out also of HCFCs. 449

In contrast to fully substituted chlorofluorocarbons, HCFCs are to a varying extent metabolized in the body. The toxicity of HCFCs in animals, even from long-term studies, is low. The main health concerns have been their potential to induce cardiac arrhythmias, and for some PCBs the issue of carcinogenicity has also been raised as a cause of concern.

CHLORODIFLUOROMETHANE

[CAS No. 75-45-6]

Chlorodifluoromethane (HCFC22) is a non-flammable gas (at room temperature and normal atmospheric pressure), colourless and practically odourless. It is used as a
refrigerant, aerosol propellant and blowing agent for polystyrene. It is an intermediate in the production of tetrafluoroethylene.\textsuperscript{450}

**Clinical effects and epidemiology**

Increased palpitations were reported in a limited study among people exposed to HCFC22, but the study is very difficult to interpret. In a 24-hour electrocardiogram (ECG) recording of a small number of people exposed to HCFC12 and 22, no clear-cut connection between the exposure and different arrhythmias was observed.\textsuperscript{451}

In mice and dogs, exposure to HCFC22 in most studies at concentrations in excess of 1000 g/m\textsuperscript{3} has been reported to increase the sensitivity of the animals to adrenaline-induced arrhythmias.\textsuperscript{450} Based on findings of an increased incidence of subcutaneous fibromas and Zymbal gland tumours in male rats, and no evidence of carcinogenicity in mice or female rats, the IARC concluded that the evidence of carcinogenicity of HCFC22 in experimental animals is limited.\textsuperscript{452} HCFC22 induced base-pair substitution mutations in *Salmonella typhimurium*, but was otherwise negative in genotoxicity testing. High concentrations of HCFC22 induced eye malformations in rats.

**Metabolism and monitoring**

HCFC22 is absorbed from the respiratory tract. It is not significantly metabolized; it is excreted unchanged in exhaled air, the bulk of the absorbed amount being excreted within a few minutes.

**DICHLOROTRIFLUOROETHANE**

[CAS No. 306-83-2]

\begin{center}
\begin{tikzpicture}

\draw (d) -- (e);
\draw (e) -- (f);
\end{tikzpicture}
\end{center}

Dichlorotrifluoroethane (HCFC123) is a non-flammable volatile liquid with a faint ethereal odour. The principal use for HCFC123 is as a refrigerant in commercial and industrial air-conditioning installations, in fire extinguishers, as a foam-blowing agent, and in metal and electronics cleaning.\textsuperscript{453}

**Clinical effects and epidemiology**

Four case series convincingly demonstrate that repeated occupational exposure to HCFC123 leads to liver damage.\textsuperscript{454–457} This effect has also been seen in experimental animals. No reports are available on cardiac arrhythmias in humans exposed to HCFC123. In dogs, exposure to HCFC combined with an adrenaline challenge induced fatal arrhythmias. In a carcinogenicity study in rats, there was an increased incidence of hepatocellular adenomas in females and males, of cholangiofibromas in females administered the highest dose, and of pancreatic acinar cell adenomas and Leydig cell adenomas in males. With the exception of clastogenicity reported in vitro, studies on mutagenicity were negative. All tumour types observed were benign; HCFC123 is apparently non-mutagenic in vivo, and the carcinogenic mechanism is therefore probably not through a genotoxic mechanism. However, in the view of the International Programme on Chemical Safety (IPCS) of the World Health Organization (WHO), the elevated incidence of several types of tumours raises a concern for possible carcinogenicity in humans.\textsuperscript{453}

HCFC123 did not show teratogenicity or other reproductive toxicity in experimental animals.

**Metabolism and monitoring**

HCFC123 is metabolized by cytochromes P450 reductively and oxidatively. Both reaction pathways lead to the metabolites trifluoroaldehyde and trifluoroacetic acid that are common to halothane (CHClBrCF\textsubscript{3}), a known hepatotoxic anaesthetic.

**CHLOROTETRAFLUOROETHANE**

[CAS No. 63938-10-3]

\begin{center}
\begin{tikzpicture}
\node [shape=circle,draw,minimum size=0.75cm] (a) at (0,0) {F};
\node [shape=circle,draw,minimum size=0.75cm] (b) at (0,-1) {Cl};
\node [shape=circle,draw,minimum size=0.75cm] (c) at (1,0) {F};
\node [shape=circle,draw,minimum size=0.75cm] (d) at (1,-1) {F};
\draw (a) -- (b);
\draw (b) -- (c);
\draw (c) -- (d);
\end{tikzpicture}
\end{center}

Chlorotetrafluoroethane (HCFC124) is a non-flammable, colourless and odourless gas. It is used as a blowing agent for polystyrene and polyolefin foams and as a blend in refrigerants.

**Clinical effects and epidemiology**

Human health effects from exposure to HCFC124 have not been reported. The main effects seen in experimental studies are lethargy and other signs of depression of the central nervous system. No liver toxicity was observed in rats in 90-day or two-year studies at exposure levels up to 50000 ppm. Benign mammary fibroadenomas were observed in female rats exposed to 50000 ppm for two years. HCFC124 was not genotoxic and did not result in adverse developmental or fertility effects in animals. Inhalation exposure to 2.5 per cent or more of HCFC124 to dogs increased the sensitivity of the animals to adrenaline-induced arrhythmias.\textsuperscript{458–461}

**Metabolism and monitoring**

HCFC124 is metabolized by cytochrome P450 IIE1 to trifluoroaldehyde and trifluoroacetic acid (which are the hepatotoxic metabolites from halothane produced by the oxidative pathway); however, to a much smaller extent than HCFC123.\textsuperscript{461}
1,1-DICHLORO-1-FLUOROETHANE

[CAS No. 1717-00-6]

1,1-Dichloro-1-fluoroethane (HCFC141b) is a non-flammable volatile liquid with a faint ethereal odour. It was developed as a substitute for CFC-11, a fully halogenated chlorofluorocarbon mainly for use as a blowing agent for polyurethane and polyisocyanurate insulating foams and as a solvent in electronic and other precision cleaning applications. It is being phased out following the Montreal protocol.\(^4\)

Clinical effects and epidemiology

No information on adverse effects after occupational exposure of humans to HCFC141b is available; a six-hour experimental inhalation exposure to 1000 ppm did not lead to adverse effects.

In experimental animals, HCFC141b induced narcosis at concentrations of approximately 40 000 ppm. HCFC141b was not hepatotoxic; it did not induce teratogenesis or other adverse effects on reproduction. HCFC141b caused Leydig cell hyperplasia and adenomas in male rats, but induced no malignant tumours in either female or male rats. It was negative in tests for bacterial mutagenicity, but gave both negative and positive results in cytogenetic studies \(\text{in vitro}\). It did not induce micronuclei in mouse bone marrow \(\text{in vivo}\).

HCFC141b increases the sensitivity of dogs to adrenaline-induced arrhythmias at inhalation exposure levels of 10 000 ppm.\(^4\)

Metabolism and monitoring

HCFC141b is metabolized slowly by cytochrome P450 IIE1 to 2,2-dichloro-2-difluoroalcohol, and to an even smaller extent, further to 2,2-dichloro-2-difluoroacetic acid. In contrast to the metabolites (trifluoroacetaldehyde and trifluoroacetic acid) of HCFC123, no binding to proteins of these metabolites was observed.\(^5\)

1-CHLORO-1,1-DIFLUOROETHANE

[CAS No. 1717-00-6]

1-Chloro-1,1-difluoroethane (HCFC142b) is a flammable, colourless and odourless gas mainly used as a blowing agent in the production of fluoropolymers. Small amounts are used as a component of refrigerant fluids. Its use is being phased out in compliance with the Montreal protocol.\(^4\)

Clinical effects and epidemiology

No information on the toxicity of HCFC142b in humans is available. It caused anaesthesia at high concentrations in experimental animals, but with no morphological adverse effects in the central nervous system. It was not hepatotoxic, did not induce teratogenesis or other reproductive toxicity, and was not carcinogenic to rats.\(^4\) It was mutagenic to \(\text{Salmonella}\), but did not induce cytogenetic abnormalities in mouse bone marrow \(\text{in vivo}\).

HCFC141b sensitized dogs to the arrhythmogenic effect of adrenaline at inhalation exposure levels of 25 000 ppm.\(^4\)

Metabolism and monitoring

HCFC142b is mostly excreted unchanged. Dechlorination has however been observed \(\text{in vitro}\) and chlorodifluoroacetic acid has been reported as a metabolite. The metabolic pathways are analogous to those responsible for halothane liver toxicity.\(^4\)

SULPHUR-CONTAINING SUBSTANCES

CARBON DISULPHIDE

[CAS No. 75-15-0]

\(\text{S=}\text{C}\text{=S}\)

Carbon disulphide is a clear, colourless or faintly yellow, liquid. It is mainly used in the production of viscose fibre and cellophane film. Other uses include the manufacture of carbon tetrachloride (apparently only very small amounts produced and used at present), sodium sulphite, mineral flotation agents, xanthates, mercaptans and thioureas. Carbon disulphide is also used as a solvent for fats, lipids, resins, rubbers, sulphur monochloride and white phosphorus.\(^5\)

Clinical effects and epidemiology

Single or long-term exposure to high levels of carbon disulphide led to the recognition of chronic carbon disulphide intoxication, characterized by psychoses, polyneuropathy of the lower extremities, gastrointestinal disturbances, myopathy of the calf muscles, neuroasthenic syndrome, optic neuritis and atherosclerotic vasculoencephalopathy.\(^5\)

In exposure conditions not leading to overt intoxication, the peripheral and central nervous systems appear to be the critical target for carbon disulphide-induced toxicity. The effects include reduced conduction velocity in the peripheral nerves and impaired performance in psychomotor testing.\(^5\) Brain nuclear magnetic resonance (NMR) images usually show multiple high signal intensities in the basal ganglia and subcortical white matter suggesting a vascular event particularly in the small
vessels. NMR of the brain also revealed cerebral effects even among workers whose neuropsychological testing results have not been adversely affected.

Increased mortality from cardiovascular disease after exposure to carbon disulphide was described in the 1970s in a rayon producing facility. When the exposure was lowered to below 10 ppm (30 mg/m$^3$), this effect was not observed. Several larger studies have since verified the potential of carbon disulphide to cause cardiovascular mortality, notably at levels in excess of 30 mg/m$^3$. However, at these low exposure levels, i.e. less than 30 mg/m$^3$, some studies have demonstrated a decrease in carotid artery elasticity.

Carbon disulphide exposure also leads to elevated serum cholesterol levels and blood pressure, both recognized as risk factors for cardiovascular disease. While some studies have reported elevated cholesterol levels at estimated exposure levels of $<30$ mg/m$^3$, cholesterol levels were not elevated among workers, where exposures have mainly remained below 3 ppm (10 mg/m$^3$) and also in workers with an average of 20 years of exposure at mean exposure levels of 5 ppm (15 mg/m$^3$).

Carbon disulphide exposure potentiates the effect of noise on hearing loss and induces ophthalmologic effects, including those on colour vision and damage to the blood vessels of the retina.

Cancer has not been well studied in the epidemiological studies on carbon disulphide-exposed worker groups. In the limited studies available, there is no consistent picture of an increase in any specific cancer type. No adequate carcinogenicity studies have been published on carbon disulphide in experimental animals. The database to assess the genotoxicity of carbon disulphide is limited. In bacterial mutagenicity assays, it has been negative, while mammalian cell studies are equivocal. The available limited data on genotoxicity in vivo are generally negative.

While there are several reports of reduced libido and/or impotence in male workers exposed to carbon disulphide in the viscose rayon industry, there is no clear evidence of effects on male fertility or on fetal development. An exploratory study reported an increased frequency of spontaneous abortions among female workers of a company producing rayon fibre; conflicting reports on the study have been published thereafter. In experimental animals, no effect on semen quality has been reported. Fetotoxicity has been clearly demonstrated at dose levels toxic to the mother only, and teratogenicity is seen mostly at dose levels higher than those needed to produce fetotoxicity.

**Metabolism and monitoring**

Carbon disulphide is absorbed by inhalation and via the skin. It is extensively metabolized (Figure 42.24) and
the main metabolites are thiocarbamide, thiothiazolidine-2-carboxylic acid (TTCA), and 2-thio-5-thiazolidine. Analysis of TTCA in urine is an established means for biomonitoring.91,495,496

Management and diagnosis
Carbon disulphide causes serious adverse health effects at occupational exposure limits that are close to, or even below the exposure guideline, 5 ppm (15 mg/m³), adopted in many countries and also recommended in Europe.596 This exposure guideline may well be inappropriate, and may need review and revision. Thus, regular monitoring of occupational exposure is essential to ensure that levels remain well below 5 ppm. Carbon disulphide is absorbed through the skin, and in the viscose industry this may be the main route of exposure. A well-established method for biomonitoring of the exposure to carbon disulphide is the analysis of 2-thiothiazolidine-4-carboxylic acid in urine.

Key points
- Organic substances comprise a multitude of compounds, which contain at least one carbon–carbon bond.
- Limited or no data are available on the human health effects to many organic compounds. The only way to predict possible adverse health effects for such compounds is to extrapolate from data on animals, in vitro systems and other sources. Irrespective of the basic similarity in the response to chemicals between animals and humans, this extrapolation remains uncertain. For end points such as central nervous system toxicity, there are no valid animal models.
- For most chemicals, exposure at work is likely to be much higher than exposure from the environment. Health effects from new chemicals are thus most likely to become apparent among occupationally exposed people.
- At low-level exposures, a major health concern is carcinogenicity. This chapter mainly relies on the authoritative assessments of carcinogenic hazards by the International Agency for Research on Cancer.
- This text, as all texts on chemically induced adverse health effects, only reflects what is known today, and should be reviewed periodically.
- For heavy metals with a long half-life in the body, biological monitoring has long been used successfully in the estimation of body burden and health risk. For organic chemicals, meaningful biological monitoring requires reliable information on the metabolic pathways and kinetics in humans.

ACKNOWLEDGEMENTS
The authors are grateful to Dr Ari Kaukiainen for his valuable comments related to chronic solvent encephalopathy. Ms Pia Anttila is thanked for her help with tables and figures. They thank Mr Mauri Mäkelä for his comments on polycyclic aromatic hydrocarbons. The authors are grateful to Mr Mauri Mäkelä, Dr Kristiina Alanko, Dr Juha Laitinen, Mrs Katri Suuronen and Dr Esko Toppila for providing illustrations for the text.

The editors thank Dr RD Jefferson for his careful review and helpful comments on earlier drafts of this chapter.

Pesticides and other agrochemicals

IAN BROWN, ANNALISA CHIODINI, CHIARA SOMARUGA AND CLAUDIO COLOSIO

INTRODUCTION

Pesticides are chemicals used to control noxious or unwanted living species (‘pests’). In order to be active against living organisms, pesticides must necessarily have some biological activity and, in order to reach their target, they are deliberately released into the environment. Therefore, since their toxicity may not be specific to the target organism, their use can endanger non-target species, including man. Pest control is essential in modern agriculture and it is estimated that, without such control, up to 50 per cent of the total agricultural production might be lost, particularly in tropical climates. Pesticides are widely used, with the highest use rates in tropical countries, where the growing season lasts the whole year, and where agriculture is a major source of income. On a worldwide scale, pesticide usage has doubled every ten years from 1945 to the 1980s, after which a slow-down occurred, due to changes in plant protection strategies and growing concerns for environmental and human health. The highest plant protection product users per capita in the world are the Central American countries, where large landholders favour monocultures or single crops, for example, bananas. In a similar way, pesticides are used in the United States, France and Brazil by cereal, fruit and other produce growers and in countries with a large population but a small land area for the exploitation of intensive cultivation, for example, Japan.

Pesticides are used:

- In public health, e.g. in mosquito control in public areas, or in the disinfection of hospitals. In tropical countries, an important use is in the prevention of vector-borne diseases, with practices such as ‘indoor residual application’; with the periodic treatment of the internal walls and surfaces of tropical and subtropical houses, application on mosquito nets, or the treatment of aircraft. Use in aircraft, especially those flying from tropical countries to areas where vector-borne diseases are not endemic, is to prevent long-range migration of vectors and disease.
- By the public, for example in controlling insects in the domestic environment.
- In several formulations and products to protect materials from biological degradation (e.g. paints, wood and furniture treatment, paper production, leather tanning, photographic industry, and boat production and maintenance). Based on the large-scale use of these compounds, the term ‘plant protection product’ or ‘agrochemical’ refers only to one of the possible uses (agriculture), but it does not adequately describe many other functions that these compounds may have globally.

Bio-pesticides are those derived from natural materials, such as animals, plants, bacteria and some minerals. They fall into three major classes:

1. **Microbial pesticides** which consist of a microorganism (e.g. a bacterium, fungus, virus or protozoan) as the active ingredient. The most widely used microbial pesticides are subspecies and strains of *Bacillus thuringiensis*. 
2. **Plant pesticides** that plants may produce from genetic material that has been added to the genome of the plant (genetic modification or manipulation).

3. **Biochemical pesticides** which are naturally occurring substances that control pests by non-toxic mechanisms. They include substances such as insect sex pheromones that interfere with mating, as well as various scented plant extracts that attract insect pests into traps.

Integrated pest management (IPM) programmes are a series of pest management evaluations, decisions and controls which rely on comprehensive information on the life cycles of pests. IPM is a tiered approach which starts from defining ‘action thresholds’, points at which pest populations or environmental conditions indicate that pest control action must be taken. Once pest control is required and preventive methods are no longer enough, IPM programmes provide for effective, less harmful pest control, from highly targeted chemicals or mechanical control to (if less risky controls are not effective) additional pest control methods including specific pesticides.

With regard to health risks in organic farming, products of biological origin may have different properties from ‘conventional’ agrochemicals, but they cannot be considered ‘risk free’. Pesticides such as natural pyrethrum derivatives or some essential oils are not completely safe, and some pesticides with complex molecules may possess sensitizing properties.

The use of different compounds to control pests is reported in ancient Greek and Roman texts, highlighting that since the beginning of agricultural production, the need for plant protection was important. Seed treatment, fumigation and tree banding were the first practices performed, based on easily available products, such as plant or animal derivatives, and minerals. Examples of these uses are seed treatment with ashes, or macerated pounded roots and leaves of wild cucumber for mildew control, use of soaking lupin flowers as herbicides, the practice of smearing pruning knives with bear’s blood or fat or using fumes from various vegetables, locusts, animal faeces, bones or horns as insect repellents. Among the substances used from antiquity, alum, antimony, arsenical compounds, chalk, cobalt, copper sulphate, sodium sulphate, iron and iron salts, lime, mercury and sulphur derivatives are listed.

In 1874, the first chemical pesticide was synthesized, known properly as 1,1,1-trichloro-2,2-bis[4-chlorophenyl]ethane or the dichlorodiphenyltrichloroethane (DDT), but this compound did not find any commercial use until 1939, when Muller and co-workers discovered its insecticidal properties. After 1939, its production and use grew and DDT found use either in public health, mainly against the Anopheles mosquito in an effort to eradicate malaria, and since 1946, in agriculture for the protection of cotton, deciduous fruits, cereals and potatoes. The effective insecticidal activity, together with low acute toxicity to humans, brought about a continuous increase in the use of DDT, including private indoor use and treatment of human external parasites, such as pediculosis. During the second half of the 1960s, the first concern for the bioaccumulation potential of DDT arose, and the suspicion of possible effects of this on human health resulted in a significant reduction of DDT production and use in the 1970s.

Today, DDT is still authorized for selected use in public health, such as indoor residual application or mosquito net treatment in tropical countries.

Apart from these selected uses in vector-borne disease control, DDT was substituted, from the end of the 1960s, by organophosphorous compounds (OPs), characterized by a highly effective insecticidal activity (cholinesterase inhibition) and by low or absent bioaccumulation and biomagnification characteristics. At the very start of their use, cases of acute poisonings and fatalities attributable to the high toxicity of these compounds were reported. Research thereafter focused on the development of less toxic but equally effective, or more specifically targeted chemicals. This objective was at least partially met with the synthesis of OP compounds that were easily metabolized by carboxylesterase, which is very well represented in mammals, but poorly represented in insects, or the less toxic chlorinesterase inhibitors, such as the carbamates. In 1978, fenvalerate, the first representative of pyrethroids, a chemical class derived from natural pyrethrum, was synthesized. Due to their effective insecticidal activity and low toxicity to mammals, pyrethroids are the most commonly used group of insecticides today.

The examples and the history described above indicate that the major challenge has been the production of highly selective molecules toxic to their target species, but at the same time characterized by low toxicity to non-target species, including humans. The presence of biological activity in products deliberately spread into the environment requires specific risk assessment and management. Tests carried out before a new pesticide is released on to the market (pre-marketing phase) and after its release (post-marketing phase) include an assessment of any unacceptable risk to human or non-target species, and the environment. A safe pesticide management programme is achieved through action at international, national and local level. At the highest strategic level, international agencies and organizations such as the FAO (Food and Agriculture Organization of the United Nations), WHO (World Health Organization), EU (European Union) and OECD (Organisation for Economic Co-operation and Development), produce directives and guidelines for adoption at a national and local level within the existing legislation of a country. The process includes consideration of best practices, health surveillance and training of operators.

**CLASSIFICATION OF PESTICIDES**

The basis for classifying pesticides can be structural (by chemical formula) or functional (by mode of action). Data
The mechanisms for pesticide toxicity

The mechanisms of toxicity for specific classes of pesticides can be discussed according to approximate order of toxicity.

**Insecticides**

Most insecticides with toxicity relevant to humans affect the nervous system. The major groups are as shown in Table 43.2.

**Classification by target organism**

The simplest primary classification is illustrated in Figure 43.1.

**Classification by mode of action**

An alternative classification is by mode of action. A table that identifies the system or organ affected, with subcategories indicating the principal biochemical effect (mode of biochemical action) may be of use in dealing with clinical cases (see Table 43.1). In a case of poisoning, if the pesticide is known, then the major systems or organs affected can be considered and monitored. If the pesticide is unknown, but pesticide poisoning is suspected or on the list of differential diagnosis, then system or organ damage will help identify possible candidate chemical classes which can then be associated with the potential exposure or job, e.g. backpack spraying of an organophosphorus compound.

**THE MECHANISMS FOR PESTICIDE TOXICITY**

The mechanisms of toxicity for specific classes of pesticides can be discussed according to approximate order of toxicity.

**Insecticides**

Although mammals and insects share much in common with regards to their respective nervous systems, there are some very important differences which affect the toxicity of insecticides, for example:

- Insects have non-myelinated nerve fibres.
- Cholinergic (acetylcholine) transmission in insects only occurs in the central nervous system (CNS). In mammals, it occurs in the CNS and many peripheral nerves.
- Carboxylesterase activity is significantly less represented in insects than in mammals.
- Neuromuscular junctions in mammals are cholinergic (in insects, they are glutaminergic if excitatory and GABA-ergic if inhibitory).

The mechanism of neurotoxicity of insecticides is demonstrated in Figure 43.2, which indicates the site of action and biochemical mechanism of neurological disturbance.

The anticholinesterase class of insecticides exert their effect by mimicking the naturally occurring and widely distributed neurotransmitter acetylcholine (ACh). ACh is essential for opening ligand-binding sodium channels and requires two ACh molecules per channel. Within the post-synaptic membrane in junctional clefts, the enzyme acetylcholinesterase is present and this breaks down the ACh to non-active acetic acid and choline. The enzyme is therefore temporarily acetylated (Figure 43.3).

The neurotransmitter binding and cleavage into inactive choline and acetic acid is extremely rapid and one molecule of enzyme will hydrolyze 300,000 molecules of acetylcholine every minute. If an organophosphate is absorbed and finds the active site, then its similarity to ACh will allow it to bind to the esteratic site of the enzyme and phosphorylate (rather than acetylate) the enzyme and the esteratic bond is relatively stable to hydrolysis (Figure 43.4). This is therefore almost a permanent bond with one molecule of enzyme able to hydrolyze only 0.008 molecules of organophosphate per minute.

Carbamates have a similar pathophysiological action as organophosphates, but they compete with the acetylcholine for the enzyme surface and if successful, carbamylation.
occurs. This relationship between enzyme and carbamate substrate is one of electrochemical alignment rather than chemical binding and competitive reversal may occur when the normal substrate ACh is in excess.

The action of anticholinesterase compounds is to allow the normal neurotransmitter, acetylcholine, to accumulate at the active site and cause excessive stimulation of the post-synaptic cells. In the normal course of events, ACh is

The mechanisms for pesticide toxicity

...rapidly destroyed soon after it has been released from the
synaptic cleft and this is usually accomplished by the
strategic localization of acetylcholinesterase (AChE) in
the post-synaptic and pre-synaptic membranes of the neu-
romuscular junctions. Failure to destroy ACh causes
hyperactivity and then depression of activity at the auto-
nomic ganglia, somatic muscles and some CNS neurones.
Organochlorine (OC) insecticides also have specific and
well-documented neurotoxicological effects on the nerv-
ous system. The primary effects appear to be repetitive dis-
charge of neurones, hyper-responsiveness and irritability,
with the nerve membrane remaining in a potentially depo-
larized state and extremely sensitive. (This will lead to
tremors and even convulsions as the physical signs in the
affected species.) The mechanisms postulated at the level
of the neuronal membrane affect the permeability of
potassium ions, reducing potassium transport across
the membrane. The organochlorine DDT also alters the
porosity of sodium channels and causes them to close
more slowly, interfering with repolarization. In addition,
DDT inhibits the enzyme ATPase (which is also critical to
repolarization) and interferes with calcium transport
(Figure 43.5).

Synthetic pyrethrins also have a number of neuro-
toxicological actions that are somewhat similar to the
organochlorines and affect the gating kinetics of sodium
channels. The inward flow of sodium ions (producing the
action potential in cells where the channels are normally
closed at the resting potential) are affected. Pyrethrins affect
both activation (opening) and inactivation (closing)
of the channel resulting in a hyperexcitable state as a conse-
quence of a prolonged negative after-potential and therefore
producing abnormal repetitive discharges (Figure 43.6).

There is also evidence that pyrethrins affect calcium
channels and voltage-sensitive calcium-independent chloride channels, and this would also contribute to the excitability.
Sodium and calcium channels are common in both insects
and mammals and the difference in toxicity between the
species to synthetic pyrethrins is directly related to the
slightly different stereochemistry between mammalian and
insect ion channels (mammalian ion channels are far less
sensitive). Mammals also possess specific enzyme systems
that can rapidly metabolize and detoxify the synthetic
pyrethrins, rendering them harmless.

Herbicides

Herbicides are substances that are designed and selected
to kill plants with different degrees of specificity. As a
general rule, the greater the specificity, the lower the
mammalian toxicity.

The main groups in approximate order of toxicity and
specificity are listed in Table 43.3.

SODIUM CHLORATE

Sodium chlorate is a non-selective herbicide and has
been used as a desiccant. Ingestion causes acute gastroin-
testinal symptoms, methaemoglobinemia and intravas-
cular haemolysis.

BIPYRIDYL HERBICIDES

Bipyridyl herbicides are non-selective and have a toxicological
mechanism of action involving cyclic reduction-oxidation
reactions producing reactive oxygen species, the depletion of
NADPH and the production of lipid peroxidation. Paraquat
and diquat, are examples of bipyridyl herbicides and have
similar mechanisms for toxicity, although paraquat is more
widely used than diquat.

Paraquat is one of the most specific pulmonary toxicants
known and it is a highly polar compound, poorly absorbed
by the gastrointestinal tract. Because of a unique amine/poly-
amine transport system in the alveolar cells, pulmonary
tissue acquires high concentrations of paraquat which, in
turn, undergoes a NADPH-dependent reduction to a free
radical that reacts with molecular oxygen to regenerate the
paraquat cation and the superoxide anion which is converted
into hydrogen peroxide by the enzyme superoxide dismu-
tase. Both O2 and H2O2 free radicals can damage the alveolar
membrane by attacking polyunsaturated lipids. When
ingested, concentrated paraquat can cause either rapid death
from multisystem failure and cardiovascular shock or
delayed death from progressive pulmonary fibrosis (see

under Acute effects, p. 403, and The management of acute pesticide poisoning, p. 409).

Diquat ingestion does not usually cause pulmonary fibrosis, but can produce early onset acute renal failure, although toxic effects are rarely reported.\textsuperscript{11}

**CHLOROPHENOXY COMPOUNDS**

The organic chlorophenoxy acid herbicides are more selective as they are chemical analogues of auxins, a plant growth hormone. There is no equivalent hormone in animals. Chlorophenoxy acids have both agricultural and domestic uses. A number of compounds are included in this group, most notably 2,4-dichlorophenoxyacetic acid (2,4-D), 4-chloro-2-methylphenoxyacetic acid (MCPA), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and mecoprop (MCPP). Chlorophenoxy herbicides are used widely for the control of broadleaved weeds. They exhibit a variety of mechanisms of toxicity including dose-dependent cell membrane damage, disruption of acetyl coenzyme A metabolism and an

---

**Figure 43.2** Typical motor neurone and site of action of neurotoxic insecticides.
The mechanisms for pesticide toxicity

Effect related to their degree of chlorination (uncoupling oxidative phosphorylation). Details are given under Acute effects, p. 403.

Epidemiological studies suggest that an association exists between the manufacture and application of phenoxy herbicides, non-Hodgkin’s lymphomas and soft tissue sarcomas. However, many of the studies have been confounded by an absence of quantitative data on exposure, multiple exposures to other substances and possible contamination of the phenoxy acids with other chemicals during manufacturing, especially highly carcinogenic and teratogenic dioxins (see under Cancer, p. 409).

OTHER HERBICIDES

Substituted anilines, ureas and thioureas are not of high toxicity, but may cause methaemoglobinaemia and interfere with red blood cell survival. Nitriles, such as ioxynil, act by inhibiting or uncoupling oxidative phosphorylation, but are not a major toxic risk to humans. Triazines and triazoles, and the non-cholinesterase inhibiting herbicide organophosphates, e.g. glyphosate, are highly plant specific and of low toxicity to humans.

Fungicides

These are a mixed group of substances that do not easily fit into a toxicological or chemical classification. They are in general of low to moderate acute toxicity to mammals and can vary from simple organic compounds, such as sulphur and copper sulphate, to complex metal-containing derivatives of organic chemicals, such as thiocarbamic acid. Acute toxicity varies from greater than 10 000 mg/kg (oral LD₅₀ in the rat) for substances, such as vinclozolin (a dicarboximide), to around 400 mg/kg for some dithiocarbamates and chlorinated alkenes, and then down to 150 mg/kg for some fungicides with cholinesterase inhibitory effects, such as pyrazophos. This gives a relative toxicity of less than ethyl
Pesticides and other agrochemicals

alcohol at best, down to the toxicity of phenobarbitone at worst.

The toxicological mechanisms have some common characteristics and many act upon the cellular or other supporting structures of the fungus. Others are barrier protectors on the plant cuticular surface or systemically toxic to the developing fungus. The low toxicity of fungicides may appear contradictory to their cytotoxic and mutagenic nature and, although not usually acutely poisonous, almost 90 per cent of all agricultural fungicides are carcinogenic in animal models and are considered to account for more than 50 per cent of the total estimated dietary carcinogenic risk. The withdrawal of more actively toxic fungicides, such as the organomercurials and organotins has considerably improved their safety profile.

Figure 43.5 A recording of the depolarization and repolarization of a normal (untreated) neurone (—) and a DDT-treated neurone (---). Reproduced with permission from Ecobichon DJ. Toxic effects of pesticides. In: Klaassen CD (ed.). Casarett and Doull’s Toxicology. The basic science of poisons, 6th edn. New York: McGraw-Hill, 2001: 763–843.

Rodenticides and molluscicides

Anticoagulant rodenticides are widely and commonly used, and resistance has led to the introduction of the ‘superwarfarins’ which have a much longer duration of action. Their mechanism of toxicity is to inhibit the synthesis of blood clotting factors VII, IX and X, which are dependent on vitamin K.

Molluscicides kill slugs and snails and the most commonly used is metaldehyde. Its toxicity is due to its metabolism to acetaldehyde, but human poisoning is rare, unless significant quantities are ingested (more than 50 mg/kg).
Clinical effects of pesticide toxicity

EPIDEMIOLOGY AND INCIDENCE OF PESTICIDE POISONING

Pesticide poisoning is one of the most common causes of chemical poisoning. Acute poisoning can cause a range of symptoms in adults and children, depending on the type and quantity of pesticide, and can result in death, either rapidly or delayed, depending upon the characteristics of the formulation. Individuals can be exposed to pesticides while working, via food, soil, water or air, or by directly ingesting pesticide products. Pesticides are known to cause millions of acute poisoning cases per year. It has been estimated that 1–3 per cent of agricultural workers in the world suffer in their lifetime from at least one acute pesticide poisoning episode. Among acute intoxications worldwide, no less than one million require hospitalization with deaths amounting to an estimated 300,000 cases annually. Safe storage promotion projects have been identified as a priority in the prevention of serious accidental pesticide poisoning, since poor storage of pesticides and bad management of used containers is an important determinant of risk.

Epidemiological surveillance is an important tool to monitor acute pesticide-related illness and to identify associated risk factors. Some attempts to monitor pesticide-related illness have been undertaken across the globe. In the United States, the National Institute for Occupational Safety and Health (NIOSH), Centre for Disease Control and Prevention (CDC), through the Sentinel Event Notification System for Occupational Risks (SENSOR) programme has provided technical and financial support for state-based surveillance of acute occupational pesticide-related illness and injury since 1987. According to data generated by SENSOR, workers employed in agriculture have been found to have a greater incidence rate of acute occupational pesticide-related illness when compared to non-agricultural workers. Most of the cases (69.7 per cent) were of low severity. Severity was moderate in 29.6 per cent of the cases and high in 0.4 per cent. Insecticides were found to be the causative agent in 49 per cent of all cases.

CLINICAL EFFECTS OF PESTICIDE TOXICITY

Acute effects

Acute effects are described as any effect on the human organism in which symptoms develop rapidly and often subside after the exposure stops, and can be divided into local and systemic. In some cases, acute effects may arise following the storage in the body of large amounts of slowly metabolized compounds. Local acute effects consist mainly of dermal or mucosal injuries, from mild irritation to severe ulceration. Local acute effects are the result of both toxicological properties of the compound and physical/chemical properties of the formulation used and usually consist of damage to the body barriers, such as skin and respiratory tract, the eyes or gastric mucosa. Irritation, corrosion and ulcerative lesions are examples of such effects. Systemic effects consist of organ or system impairment following the absorption of an effective dose.
**Insecticides** can easily affect non-target organisms since they are often non-selective and the target sites and toxicity mechanisms may be similar in all species (see under The mechanisms for pesticide toxicity, p. 397). The target organ of the majority of chemical insecticides presently used is the nervous tissue. Since a certain analogy can be found in the organization and function of the central and peripheral nervous system between insects and humans, insecticides can elicit (following adequate exposure in terms of dose and duration), similar effects in the two species. Generally, insecticides interfere with the membrane transportation of sodium, potassium, calcium or chloride ions.11

Organochlorine insecticides exert their toxicity on the intact reflex arc consisting of a peripheral, afferent (sensory) neurone, inter-neurones and a peripheral, efferent (motor) neurone which in turn innervates a muscle. DDT is known to interfere with potassium, sodium and calcium transport across the neuronal membrane, leading to repetitive discharges in neurones and, consequently, to repetitive tremors, seizures and electrical activity triggered by tactile and auditory stimuli (see Figure 43.5). The clinical picture following organochlorine acute intoxication is characterized by tremors, motor seizures and respiratory failure. Organochlorine pesticides and their metabolites can be measured in blood samples by gas-liquid chromatography within a few days of exposure.

Anticholinesterase insecticides comprise the esters of phosphoric or phosphorothioic acid and those of carbamic acid (carbamates), and share a common mechanism of toxic action: the inhibition of the nervous tissue acetylcholinesterase (AChE), the enzyme responsible for the destruction of the neurotransmitter acetylcholine (see Figures 43.3 and 43.4). This inhibition leads to the accumulation of free ACh at the endings of all cholinergic nerves which results in a prolonged stimulation of electrical activity at:

- muscarinic receptors of the parasympathetic autonomic nervous system, with consequent increased secretions, bronchoconstriction, miosis, gastrointestinal cramps, diarrhoea, micturition and bradycardia;
- nicotinic junctions between nerves and muscles, with tachycardia, hypertension, muscle fasciculation, tremors, muscle weakness and flaccid paralysis;
- the central nervous system, with restlessness, emotional liability, ataxia, lethargy, mental confusion, memory loss, convulsions and coma.

Increased pulmonary secretions and respiratory failure are the usual causes of death from organophosphorus poisoning and recovery depends on regeneration of the enzyme within the critical tissues. The phosphorylation of AChE is irreversible in the case of the esters of phosphoric or phosphorothioic acid (organophosphorus compounds) and temporary for the derivatives of carbamates, leading to a wide ranging clinical picture in terms of seriousness and signs of the illness and the risk to life. The carbamyl–acetylcholinesterase combination dissociates more readily than the phosphoryl–acetylcholinesterase complex produced by organophosphorus compounds. Thus, carbamate poisoning tends to be of shorter duration and less serious. Most clinical manifestations of acute organophosphorus poisoning are resolved within days or weeks, although some symptoms, especially those of neuropsychological nature, can persist for months or longer.11,14

A second phase of organophosphorus insecticide poisoning is termed the ‘intermediate syndrome’, a paralytic condition consisting of neurological signs which appear 24–96 hours after the acute cholinergic crisis. Major effects are muscle weakness primarily affecting muscles innervated by cranial nerves, as well as those of the limbs. This is a life-threatening condition due to the unresponsiveness of the respiratory depression to atropine or oximes.15 A third phase termed ‘delayed neuropathy’ (also termed ‘organophosphorus pesticide-induced delayed polyneuropathy’) is caused by some, but not all OPs, and is characterized by initial flaccidity (second motor neurone syndrome), followed in some cases by spasticity, hypertonicity, hyperreflexia and clonus indicative of a damage to the pyramidal tract. At a pathological level, the delayed neuropathy is accompanied by a Wallerian ‘dying-back’ degeneration of large diameter axons. Biochemical studies have demonstrated an inhibition of the neuropathic target esterase, a neuronal non-specific carboxylesterase, which is involved in the lipid metabolism of neurones.16,17 The time scale for the acute and more chronic effects is shown in Figure 43.7, and greater detail is given about the ‘chronic syndrome’ and ‘dippers’ flu’ under Chronic and long-term effects, p. 406.

**Figure 43.7** The spectrum of human response to organophosphorus chemicals.
Pyrethroids represent a group of widely used pesticides, obtained from chemical synthesis, but similar to the natural pyrethrum, a complex chemical mixture found in some species of chrysanthemum flowers, while the compounds obtained through extraction from a vegetable matrix are called pyrethrins. Pyrethroids and pyrethrins are similar from a toxicological point of view; in particular, they impair ion transport through the membrane of nerve axons, causing a rapid uncoordinated hyperactivity and then muscular paralysis in the insect, through an effect on sodium channels (see Figure 43.6). Systemic non-target species toxicity is limited because of low dermal and gastrointestinal absorption and their rapid degradation by mammalian liver enzymes and urinary excretion. Therefore, they usually do not cause any severe acute effect in humans, even after relatively high exposure. The main symptom observed is skin paraesthesia involving the face, hands or arms (without inflammatory signs), caused by the contact of the active ingredient with dermal nerve endings and consequent hyperstimulation. A further sign of exposure is the so-called 'upper respiratory tract sensory irritation', similar in mechanism of action to paraesthesia, but involving the mucosa.18,19

HERBICIDES

Chlorophenoxy herbicides are largely excreted unchanged in urine. They have long plasma half-lives of up to 220 hours in humans. The acute toxicity of the phenoxy acids is moderate to low and large doses are required to produce major toxic effects, which include alterations in consciousness, muscle fasciculation, vomiting and convulsions, all of which may be associated with a metabolic acidosis.

After acute exposure to lethal doses of paraquat, mortality is delayed by at least two days, although may take much longer. Damage is initially to the alveolar epithelial cells and progresses to the loss of large areas of alveolar epithelium followed by oedema, inflammatory infiltration and fibrosis which rapidly leads to death due to anoxia. Paraquat is by far the most toxic bipyridyl and is a non-specific herbicide that has caused worldwide accidental and suicidal deaths since its introduction as a pesticide in 1962. Once absorbed, paraquat accumulates in the lung and kidney and it is these two organs that are the most susceptible to injury. The major toxicological concern is the acute localized effects, particularly in the lung and more specifically the affect on type 1 and type 2 alveolar epithelial cells and Clara cells. This specific toxicity is due to at least three biochemical mechanisms involving redox recycling, the formation of free radicals and eventually cell death. Poisoning can take place by ingestion, inhalation or dermal exposure. Following ingestion, an early clinical feature is vomiting, accompanied by abdominal pain, diarrhoea and, occasionally, gastrointestinal haemorrhage. Gastrointestinal fluid loss can lead to severe hypotension with cardiogenic shock and multiorgan failure. Hypotension can also result from direct myocardial toxicity, demonstrated by ECG changes such as T-wave flattening or inversion and QT interval prolongation. Neurotoxic features include coma, hypertonia, hyper-reflexia, ataxia, nystagmus, miosis, hallucinations, convulsions, fasciculation and paralysis. Respiratory failure can develop because of hyperventilation, usually in association with central nervous system depression, or because of myopathic symptoms including respiratory muscle weakness. Clinical signs include loss of tendon reflexes and myotonia, together with increased creatine kinase activity. Other clinical features are metabolic acidosis, rhabdomyolysis, renal failure, increased amino-transferase activity, pyrexia and hyperventilation. Dermal or inhalation exposure to 2,4-dichlorophenoxyacetic acid occasionally leads to systemic features, but no fatalities have ever been reported. Substantial dermal exposure has been reported to cause mild gastrointestinal irritation after a latent period followed by a progressive mixed sensorimotor peripheral neuropathy.11,20

FUNGICIDES

Pentachlorophenol (PCP), a very toxic, but nowadays rarely used fungicide, is readily absorbed by ingestion and inhalation in humans, but is less well absorbed by dermal contact. Its systemic distribution is limited, its metabolism extensive and it is slowly excreted. Severe exposure by any route may result in an acute and occasionally fatal illness caused by the uncoupling of oxidative phosphorylation. Tachycardia, tachypnoea, sweating, altered consciousness, hyperthermia and convulsions are the most notable features. Pulmonary oedema, intravascular haemolysis, pancreatitis, jaundice and acute renal failure have been reported. Survivors often display dermal irritation and exfoliation, irritation of the upper respiratory tract and possible impairment of autonomic function and circulation.21 Apart from the 'historical example' of PCP poisoning, modern fungicides are, as a general rule, less toxic than insecticides and their acute toxicity to human beings is non-specific.

RODENTICIDES

Rodenticides comprise a diverse range of chemical structures with a variety of mechanisms of action. Although most rodenticides are formulated in baits that are unpalatable to humans, several rodenticide intoxications are registered each year. Among rodenticides, anticoagulants derived from coumadin are listed. Their toxicity is exerted through the antagonism of vitamin K in the synthesis of clotting factors (factors II, VII, IX and X). The emergence of warfarin-resistant strains of rats led to the introduction of a new group of anticoagulant rodenticides variously referred to as 'superwarfarins', which are very long acting. This group includes the second-generation 4-hydroxycoumarins: brodifacoum, bromadiolone, difenacoum, flocoumafen, and the indanedione derivatives chlorophacinone and diphenacoum. Over 95 per cent of all rodenticides used in United States consist of superwarfarin, and brodifacoum is the
most commonly used substance. Since the introduction of superwarfarins, a number of cases of ingestion resulting in coagulopathy have been reported, usually with minor outcomes, rapidly resolved and with no residual disability. Moderate outcomes (defined as more pronounced signs and symptoms of exposure with some form of treatment required), but no residual disability present or major outcomes (life-threatening event, resultant disability or death) have been reported. This is especially so with a prolonged coagulopathy due to the superwarfarin brodifacoum. The anticoagulant effect appears from eight to 12 hours after the ingestion, according to the half-lives of the various clotting factors. Following consumption over a period of days, bleeding of the gingival membranes and nose occurs, with haematomas at the knee and elbow joints. Gastrointestinal bleeding with spontaneous haemoperitoneum, haematuria and cerebrovascular accidents can also occur. Patients may remain anticoagulated for several days (warfarin) or days, weeks or months (longer-acting anticoagulants), after ingestion of large quantities.11,22,23

Chronic and long-term effects

The term ‘chronic toxic effects’, usually means effects as a consequence of prolonged exposure to toxic substances, at doses lower than those able to cause acute effects, or effects characterized by a prolonged latency, after exposure periods not necessarily prolonged, such as the appearance of tumours (‘long-term effects’). A typical property of chronic effects is their slow development over time, and their persistence after the end of the exposure. Long-term pesticide exposure might affect farmers, professional pesticide applicators, and, to a lesser extent, the general population, exposed to pesticide residues via the environment, food and water consumption.

The causal attribution of such effects is complicated because of temporal considerations. For chronic and long-term effects, the identification of subjects who might have been chronically exposed to pesticides at the workplace is relatively easy, but the identification of the compound and source of exposure is less easy, because of the time elapsed since exposure and the exposure of agricultural workers to several different chemical substances over their working lifetime. Therefore, the identification of a single substance, or group of substances, to which the effects might be attributed, is difficult with poor historical exposure data and because most people are exposed to low doses of pesticide mixtures where delayed health effects are difficult to link to specific past exposures. Exposure assessment is therefore a crucial process in studying these associations, but the collection of historical exposure data is a complicated and often uncertain task.

The chronic and long-term effects that have been variably attributed to pesticide exposure are carcinogenesis, neurotoxicity (including behavioural impairment), immunotoxicity, reproductive effects and endocrine disruption. A summary of the existing evidence for these health outcomes is provided in the following paragraphs.

As a general rule, the epidemiological evidence suggests that agricultural workers experience a lower overall mortality rate with respect to the general population with a lower incidence of some specific causes of death, such as respiratory, cardiovascular diseases and tumours.24–27 These findings are reasonably attributable to a healthier lifestyle and to the lower tobacco consumption of this employment sector.27 However, pesticide exposure may also be associated with specific diseases. In particular, some pesticides may cause allergic or irritant dermatitis and, in some cases, the same compound may cause both of these problems.28 The effects might also be attributable to co-formulants, instead of the active ingredients themselves, e.g. the solvents often present in the plant protection product. Irritant effects may also affect the respiratory tract and eye mucus membrane, which can be avoided by the use of personal protective equipment. The liver may be a target of the toxic effects of pesticides, but severe damage is now mainly a historical finding, with liver cirrhosis described in workers exposed to arsenical compounds in France in the 1940s and 1950s, or metabolic disturbances, such as diabetes observed in subjects heavily exposed to organochlorine compounds, such as DDT, hexachlorobenzene and lindane.29 Inorganic metallic compounds and some solvents used as co-formulants may also affect the kidney. The respiratory tract may suffer non-specific irritant effects due to chronic exposure to some pesticides, and more unusually vineyard workers exposed to a mixture of calcium hydride and copper sulphate (Bordeaux mixture) develop an uncommon pulmonary granulomatosis also known as ‘vineyard sprayer’s lung’.30 The reproductive system may be a target of pesticide effects and a historical example is represented by the cases of reduction in spermatoocyte count, up to complete azoospermia, observed in workers exposed to the nematocide, dibromochloropropane (DBCP) which led to its ban in the United States.31 Ethylene dibromide can also affect fertility by reducing semen quality (decreased sperm count, increase of percentage of morphologic abnormalities).32,33 The effect is usually reversible after 12 to 18 months following the end of the exposure, but in the most severe cases permanent sterility has been observed. More recently, concerns have been focused on less direct effects, such as an alteration in the rate of male to female births, possibly as a consequence of a disturbance to the endocrine system.

The immune system

There is evidence that pesticides may cause direct immunotoxicity in exposed workers. Pesticides may affect the immune system by a variety of mechanisms of action, causing structural and functional alterations possibly resulting in decreased immunity, as well as an increase in immune response.34 The immunotoxicological effects of xenobiotics include histopathological changes in immune tissues and organs, cellular pathology, altered maturation of
exposed agricultural workers. However, apart from some evidence that neurological symptoms and changes in neurobehavioural performance, reflecting cognitive and psychomotor dysfunction,40,41 Most of the studies available suffer major limitations due to the different methodologies applied by the researchers, and to the possibility of bias related to significant differences in education between the exposed and the control population. There is good evidence that neurobehavioural impairment can be the consequence of a severe acute poisoning, with brain injury, but this may not be a specific toxic effect as similar impairments have been observed in subjects with evidence of other types of brain injury, including traumatic events and carbon monoxide poisoning.40 Studies conducted on subjects chronically exposed to OPs, but never acutely poisoned, do not provide evidence of neurological impairment, but data suggest that neurobehavioural impairment can be observed in workers heavily exposed to OPs such as, for example, sheep dippers.40 Major limitations for the interpretation of the existing data are demonstrated by the difficulties in the comparison of the single studies, the limited knowledge of exposure levels, and the absence of a study protocol validated and accepted by most of the researchers. In conclusion, the only fully described effect on the peripheral nervous system is the OP-induced 'delayed neuropathy', which is a sequelae of acute poisoning, rather than a long-term or chronic effect (see under Acute effects, p. 403). As for other pesticides, some limited data suggest that chronic exposure to DDT and fumigants might be associated with a change in neurobehavioural functioning and increase in psychiatric symptoms, but this is inconclusive.41

Greater detail on the organophosphate-induced 'chronic syndrome' and 'dippers’ flu' is given below.

The chronic syndrome and sheep dippers’ flu

The clinical effects of acute exposure to OPs has been thoroughly investigated and documented with thousands of animal studies and reports of human poisoning. The pathophysiology of these acute effects is well understood. The possibility of more long-term effects, where there are no measurable cholinergic signs is less well understood and remains controversial. An extensive review of the literature was undertaken in 1997 and 1998 by the European Centre of Ecotoxicology and Toxicity of Chemicals.42,43 This review investigates published work and other studies on the long-term effects of OP exposure in humans, discriminating between the chronic effects of acute exposure or repeated acute exposure with the dose being large enough to produce clinical signs and symptoms and the effects of chronic low level, apparently asymptomatic exposure. The report concludes the evidence at that time (1998) for chronic effects arising from low level exposure to be insufficient. The report goes on to state that there is no pharmacokinetic evidence for cumulative effects of chronic exposure to OPs at levels which are not acutely toxic and sensitivity even starts to decrease because of the development of tolerance. The authors also state that the insufficient evidence in the epidemiological literature for the description of a ‘chronic syndrome’ resulting from chronic, apparently asymptomatic OP exposure. The task force did recommend that further epidemiological studies should be undertaken. A further report was published in November 1998 by the Royal College of Physicians and Royal College of Psychiatrists.44 This was the result of the findings of a working party on OP sheep dip exposure with a widely

THE NERVOUS SYSTEM

Apart from the well-described, pesticide-induced acute neurological effects (insecticides, especially OPs and carbamates), a small body of evidence is available suggesting that chronic exposure to some neurotoxic compounds may be responsible for the development of neurological disorders, affecting the central and/or peripheral nervous system (parkinsonism, neurobehavioural changes, suicidal ideation or behaviour). In particular, some studies conducted on (pesticide) exposed workers show only minor changes in some cell populations or in the blood concentration of mediators, without any sign of overt disease. Even though some doubt remains on the significance of these changes, it is evident that direct pesticide immunotoxicity in low-dose chronic exposure conditions, if present at all, is very low or undetectable.
They also state that consideration should be given to setting thought, should be managed vigorously in the usual way. Such as depression, fatigue, sleep disorders and suicidal therapy has been found to be useful and specific symptoms, and management goals. Cognitive-behavioural therapeutic alliance with the patient and agreeing specific treatment and management goals. Eclectic and pragmatic approach to the management of OPs. Physicians and Psychiatrists, recommend an open-minded,.info/rcp.php), the joint report of the Royal College of Physicians and Psychiatricians, recommend an open-minded, drawing membership to hear evidence from sufferers, from those representing them, and from experts in the field. They concluded that the symptoms and distress were quite genuine and in some cases very long-standing. The report goes on to suggest that OP-exposed populations have shown subtle cognitive changes, perhaps suggesting that OPs may underlie some of the symptoms or perhaps that there are co-morbidities, such as severe anxiety or depression, that have been intuitively attributed by the sufferers to OP exposure. The report does though, make the point that the severity of the symptoms and the consequent disturbance to family life and work, make it essential to provide an adequate level of clinical care for those who experience symptoms following OP sheep dip exposure and existing clinical services do not appear to provide satisfactory management of the cases in the UK. The report recommended that the exposed patient with symptoms required particularly sympathetic handling with the symptoms and signs treated seriously and at face value. They also suggested that over-investigation is not recommended, as many of the patients have been found not to have abnormalities on specialized testing. More recently (2007), an extensive questionnaire-based survey on acute symptoms following work with pesticides was undertaken by Solomon et al. They analysed 10,765 responders in three rural areas of England and Wales. They were particularly interested in the occurrence of flu-like symptoms following the use of sheep dip, although the study did not specify the nature of the chemical in the dipping solutions. They concluded that flu-like symptoms did not cluster unusually among the users of sheep dip and that acute symptoms were common following work with pesticides, but in many cases the illness may have arisen through psychological rather than toxic mechanisms. There is still considerable ongoing work on the aetiology and susceptibility of individuals to ‘dippers’ flu’, but the present evidence does not appear to support this reported disorder as a specific syndrome and its relationship to organophosphate chemical exposure remains uncertain.

Evidence describing long-term neuropsychological or neuropsychiatric effects in humans following low-dose chronic exposure appears contradictory and relatively recent expert reviews conclude that the evidence does not support the existence of clinically significant neuropsychological effects, neuropsychiatric abnormalities or peripheral nerve dysfunction.

Despite a 2004 summary of their 1998 report and consideration of more recent concerns about OPs (www.opin.info/rcp.php), the joint report of the Royal College of Physicians and Psychiatrists, recommend an open-minded, eclectic and pragmatic approach to the management of OP-related illness. This would include establishing a therapeutic alliance with the patient and agreeing specific treatment and management goals. Cognitive-behavioural therapy has been found to be useful and specific symptoms, such as depression, fatigue, sleep disorders and suicidal thoughts, should be managed vigorously in the usual way. They also state that consideration should be given to setting up specialist centres in appropriate areas to complement existing clinical services.

Perhaps, most importantly, two themes for research have emerged from the working party’s original deliberations:

1. epidemiological studies aimed at developing a means of quantifying OP sheep dip exposure and relating this to clinical symptoms;
2. prospective trials to assess the efficacy of treatment.

In the United Kingdom, a number of government expert scientific advisory committees are again reassessing the evidence and will, in due course, make further recommendations.

Other neurological disorders

The 30–35 studies exploring the relationship between Parkinson’s disease and pesticide exposures are hardly comparable with different criteria used even for the definition of parkinsonism, and they show major limitations in the assessment of the levels of exposure. The available data suggest that the relationship between pesticide exposure and Parkinson’s disease is therefore weak and there is no evidence of the development of a peripheral neuropathy without a previous history of severe, possibly life-threatening, OP poisoning.

THE ENDOCRINE SYSTEM

Few human data studies are available suggesting a possible effect of some pesticides on the endocrine system. Some organochlorinated compounds, such as DDT (and its metabolites), chlordécone, dicofol, methoxychlor, endosulfan and lindane exert oestrogenic activity, while fungicides, such as vinclozolin and iprodione, may act as anti-androgens. Some triazine herbicides, such as atrazine, may also interfere with oestrogens via indirect pathways.

Menstrual abnormalities, prolonged time-to-pregnancy and miscarriage have been described in some studies of pesticide-exposed women, but firm conclusions could not be drawn because of potential bias, uncertainty on exposure levels, concurrent exposure to a complex mixture of chemicals and other risk factors for miscarriage, such as heavy workload and high temperatures. Due to the vulnerability of mother and fetus during pregnancy, endocrine disruption might potentially alter fetal and neonatal development, with the highest risks during prenatal and early post-natal development. In some studies, pesticide exposure has been associated with defects, such as cleft lip and palate, limb defects, cardiovascular malformations, spina bifida, hydrocephaly, cryptorchidism and hypospadias.

Pentachlorophenol, a rarely used wood preservative, binds to human thyroid binding protein and may directly reduce the thyroxine uptake (T4) into the brain. Ethylene bisdithiocarbamates fungicides exert, at high doses, an inhibitory effect on thyroid hormone synthesis, and other currently used pesticides, including dicofol and bromoxynil,
have, at least in the experimental model, effects on thyroxine binding, as does the restricted dinoseb.\textsuperscript{53} Due to their short environmental persistence and low acute toxicity, ethylenebisdithiocarbamate (EBDCs) fungicides are largely used worldwide.\textsuperscript{24} As a consequence, these compounds are a potential source of fungicide exposure for many agricultural workers. While the low acute toxicity of EBDCs is well known, data on possible effects due to prolonged, low-dose exposure are lacking. In the case of very high exposure to EBDCs, a goitrogenic effect has been observed, attributable to the main metabolite of these compounds, ethylenethiourea (ETU). ETU exerts its effect by the inhibition of the iodine peroxidase enzyme, with an impairment of the synthesis of thyroid hormones, and a consequent feedback activation of thyroid stimulation hormone (TSH) and a goitrogenic effect.

One of the possible outcomes of endocrine disturbance may be cancer, especially in organs strongly dependent on hormonal control (see under Cancer).

**CANCER**

In the context that the risk of cancer is lower than predicted in agricultural workers, some studies have shown an increased risk of certain specific malignancies, in particular leukaemia, myeloma, non-Hodgkin’s lymphomas (NHL), lip, stomach, skin, brain and prostate tumours.\textsuperscript{27} In some cases, the observed excesses might, at least in theory, be attributed to quite specific risk factors, for example, skin and lip tumours and exposure to ultraviolet radiation, or endocrine-mediated tumours and exposure, mainly during fetal life, to endocrine disruptors.\textsuperscript{55} The epidemiology of cancer in agricultural workers is complex and a clear picture of the risk in relation to agricultural exposure is still unavailable.\textsuperscript{56} Apart from the problem of multiple exposures, a further confounding factor is the concurrent exposure of agricultural workers to different non-pesticide risk factors, e.g. zoonotic viruses, solvents, oils and fuels, dusts, paints and welding fumes.\textsuperscript{27}

The mechanisms by which pesticides could contribute to cancer causation vary, and one pesticide may operate by more than one mechanism. These include genotoxic effects (producing direct changes in DNA), promotion, causing fixation and proliferation of abnormal clones, immunotoxic effects, disturbing the body’s normal cancer surveillance mechanisms, and epigenetic effects, causing enhancement or inhibition of specific genes involved in cell proliferation or apoptosis.

In respect of data available on specific compounds, some studies have linked phenoxy acid herbicides, in particular 2,4-D, with NHL.\textsuperscript{57–62} Although phenoxy herbicides and their contaminants, mainly dioxins, are the most consistently NHL-associated chemicals, some investigators have raised carcinogenic and NHL concerns about other pesticides, including lindane (used also in some head and body lice treatments),\textsuperscript{63} carbaryl, chlordane, DDT, diazinon, dichlorvos, malathion, nicotine and toxaphene.\textsuperscript{64} Chlorophenols have also been associated with thyroid cancer.\textsuperscript{65}

Organochlorine exposure has been linked with a variety of gastrointestinal and pancreatic malignancies.\textsuperscript{66,67} The pesticides involved are DDT, chlordane, heptachlor, endrin, aldrin and dieldrin, which are no longer used in developed countries. However, exposure to these compounds may still occur because of their environmental persistence and, in some cases, illegal use. Some studies demonstrate small but significant correlations between prostate cancer and specific jobs involving pesticide exposure.\textsuperscript{68}

The fungicide ethylenebisdithiocarbamate, the main metabolite of which is ethylenethiourea, has also been suspected of possible carcinogenic activity (thyroid neoplasm) but it is now known that the tumours observed in the experimental model (rat) are attributable to a specific metabolic mediated susceptibility of these animals and the existence of a carcinogenic risk to humans, under the usual conditions of exposure, has been excluded.\textsuperscript{69}

Despite the enormous amount of variable work undertaken, the results of positive studies are often contradicted by negative studies, and significant limits and confounders affect the interpretation of the results. It is therefore reasonable to conclude that, apart from the well-known historical carcinogens, e.g. arsenic, there is not at present a convincing body of evidence to show that repeated exposure to pesticides at the workplace causes cancer in humans.

Pesticide carcinogenicity is usually fully evaluated in the experimental model before the formal registration of a compound, and compounds shown to be carcinogenic in animal models do not enter the market. However, the compounds that have been in use for some considerable time may not have been subject to such thorough testing. The International Agency for Research on Cancer (IARC) has evaluated more than 60 active pesticide substances and only a few of them are still in use today (ethylene dibromide in group 1A (carcinogenic in humans) and amitrole and dichlorvos in class 2B (possibly carcinogenic in humans)). The use of the most toxic and carcinogenic compounds (for example, arsenical derivatives) has been forbidden in many countries for many years. Therefore, the present risk is significantly reduced, but due to the long latency period for most occupational cancers, a comprehensive personal history together with accurate exposure data remain of paramount importance for the diagnosis and reporting of suspected tumours and malignancies caused by exposure to pesticides.

**The management of acute pesticide poisoning**

**The general principles of management**

Most pesticide-related diseases have a presentation that is similar to other common medical conditions and display non-specific symptoms and physical signs. Diagnosis of
The treatment of pesticide poisoning

INSECTICIDE POISONING

Organophosphate poisoning

General principles of treatment

Any suspected case of organophosphorus pesticide intoxication must be considered a serious medical emergency and the patient should be hospitalized as soon as possible. Symptoms usually develop within 12 hours and in severe poisoning symptoms occur within four to six hours. However, this may be delayed in highly fat soluble organophosphates, such as fenthion. Blood samples should be taken in order to measure plasma pseudocholinesterase or preferably red blood cell acetylcholinesterase levels. In any remote rural area, it is strongly recommended that health personnel have available specific kits that are able to provide a quick and reliable estimate of the levels of cholinesterase inhibition based on a few drops of blood collected from a finger of the patient (the so-called 'paper test'). The severity of the clinical picture is directly proportional to the level of enzyme inhibition. Symptoms may arise when 50 per cent of cholinesterase activity is inhibited, with the most life-threatening situation occurring at 90 per cent or more enzyme inhibition. An excellent guide is provided by the Health and Safety Executive Laboratories in the United Kingdom and this can be found in the Appendix.

In addition to support of vital functions, specific therapeutic pharmacological agents should be used. Intravenous, intramuscular or endotracheal atropine sulphate is used to counter the effects of excessive concentrations of acetylcholine at the muscarinic nerve endings in target organs. Atropinization should be maintained through repeated doses according to clinical status and AChE levels. The administration of an oxime, usually pralidoxime chloride (2-PAM chloride), a highly specific antidote, is effective in reactivation of acetylcholinesterase when administered within 48 hours. However, pralidoxime is far less effective if used later when the phosphorylation of the enzyme is strengthened by the loss of one organophosphate alkyl group, a phenomenon known as 'ageing'.

Blood pressure should also be monitored during treatment because of the occasional occurrence of a hypertensive crisis. Favourable prognostic signs are the reversal of muscarinic symptoms and signs and the improvement of respiratory function and blood oxygenation. In organophosphate poisoning, treatment with activated charcoal is of little benefit because of the rapid absorption of the pesticide into the bloodstream. Management of a moderate to severe poisoning case (50–90 per cent cholinesterase inhibition), is best undertaken in an intensive care unit as mortality from severe poisoning is around 10 per cent and prompt skilled management will improve outcomes.71

Specific clinical detail

The effects of organophosphates on human physiology are complex, but inhibitions of esterases, particularly acetylcholinesterase is the most clinically important and leads to a collection of symptoms known as the 'acute cholinergic crisis'. This will be a mixture of muscarinic and nicotinic receptor responses, initially stimulation and then blockade. The balance depends upon the particular organophosphate and its absorption and activation characteristics, but muscarinic responses are essentially 'secretory and excretory' and are a mixture of diarrhoea, bronchorrhea, urinary frequency, emesis, lacrimation and salivation, together with...
meiosis, bradycardia, bronchoconstriction, hypertension and possibly cardiac arrhythmia. These can be treated symptomatically and may not be life-threatening; although very severe bronchorrhoea can occur with some organophosphates, such as chlorpyrifos. Nicotinic responses are primarily neuromuscular, initially with fasciculation and then muscle weakness that may progress to paralysis and life-threatening respiratory failure. Mydriasis, tachycardia and hypertension may also paradoxically occur depending upon the balance of muscarinic to nicotinic responses.

Central nervous system responses always accompany this constellation of symptoms and signs and can be quite non-specific, for example anxiety, but severe poisoning will cause altered levels of consciousness and convulsions and will contribute to the respiratory distress. Respiratory embarrassment and even failure may reoccur after the acute cholinergic crisis and this is known as the ‘intermediate syndrome’. This occurs some 24–96 hours after the primary symptoms and the patient may well be starting to recover. A useful early sign of the intermediate syndrome is weakness of the neck flexors and cranial nerve palsies and this ‘secondary’ or type 2 paralysis usually lasts from five to 18 days and recovers spontaneously if the patient is supported. The cause is postulated to be later dysfunction of the nicotinic receptors situated at the neuromuscular junction.

The use of antidotes in acute organophosphate poisoning

Antidotes in the treatment of any poisoning are the exception rather than the rule and decontamination and support of vital functions remain the cornerstone of preliminary clinical responsibilities. Organophosphate poisoning is, however, exceptional and there are three broad classes that are used as specific antidotes:

1. Muscarinic antagonists. Atropine is the most commonly used agent and the dose is carefully titrated to reverse the muscarinic effects. This will reduce bronchorrhoea and increase the heart rate (which is a good measure of atropinzation and should be kept at more than 80 beats per minute). The dose is much larger than that used in other therapeutic indications and in adults may be 1–3 mg initially by an intravenous route (0.02 mg/kg in children). Atropine will have no effect on the neuromuscular junction or on muscle weakness and therefore breathing will still be compromised.

2. Oximes. These are administered as an infusion and will facilitate dephosphorylation of the acetylcholinesterase enzyme, thereby restoring the catalytic site. This is only possible before ‘ageing’ of the enzyme–organophosphate complex and therefore early use is recommended in a confirmed case and the infusion should be continued until recovery. With praladoxime chloride, (2-PAM chloride), a loading dose of 30 mg/kg is given intravenously over 20 minutes followed by an infusion 8 mg/kg per hour.

3. Benzodiazepines. These agents will control some of the central nervous system effects, especially agitation and seizures. Most benzodiazepines are suitable and should be administered by an intravenous route. Diazepam is the most commonly given, at a starting dose of 0.05–0.03 mg/kg.

For greater practical detail on managing organophosphate poisoning, the authors strongly recommend the clinical review by Roberts and Aaron published in the British Medical Journal in March 2007. This has a particularly useful ‘decision tree’ which compares the treatment of minor toxicity with major toxicity.

Carbamate poisoning

Carbamates very rarely cause life-threatening events, even with attempted suicide. In occupational poisoning, symptomatic treatment and fluid balance support is usually all that is required to manage the patient. A prompt differential diagnosis from OP poisoning is essential since symptoms are similar, but the use of pralidoxime is not recommended. Early management of the more severe cases relies on the early stabilization of the patient and the titrated administration of atropine to treat muscarinic symptoms. Assisted ventilation may rarely be required.

Organochlorine poisoning

Treatment involves supportive care and avoiding exogenous sympathomimetic agents, since organochlorine pesticides are toxic to the central nervous system and sensitize the myocardium to catecholamines. Apart from decontamination and general supportive measures, diazepam and petharbione are used to control irritability and seizures.

Pyrethrum and pyrethroid poisoning

Apart from the allergic reactions observed as a consequence of exposure to natural pyrethrum compounds contaminated by allergens (such as resins), acute occupational or intentional poisoning from these compounds are only very seldom observed and, never so severe as to become a life-threatening event.

HERBICIDE POISONING

Paraquat and diquat (bipyridyl compounds)

Paraquat is poorly absorbed from the gastrointestinal tract and the skin, and if its absorption can be prevented death may be avoided. Speed of interventional therapeutic action is therefore very important. Treatments have therefore focused on the prevent of absorption, removal of the chemical from the bloodstream by haemodialysis or haemoperfusion, prevention of its accumulation in the lung, the use of free-radical scavengers and the prevention of lung fibrosis. In practice, only the prevention of absorption by emesis or purgation of the gastrointestinal tract has been found to be effective. To avoid accidental ingestion, the manufacturers have added a blue pigment, a stenching compound
and an emetic substance to the formulation and this has been effective in reducing morbidity and mortality. A dose of 20–30 mg/kg of paraquat can cause mild poisoning, while 40–50 mg/kg can cause delayed development of pulmonary fibrosis, which can be lethal. Higher doses usually cause death within a few days due to pulmonary oedema and renal and hepatic failure. Levels can be monitored by measuring the unchanged chemical in the urine.

The similar herbicide diquat is different toxicologically and does not accumulate in the lungs. On chronic exposure, the target organs for toxicity are the gastrointestinal tract, the kidney and in particular the eye. Diquat has been found to cause cataracts in mammals by a free-radical mechanism. Acute clinical symptoms include nausea, vomiting and diarrhoea, ulceration of the mouth and oesophagus, decline in renal function and neurological effects. There have been very few cases of human intoxication with diquat and the treatment remains the prevention of absorption and enhancing elimination, as with paraquat.74

**Chlorate**

Poisoning following ingestion of chlorate salts is characterized by methaemoglobinaemia (MetHb), haemolysis, disseminated intravascular coagulation and renal failure. The clinical features include nausea, vomiting, diarrhoea, cyanosis and dyspnoea. Very few data are available regarding the pathophysiology and specific effective treatment of sodium chlorate poisoning. Chlorate salts, which are powerful oxidizing agents, induce the formation of methaemoglobin from the oxidation of the ferrous ion in haemoglobin to the ferric state. Methylene blue, an effective reducing agent, is unfortunately unable to ‘reduce’ methaemoglobin from chlorate salts because of the concomitant denaturation of glucose-6-phosphate dehydrogenase caused by the chlorate per se. In severe poisonings, haemodialysis is recommended.10

**Chlorophenoxy herbicides**

In the absence of a specific antidote for chlorophenoxy herbicides, urinary alkalinization is the treatment of choice in promoting elimination. Alkalinization increases urinary flow and will dilute the concentration of chlorophenoxy herbicide in the glomerular filtrate which also decreases the rate of passive reabsorption (often termed ‘forced diuresis’).75

**Glyphosate-containing herbicides**

The mechanisms of toxicity of glyphosate formulations are complicated since it has at least five different salts and commercial formulations contain a number of different surfactants. Human poisoning usually follows exposure to a variable mixture where the toxicity of the surfactant polyoxyethyleneamine (POEA) contributes more to the toxicity than glyphosate alone. Accidental ingestion of glyphosate formulations is generally associated with only mild, transient, gastrointestinal effects, although there is a reasonable correlation between the amount ingested and the likelihood of serious systemic sequelae or death. Advancing age is associated with a less favourable prognosis and corrosion of the gastrointestinal tract has been observed. Renal and hepatic impairment are also frequent findings in significantly large absorbed doses and usually reflect reduced organ perfusion. Respiratory distress, impaired consciousness, pulmonary oedema with infiltration shown on the chest radiograph, shock, arrhythmias, renal failure (requiring haemodialysis), metabolic acidosis and hyperkalaemia may all occur in severe cases. Bradycardia and ventricular arrhythmias are often present in the preterminal phase. Management is symptomatic and supportive.11

**Triazine herbicides**

Severe poisonings have rarely been observed and over-exposure has resulted mainly from accidental or suicidal ingestion. In these cases, administration of activated charcoal is recommended.

**RODENTICIDES**

With aluminium phosphide poisoning, no antidote is available and many patients die despite intensive care and supportive measures are all that can be offered.76 Some studies suggest a beneficial effect of magnesium sulphate, but available data are not sufficiently robust to recommend this treatment in standard treatment protocols.

In anticoagulant rodenticide poisoning, the international normalized ratio (INR) should be measured 36–48 hours post-exposure. If the INR is normal at this time, no further action is required. If active bleeding occurs, prothrombin complex concentrate, recombinant activated factor VII or fresh frozen plasma and phytomenadione i.v. should be given.

**MOLLUSCIDES**

Although some cases of acute metaldehyde poisoning have been reported, the occurrence of severe poisonings is very uncommon. Supportive measures are all that is required (correction of acid-base balance, ventilatory support, correction of haemodynamic instability and anticonvulsant therapy, when appropriate).77

**THE MONITORING OF EXPOSURE**

**Operator exposure**

Risk assessment for exposure to pesticides in occupational settings starts with the definition of the hazard, as for any other chemical. Labelling the pesticide provides useful information about intrinsic toxicity and possible effects due to acute and chronic exposure. The next concern is operator exposure which has to be defined in both qualitative and quantitative terms, so that it can be compared with the acceptable operator exposure level, when available, or with any other appropriate occupational exposure limit (OEL).
Several factors can affect pesticide exposure in agricultural settings. With the same applied dose, wide ranges of pesticide exposure levels can be measured depending on weather conditions, machinery, personal protection equipment and operators’ tasks and skills. In addition, since agricultural activities are performed outdoors and with typical seasonal variability, exposure levels show a significant variability over time. It is therefore often difficult to perform representative environmental monitoring. Thus, more than in any other occupational setting, exposure assessment has to be tailored to the worker.

As a general rule, exposure to pesticides in agriculture – especially in open field crops – is almost exclusively dermal. Dermal exposure occurs in part from direct physical contact with the pesticide and in part from cross-contamination of surfaces and work instruments. Respiratory exposure is minimal and does not significantly affect the overall operator’s contamination.78

Operator exposure can be estimated by the measurement of the total amount of pesticide that can be found on patches applied on the surface of various parts of the body. The US Environmental Protection Agency (EPA) sets out in detail how dermal exposure assessment is to be performed.79 Personal air sampling and environmental monitoring can also be applied when inhalation can contribute to the overall exposure, such as in greenhouse work and in pesticide production factories. Pesticide exposure can be significantly reduced through the prudent use of personal protection equipment (PPE). Due to the previously described characteristics of agricultural work, dermal protection is in general more important than respiratory protection. Overalls and gloves are essential personal protection devices, taking into account the covered body surface (see Table 43.4) and the relative importance of different body areas in dermal contamination. Also, the wearing of protective boots has been shown to significantly reduce dermal exposure.80

There is a continuity of exposure to the human population from manufacturing of the active product to possible residues in the treated crop or environment where spraying or distribution has taken place. The biological effect on a human population increases in an exponential fashion if plotted against the log of the dosage in milligrams per kilogram of body weight and can be illustrated as shown in Figure 43.8.

Acute symptomatic poisoning may occur at dosage levels hundreds if not thousands of times greater than exposure to the general population in food, air and water, but occupational exposure is on the upward slope and can end in an acute poisoning if poor systems of work practice are adopted (e.g. failure of enclosure of process, poor separation of employees and inadequate personal protective equipment).

Pesticide use in agriculture runs through three major phases: mixing and loading, application and re-entry. Pesticide exposure during mixing and loading contributes to less than 10 per cent of the total exposure.81 A more practical approach to workplace exposure is illustrated in Figure 43.9, which follows the manufactured pesticide from the reaction vessel of the manufacturing plant to the end user and end usage, where some residual contamination may remain. This pathway history of the active ingredient pesticide is divided into distinct stages.

Exposure to the active product on the manufacturing plant must always be a safety consideration as the finished product will need to be tested and then dispatched to storage, usually in a holding tank (see stage (1)). It is rare for chemical processes to be completely contained, and worker exposure can occur during product sampling, maintenance, during decanting to bulk storage and packaging into containers for onward distribution (see stages (2) and (3)). Once the concentrate is bottled and packaged, exposure is minimized until the concentrate bottle or container is

opened and decanted into a spray tank for dilution and distribution to the target crop or other environment (see stages (4) and (5)). A thorough review of organophosphate contamination risk in agricultural workers by the Committee on Toxicity of Chemicals in Food, Consumer Products and the Environment\textsuperscript{82} demonstrated that potential exposure was greatest at the concentrate to dilution stage because of splashing and inadequate personal protective equipment and they suggested better pouring and dilution techniques with improved concentrate containers to facilitate this. Sole reliance on following the manufacturer’s instructions and correct PPE may not always give adequate protection. Studies undertaken on manufacturing plants synthesizing the organophosphorus compound chlorpyrifos\textsuperscript{83} revealed statistically significant depressions of the enzyme cholinesterase in apparently well-protected employees.

The total operator’s exposure during application of a pesticide on to the crop can be higher than during
mixing, loading and re-entry, with the most important determinant of a worker’s contamination being the application technique. Backpack sprayers have higher exposure potential compared to tractor applicators. During tractor application, the use of an air-conditioned closed tractor can reduce exposure to negligible levels. Re-entry consists of all manual and/or mechanical activities performed on the crop after pesticide application. In re-entry activities, the skin is the major route of operator exposure and shows a linear correlation with the dislodgeable foliar residue (DFR), which is the amount of pesticide deposited on crop surfaces that is also available for operator contamination. The occurrence of symptoms has been used to monitor exposure to backpack sprayers in some developing countries. This is far from safe or sensible and effectively adds to the pesticide poisoning burden in these countries.

Biological monitoring, intended as the measurement of the dose that has been absorbed in the subject, is potentially the most useful tool for monitoring pesticide exposure of agricultural workers. The route of exposure for most farm workers is dermal and most pesticides in current use are metabolized rapidly, with the metabolites eliminated in urine. Urinary levels of pesticides or their metabolites can be performed with the aim of monitoring the exposure level indirectly.

Biological monitoring has several limitations, such as the difficult choice of the sampling time due to the variability (over time) of the exposure levels, the lack of biological exposure limits or reference values (for most of the compounds used) and poor knowledge of the toxicokinetics of most pesticides in humans. A single exposure is very time dependent, while repeated exposure measurements are more representative of the average with approximation to a steady state for blood or urinary level metabolites. Blood levels are usually more specific as the parent chemical is measured instead of the metabolite, but these are much more time dependent. Collection of 24-hour urine samples are inconvenient with poor compliance by exposed workers. Spot urine samples are more acceptable, but as the urine volume varies, correction factors must be used, the most common being micrograms of pesticide (or metabolite) per gram of creatinine.

Urinary measurements are specific if the parent compound is excreted in the urine unchanged, for example (2,4-dichlorophenoxy)acetic acid and glyphosate. Most organophosphates can be found unchanged in the blood for only very short periods of time and are then rapidly metabolized, often to an even more active intermediate. They may then be subsequently broken down to a specific leaving group and non-specific alkyl phosphates, which are found in the urine, usually well within 24 hours. These are useful tools for assessing exposure, especially at low doses, but this may not be as useful as measuring the biological effect of these chemicals (which is the inhibition of acetylcholinesterase), but this measurement in itself may well be complicated by inter- and intraindividual variability. However, cholinesterase inhibition remains the major clinically important measurement in a suspected case of significant exposure and possible OP poisoning.

Health surveillance is not merely the diagnosis of occupational disease or acute toxic effects. It should be carried out even when exposure is below permitted levels and to monitor the exposure and the safety of the work activity, including the effectiveness of personal protective equipment.

Health surveillance of pesticide workers include:

- a pre-employment medical examination to detect allergies or medical conditions which can be exacerbated by pesticide exposure, and to establish a baseline for comparison in any further evaluation of the worker;
- periodic medical examinations aimed at detecting any early specific adverse health effects attributable to the pesticide exposure;
- a medical examination after prolonged or repeated sickness absence to detect any significant change in health status which may compromise the ability to continue the assigned job, and to ensure that any illness is not pesticide related.

Biological effect monitoring should be considered especially when determination of a specific marker of biological effect is available, such as cholinesterase activity in plasma or red blood cells in pesticide manufacturers or applicators (see Appendix). Other parameters that have been considered as possibilities for biological effect monitoring include cytogenetic analysis of lymphocyte micronuclei and semen quality. Presently, these remain as research procedures which have not been field tested for practicality or applicability. Liver and renal function tests may be indicated depending on the compounds used and the estimated levels of exposure, but abnormal liver function tests often lack specificity.

For determination of inhibition of cholinesterase levels in workers exposed to organophosphates and carbamates, venous blood is taken from the employee at regular intervals after potential exposure. For acute exposures, the samples are best taken immediately after exposure. Sampling towards the end of the day avoids the ‘diurnal variation’ effect. During collection of venous blood samples, precautions should be taken to avoid contamination of the blood by exposure to cholinesterases in the air or on the skin of the donor or sampler. Cholinesterases are also unstable when kept at room temperature for long periods and samples should therefore be stored on ice or frozen prior to analysis.

Levels of red blood cell acetylcholinesterase, plasma cholinesterase or both can be measured. The greater the inhibition of the cholinesterase levels, the greater the extent of absorption of the pesticide. If activity is reduced to 30 per cent or more of the pre-exposure level, the test should be checked immediately, and removal of the individual from further exposure considered. Cholinesterase levels are very variable in the population, and the variability in a single individual can be by as much as ±16 per cent.
with a coefficient of variation between 7.6 and 11.3 per cent.\textsuperscript{86–89} It may be possible to determine normal variation of cholinesterase levels in personnel involved in the manufacture of organophosphate pesticides before they are asked to work with the ingredients or final product. However, it is difficult to implement a system to establish the normal variation in cholinesterase levels for any individual pesticide applicator before he/she is assigned to using organophosphate pesticides. This is especially so for pesticide applicators in developing countries where laboratory and technical support is lacking or limited. In such situations, the emphasis should be on adequate training, safe systems of work, and care in the preparation, use and disposal of pesticides.

THE IMPORTANCE OF TRAINING FOR PESTICIDE OPERATORS

Since pesticides are known to be harmful for human and environmental health when misused, their use in the field should only be undertaken by authorized and trained operators. Operator training and education activities are of paramount importance for the prevention of pesticide exposure, and knowledge of the determinants of pesticide contamination can significantly reduce operator exposure. For example, knowledge and observation of ‘re-entry intervals’ (time which must elapse after pesticide application and before the worker can safely enter and handle the crop without personal protective equipment) are critical in reducing workers’ pesticide exposure. Good training of agricultural workers is also necessary to avoid risk of contamination to the environment, as well as of the food commodities produced.\textsuperscript{89,90}

In many countries, programmes aimed at improving the operator’s safety and skills about pesticide use and application are available. Some authoritative written documents addressed to agricultural workers have been produced, such as the booklet entitled ‘Preventing health risks from the use of pesticides in agriculture’.\textsuperscript{91} These give advice on how health risks can be reduced. Also, the private sector provides communication and instruction tools for the safe use of pesticides. The European Crop Protection Association (ECPA) has launched the ‘Safe Use Initiative’ aimed at reducing workers’ pesticide exposure. Good training of agricultural workers is also necessary to avoid risk of contamination to the environment, as well as of the food commodities produced.\textsuperscript{89,90}

Based on the above considerations, it is evident that training and education represent a fundamental tool in preventing pesticide exposure risk for workers, the general population and the environment. In rural populations, the main providers of health education and training are the local healthcare practitioners, and it is therefore essential that they have adequate training on pesticide risk control.

CONCLUSIONS

The world market and registration of pesticides is very dynamic, and the oldest and most toxic substances are being eliminated or restricted. This will give a new generation of pesticides, probably safer, but toxicologically less well understood. It is essential that the occupational physician keeps properly up to date with this changing situation.

Key points

- Pesticide poisoning is one of the most common causes of chemical poisoning in the world. It has been estimated that 1–3 per cent of all agricultural workers, in their lifetime, suffer at least one acute pesticide poisoning incident. There are also 300 000 pesticide-related deaths every year.
- Pesticides are commonly classified by consideration of their target organism, but may also be described by their mode of action and this usually gives an indication of their structural chemistry and specific toxicity.
- Pesticides and agrochemicals are used throughout the world with the highest use rates in tropical countries. Around ten manufacturing companies produce 90 per cent of the 1000 or so active ingredients. Before an active ingredient can be marketed, it undergoes intensive regulatory testing in respect to its safety, efficacy and environmental impact.
- Insecticides are generally more acutely toxic than herbicides or fungicides and most affect the nervous system of the target species and possibly also humans.
- The more specific and targeted the active chemical is, the less likely it will be toxic to humans.
- Chronic and long-term pesticide affects have been extensively researched and this has been specifically investigated in relation to the immune system, the nervous system, the endocrine system and the development of cancer.
- General supportive measures remain the keystone of treatment in acute pesticide poisoning.
- Acute insecticide poisoning is usually neurological in nature and will often involve an organophosphorus chemical, a carbamate, or more rarely an organochlorine or synthetic pyrethroid.
- Acute herbicide poisoning is rare, except in the case of highly non-specific herbicides, such as paraquat and sodium chlorate.
- Exposure to the acute active chemical of the pesticide is potentially greatest at the
manufacturing plant and thereafter declines exponentially to exceedingly low doses in food, water and the environment.

- Biological and biological effect monitoring of pesticide users is very complex and usually undertaken during field trials of the chemical before formal registration for commercial use. Correct study design is essential for the generation of valid results.

APPENDIX. RECOMMENDED BIOLOGICAL EFFECT MONITORING STRATEGY FOR OCCUPATIONAL EXPOSURE TO ORGANOPHOSPHATES (OPS)

- For routine monitoring, baseline activities of both plasma and erythrocyte enzymes should be established before each exposure season begins, or at least 60 days after the last exposure, then followed by monitoring of the plasma and erythrocyte enzymes at intervals which reflect work activities and likely risk of exposure. Multiple subclinical exposures can lead to cumulative depression of the blood enzymes.
- In cases of acute or suspected poisoning, both plasma and erythrocyte enzymes should be measured. An acute exposure will be obvious in the blood enzymes, if the blood sample is taken within three days of exposure. Detection of subclinical exposures may need the collection of a baseline post-exposure (60 days) and delay between exposure and venepuncture will limit the ability to detect exposure.
- To some extent, after OP inhibition, both blood enzymes undergo spontaneous reactivation to normal or ‘aging’ to an inactive enzyme where activity is only replaced by new enzyme synthesis. The rates of spontaneous reactivation and aging depend on the OP and enzyme. Aged plasma enzyme is replaced with a half-life of six to 12 days compared with the erythrocyte enzyme half-life of about 32 days. Thus, the erythrocyte enzyme may be depressed longer than the plasma enzyme. However, in our experience most OPs preferentially inhibit the plasma enzyme. Thus, the delay between exposure and venepuncture may alter the pattern of inhibition in the two blood enzymes.
- Ideally there should be little delay between exposure and venepuncture so as to minimize the recovery of enzyme activities. It is preferable to keep a blood sample for a couple of days under refrigeration after venepuncture close to the exposure period, rather than delaying venepuncture until the laboratory can receive the sample by post the next day.
- It is important that serial analyses should be performed by an established method in the same laboratory and subject to stringent quality control procedures.

Interpretation of results

With the analytical precision attained in the Health and Safety Laboratory, significant absorption of OPs is indicated if the percentage drop between successive estimations is:

- plasma > 15 per cent;
- erythrocyte > 12 per cent.

Welding

GRANT McMillan

INTRODUCTION

‘Welding’ is a generic term for any of the processes of joining materials at areas or points softened or liquefied by the application of heat derived in a variety of ways. Welding metal is the most ubiquitous of the industrial processes and welders are among the last craftsmen in industrialized and industrializing economies. Several sources of heat are used. These include friction, electron beams, lasers, ultrasound and combustion of fuel gases, but by far the most common source is an electric arc struck between two electrical conductors. Further consideration of the health and safety hazards of welding here will be limited almost entirely to arc welding processes.

Estimates suggest that well over three million workers worldwide use welding to some extent in their work. Welders and the many other individuals who work with them, or in their vicinity, may be exposed to emissions that pose a wide range of potential health hazards. With such large numbers of workers involved, a sound knowledge of welding processes and their emissions is important for controlling the hazards to health.

Over the last decade, specific concerns for the occupational health and safety of welders and related workers have resurfaced yet again. This has been prompted by legislation, research findings, impending legislation on protection from electromagnetic fields and, from the United States, a catalyst for research provided by litigation over assertions that inhaled manganese compounds in fume from very commonly used welding and related processes may exert significant irreversible neurotoxic effects on exposed workers.

The industry’s desire to shake off the ‘dirty and dangerous’ mantle has helped to prevent these new developments totally overshadowing and diverting attention from the need for more to be done about long-recognized hazards and their effects. These include wholly avoidable deaths at work; the damage done daily to hundreds of thousands of workers by ‘minor’ but painful injury accidents related to welding processes; respiratory diseases and the long-term toll of largely avoidable wear and tear of the musculoskeletal system which is one of the main causes of ‘medical wastage’.

In the area of respiratory diseases, the spotlight has widened to highlight not only continuing uncertainty about causal links with chronic obstructive pulmonary disease (COPD), and chronic bronchitis and emphysema (CBE), and the long-standing apparent excess risk welders
have for lung cancer, but also to include the hypothesis that inhaling welding fume may facilitate pneumonic infections.

Making health and safety of welders a naturally integrated part of education, training and good practice at all levels of the workforce and from project conception through to completion, and beyond to maintenance and repair, must be at the heart of moves to make welding less ‘dirty and dangerous’. There is an urgent need to conclude research to clarify the situation regarding hazards such as manganese; for more pro-active measures to recognize, evaluate and control exposure to welding fumes without significant loss of productivity; and to make improvements to the ergonomics of the processes and workplaces. Welders need to be better trained, motivated and equipped to exercise their responsibility to contribute to protecting their own health and that of fellow workers by using their skills, knowledge and common sense to better effect, for example, to reduce exposure to potentially harmful materials by using the ventilation which is provided and keeping their head out of the plume of fume.

**PRINCIPAL WELDING PROCESSES**

A basic understanding of the principal welding processes is necessary to understand and appreciate the source and nature of the emissions and the potential which exists to control them. The main welding and allied processes are arc welding, resistance welding, gas welding, forge welding, brazing and soldering. Prime among these in terms of usage is arc welding, the main topic in this chapter, probably followed by resistance welding. Much information and technical details on these and the range of joining and related processes such as hardfacing, arc air gouging and burning are available at ‘Job Knowledge’ and other sections within the technical information area of the website of TWI World Centre for Material Joining Technology.¹

### Arc welding processes

In arc welding processes, in general terms, the great heat generated by an electric arc struck between the workpiece and an electrode held in a machine or by a manual welder in a handpiece melts abutting edges of the metal to be joined sufficiently for these to contribute molten metal to a common weld pool which, when cool, forms a solid joint. When the workpiece cannot contribute sufficient metal to the pool, metal may be added from a filler wire held in the arc. Alternatively, the filler wire may also conduct the electricity and act as the electrode which is the source of the arc. It is then called a ‘consumable electrode’.

The wire may have a coating or core comprising a mixture of materials which together have properties to facilitate welding and improve the quality of the weld. It is usual for a gas shield to be formed over and around the arc and weld pool creating a bubble-like stable and reproducible micro-environment restricting access of oxygen and other gases, thus minimizing oxidation and other inclusions which could weaken the weld. This shield may be produced by combustion of components of the core or coating of the filler metal wire or be provided directly as a flow of inert or active gas, such as argon or carbon dioxide, respectively.

In manual metal arc (MMA) welding (Figure 44.1), the arc is struck between the workpiece and a consumable electrode in a holder held by the welder. The wire of the electrode is short to allow it to be controlled and is usually coated with a mixture of chemicals and alloying metals. In addition to forming a shield of combustion gases over the arc and weld pool this may contribute to the properties of the weld. It forms a temporary ‘slag’ over the weld bead to reduce oxidation and slow cooling. Slag is chipped off once the weld has cooled. This is a common source of foreign body eye injuries.

In tungsten inert gas (TIG) welding (Figure 44.2), the arc is formed between the workpiece and a contoured non-consumable electrode in the form of a conical spike of tungsten alloy in a pen-type holder. This may contain thorium (see under Radiation, p. 423). The electrode tip must be kept correctly contoured by periodic grinding at intervals of up to several weeks depending on use. Metal may be added from a filler wire fed into the weld pool by the operator independently of the electrode, resulting in both
hands being used. The arc and weld pool are shrouded in inert (and thereby asphyxiant) shielding gas, such as argon and/or helium.

In metal inert gas (MIG) and metal active gas (MAG) welding, the electrode is a continuous consumable small diameter bare wire fed at a constant speed on to the parent metal of the workpiece. This wire is melted in its own arc to contribute directly to the weld pool. The wire may contain a flux in its core (flux core arc welding). The weld pool, tip of the electrode and arc are shrouded in a shield of piped inert and/or active gas. As the operator does not have to be concerned with controlling the arc length, this process is much favoured by amateur welders.

New processes

Although these arc welding processes are generally cheap and reliable, limitations in all of them have become evident. Improvements and new technologies are required. Whether it is an established welding process which is being optimized or a new process being introduced, it is necessary to include an assessment of its impact on the health and safety of welders, and others, in the multidisciplinary development process of proving its suitability for purpose. New processes, such as laser and laser-hybrid processing, electron beam welding, magnetic pulse welding and friction stir welding, have been developed and are being or have been introduced with advantage to productivity and the health of workers.

Of the new technologies mentioned, friction stir welding (FSW) is of particular interest for improved occupational health because it welds in the solid phase – there is no melting and so no fume, and no arc so no ozone. Put simply, in friction stir welding, a wear-resistant, specially shaped tool is rotated at a very high speed and slowly plunged under a downward force by a machine into the joint line between the parts to be joined. These have to be clamped together so that the abutting faces cannot be forced apart. As it rotates, the tool heats the material by friction to about 70–85 per cent of its melting temperature so that it softens sufficiently for the rotating tool to traverse the joint line softening as the material goes. Its contoured shape ensures that, as it passes, it leaves material trailing behind it which forms into a solid phase bond between the two pieces. FSW is now well established worldwide especially for the welding of aluminium. Work is in hand to greatly extend its application.

SOURCE, NATURE AND VARIATION OF EMISSIONS

The emissions from arc welding processes comprise ultraviolet and infrared radiation, visible light, an often biologically active mixture of particles termed ‘welding fume’ and a mixture of gases derived from the process and the action of the arc on ambient air. The formation and emission rates and the composition of each and all of these pollutants may vary within and between welding processes. This can be troublesome when sampling and when prescribing control solutions, but can be turned to advantage to select, use and perhaps modify processes to ensure the maximum reduction of the risk of harm being caused by their emissions.

Variations in emissions within a process are influenced by many factors including the materials to be welded, those in the filler wire or other consumable, electrical parameters, shield gas and the individual welder’s skill and self-protection measures, the latter being a most powerful influence which can be reinforced by good education, training and motivation.

The air in the welding operator’s breathing zone may also contain compounds originating from the surrounding workplace atmosphere, rather than the welding process, as was observed in a recent UK Health and Safety Executive investigation in which samples taken for analysis from three different arc welding techniques frequently contained commonly used solvents, such as acetone, cyclohexane and dichloromethane. These and other materials may originate from surface coatings and contaminants or from other processes, such as degreasing, being carried out in the workplace.

Radiation

Arc welding is one of the most intense artificial sources of optical radiation. Each type of welding emits a different and continually changing spectrum and intensity. For most processes ultraviolet (UV) (A, B and mainly C) and, to a much less extent, infrared radiation (IR), are the components of health and safety concern.

UV radiation is a known carcinogen. Excessive exposure to solar radiation increases risks of cancer of the lip, basal cell, and squamous cell carcinoma of the skin and cutaneous melanoma, particularly in fair skin populations. The short distance between the arc and the welders’ and, sometimes, other workers’ skin and eyes is likely to be insufficient to absorb much of the potentially damaging UVB and UVC, so they will be at significantly increased risk of eye and skin damage, including malignancy, if they have inadequate protection.

The possible health hazard of electromagnetic fields (EMF) is one of the most recent subjects of special interest in the health of welders. There is no clear-cut evidence of harm being caused to humans by this radiation other than occasional cases of local heating of the eye and male gonads. There is, however, a high level of suspicion that as-yet-undetected harm results from EMFs. It is anticipated that employers will be required to assess and measure levels of EMFs to which workers are exposed; where these levels exceed ‘action values’, to assess whether exposure limits are exceeded; to ensure that these limits are not
exceeded; to erect warning signs when EMF exposure levels may cause exposure limits to be exceeded; and to provide appropriate information and training.

Arc welders are among those groups who may be exposed to the highest intensities of fields. Although arc welding uses relatively low voltages, it requires high current. This flows through welding electrical equipment and cables. If that equipment is close to the welder and/or the welding cables are wrapped over or in direct contact with the body, as is often observed, then the welder may be exposed to relatively high intensities of field compared to other occupations. Much can be done to reduce the arc welder’s exposure and relatively simple steps can have a tremendous benefit. Expert advice can be obtained from a reputable source, such as the national health and safety regulatory body or from an international or the within-country national centre of welding expertise.

Ionizing radiation may be introduced into the welding scenario through ancillary processes, such as non-destructive testing radiography and, now unnecessarily, by the continued use of thoriated tungsten electrodes in TIG welding and, to a lesser extent, in plasma cutting. Tungsten is used because it can withstand very high temperatures with minimal melting or erosion. Performance is further improved by alloying the tungsten with small quantities of oxides of other metals. One such additive is thorium oxide which is radioactive, emitting mainly alpha particles. The main source of danger is in the ingestible and respirable dust produced during periodic grinding of the electrodes to maintain the necessary sharp point — but there is also a small external radioactive hazard.

Thorium-free tungsten electrodes incorporating alternative and only marginally radioactive additives, such as cerium, lanthanum, yttrium and zirconium oxides are available. These are technically acceptable in most welding situations and should be used, either as the only modification to the process or with equipment that eliminates the need for thoriated electrodes for arc starting. When this is not possible, strict precautions must be taken to minimize exposure to thorium-containing dust at all stages from receipt and storage of the electrodes through welding and grinding to cleaning and disposal of waste.

Particle emissions

Welding fume particles are derived from evaporation, condensation, oxidation, decomposition and combustion of materials involved in the joining process. The fume composition is largely (up to 95 per cent) determined by the composition of the filler metal and, when present, its flux core or coating. Usually less than 10 per cent of the particulate emissions derive from the metal being welded.

Twenty-first century technologies in imaging and analysing particles have provided an overall picture of welding fume previously unattainable. When particles are characterized by size distribution, morphology, structure and chemical composition, it emerges that they can be classified into two main groups. The first of these comprises fractionated mixed metal oxide particles formed from metal vaporized in the high temperature of the arc, often oxidized following reactions with oxygen in the ambient air. These are present as individual irregular particles, individual spherical particles, and chains and aggregates formed by condensation of particles. They reflect the composition of the electrode with the more volatile constituents predominating. Many of the particles have a core-shell structure which suggests that surface composition can be quite different from the bulk composition.

The second group of particles is termed ‘spatter’. These are coarse, unfracti onated particles of electrode, usually larger than respirable, but providing a secondary source of smaller respirable oxide particles as the hot metal spatter reacts with oxygen in the air, often explosively.

The size of the particles is critically important in assessing the bioavailability of their constituents as the lung is the principal potential route of entry. An important characteristic is the particle diameter (aerodynamic diameter for particles >0.1 μm, diffusion equivalent diameter for particles <0.1 μm). The size variation of welding fume particles is quite large. It has long been known that many are in the respirable range. Whereas it had been estimated that some 50 per cent of the fume inhaled reached the lower respiratory tract and 35 per cent to the alveolar level, with most then being exhaled, more recently it has been found that a substantial proportion comprises submicron/ultrafine/nanoparticles. This may change our understanding and appreciation of the power of welding fume particles to initiate and promote inflammatory processes and systemic oxidative stress deriving from the soluble transition metals and, perhaps, to greatly facilitate the transfer of metals to various organs, such as manganese to the brain.

An indication of the range of metallic oxides which may be present in the fume from several processes is given in Table 44.1 which was developed in discussion with fellow experts meeting under the aegis of the International Institute of Welding. In this context a principal component is of some occupational hygiene significance, while the key component has the greatest occupational hygiene significance and therefore requires the most stringent control measures to ensure that a welder is not exposed to an excessive level of the substance concerned.

While, as remarked earlier, emissions vary within and between processes, in general terms, of the most commonly used arc processes TIG welding gives the least fume followed by MIG/MAG and MMA, then flux cored welding which gives the most.

Although the metal compounds found in fume are considered in Section two, Metals, three (chromium, nickel and manganese) merit brief mention here solely in regard to their presence in welding fume. Further information on these substances in welding is available in separate publications.

13–15
Trivalent and hexavalent chromium compounds are found in fume from welding on or with materials that contain chromium or chromates. These include high chromium nickel alloys and low alloy steels, high alloy flux covered wires, chromate paints and coatings, and chromium plating. Chromium is typically not added intentionally to mild steel or mild steel welding consumables but, because of the nature of steel making and the use of scrap metal, it is not unusual to find low levels.

Fume from welding stainless steel is rich in hexavalent chromium and trivalent chromium compounds, the amounts varying within and between processes. Hexavalent chromium compounds are a cause of occupational asthma (see under Occupational asthma, p. 434). Some hexavalent chromium compounds are known to be carcinogenic to the respiratory system by inhalation in a range of industrial processes other than welding, e.g. chrome plating and in the production of chromates, chromate pigments and ferrochromium. Dose–response relationships have been established for hexavalent chromium and cancer and the possibility of a threshold effect has been suggested. There is coincident exposure in most circumstances to trivalent chromium compounds. The International Agency for Research on Cancer (IARC) has found there to be inadequate evidence for classification regarding the carcinogenicity of trivalent chromium for humans, nor has metallic chromium been found to be carcinogenic in humans.

When compounds containing hexavalent chromium are present in welding fume they can be absorbed and excreted. The extent to which retention, reduction and excretion of hexavalent chromium compounds and their solubility act as an important determinant of carcinogenic potential is uncertain.

IARC has classified nickel compounds as carcinogenic to man. A key component is the component that has the greatest occupational hygiene significance and therefore requires the most stringent control measures to ensure that a welder is not exposed to an excessive level of the substance concerned, i.e. it is the component whose limit value is exceeded at the lowest welding fume concentration.

<sup>a</sup>A principal component is a component that is of occupational hygiene significance.

<sup>b</sup>A key component is the component that has the greatest occupational hygiene significance and therefore requires the most stringent control measures to ensure that a welder is not exposed to an excessive level of the substance concerned, i.e. it is the component whose limit value is exceeded at the lowest welding fume concentration.

FCAW, flux-coated arc welding; GMAW, gas metal arc welding; GTAW, gas tungsten arc welding; MAG, metal active gas welding; MIG, metal inert gas welding; MMA, manual metal arc welding; SMAW, shielded metal arc welding.
Manganese compounds have been proven to be occupational neurotoxins in a range of activities other than welding. Manganese is an essential component of steel. There is no suitable substitute. Compounds containing manganese, in complexes with iron and other oxides, are present in fume particles from steel welding and allied processes.

In recent years, it has been asserted by a few authors in the scientific literature, and during litigation in the United States, that occupational exposure to manganese compounds in fume from welding of steel causes or promotes the onset of Parkinson’s disease and/or parkinsonism/manganism in welders and those around them at work. These assertions have been vigorously contested.

Clinical manganism and Parkinson’s disease are two separate diseases, which, with care and thorough investigation, can be differentiated from one another. Follow-on studies have not supported the conclusion that welders are or have been at any greater risk of developing Parkinson’s disease at all or at an earlier age than others of similar background in other occupations in their community. Whereas vast numbers of workers worldwide use arc welding to join metal, the literature contains reports of very few, if any, who have developed clinical manganism as a result of exposure to welding fume. The risk may be slightly greater in allied processes, such as thermal cutting and gouging or hardfacing in which fume emission levels are inherently higher, but again there have been very few cases. Furthermore, there is no convincing evidence that exposure to manganese-containing fume during employment as a welder can result in an increased risk of developing neurobehavioural deficiencies and loss of fine control of movements. There is, however, insufficient evidence to the contrary to dismiss the possibility with absolute certainty.

**Gaseous emissions**

Gaseous emissions comprise those formed in the arc and by the action of the arc on the ambient air, plus any shielding gases remaining after they have performed their role, and gases released from combustion or heating of surface coatings. The number of variables affecting workplace exposures means that a wide range of exposures is possible. Exposures of individual welders may come from general workshop levels rather than their own work.

The principal gases formed are ozone, oxides of nitrogen (NOₓ) and carbon monoxide – each considered in detail in Chapter 8, Gases. The arc plays a key role in their formation. When arcing is not continuous, for example in manual processes, formation and emission of these gases peaks during and diminishes or is absent between arcing, so welders may be exposed for repeated short periods to concentrations very much higher than those indicated by an averaging sampling and measuring technique.

It has been said that exposure to ozone is currently a major occupational hygiene problem with almost all gas-shielded arc welding processes and that, in recent years, the increasing use of aluminium and stainless steels, along with raised productivity, has increased the likelihood of unacceptable welder exposure. This appears to be related more to achieving control down to at least within national occupational exposure limits, many of which have been reduced in recent years, than to there being evidence in the literature of exposures to ozone in workplaces causing ill health in welders – as this has not been found.

There is, however, no doubt that ozone is an irritant to mucous membranes, can cause acute discomfort to the eyes and upper respiratory tract, readily penetrates to small airways and alveoli and, even with brief exposures, if concentrations are sufficient, will cause a disabling inflammatory response with pulmonary oedema. The possibility of there being as-yet-undetected harm occurring in welders cannot be ignored – and so exposure to ozone must be minimized to at least within the national standards.

The generation of ozone is due to photodissociation of molecular oxygen in the ambient air around the welding process under the influence of direct or reflected UV radiation emitted from the arc. The gas forms in two distinct regions: approximately half within a 10–15 cm radius of the arc by the action of UV in the 130–175 nm range and the remainder in relatively low concentrations further from the arc, up to a metre, due to UV of wavelengths 175–240 nm. It decomposes when subjected to higher wavelengths. Usually, the ozone reaches the breathing zone in a few seconds after the arcing starts and the concentration returns to the background level almost within the same time after arcing has ended.

Ozone concentration is affected by the number of welders at work (as several together can build up significant concentrations during welding in an inadequately ventilated space), the welder’s care and skill, and any of the large number of other variables which influence the rate of formation and decomposition of the gas produced by each operator. These include the magnitude of the UV in the critical ranges for production – and beyond for decomposition of the gas once formed; the presence of fume particles, dust or other gases; the composition of the filler wire; the welding process and its parameters; and, often most complex and variable, the shielding gas. Together these, and the need for specialized equipment based on chemiluminescence, make measuring welders’ exposure problematic.

All else being equal, ozone concentration is greatest in processes with low fume emission and vice versa as it reverts to oxygen in contact with particles.

Process selection is a powerful influence on ozone exposure. For example, there tends to be a very fierce arc in TIG welding and so a great deal of ultraviolet radiation and much ozone are produced, particularly when welding on aluminium and stainless steel. Process modification may be useful in reducing ozone levels, at least experimentally, as small changes to the process and its parameters can have disproportionate effects.
Oxides of nitrogen or nitrous gases (nitrogen monoxide, dioxide and peroxide) are generated as byproducts in most arc welding, cutting and heating processes as a result of heating the air in the arc or flame region. Emission rates during arc welding are very low compared to allied processes especially plasma cutting and oxyacetylene processes. The rate of formation of nitric oxide is initially slower than that of ozone as the rapid production of the former is partly dependent on the air achieving a high temperature, whereas ozone production peaks in a fraction of a second after the arc is struck and UV is emitted.

The first stage in the formation of these NOx is oxidation of atmospheric nitrogen to nitrogen monoxide, a gas of very low toxicity. This occurs in contact with the very hot gas emanating from the arc and weld pool. Between 75 and 97 per cent of the oxides of nitrogen emitted may be nitrogen monoxide. Its rates of formation and emission peak during arcing as the temperature goes above 500–1000°C. They then fall, sometimes dramatically, as the NO is diluted by the ambient air and cools to its temperature whereupon it oxidizes, at rates dependent on concentration and temperature, to the biologically more active gases, nitrogen dioxide and peroxide, which have the potential to cause harm.

The ratio of nitrogen monoxide and dioxide can change if ozone or other oxidants are present in the air. In gas-shielded arc welding, because of ozone formation by the UV of the arc, almost all of the total oxides of nitrogen generated is nitrogen dioxide.

The very low emission rates during arc welding compared to processes, such as plasma cutting or oxyacetylene burning where much higher rates may be encountered, may be of practical importance for occupational physicians and epidemiologists when seeking to select samples of workers for research studies as mixing those with superficially similar jobs may result in mixing those with notably different potential exposures to these gases, e.g. arc welders (low NOx) and flame burners (higher NOx).

Carbon monoxide is generated by thermal decomposition of carbon dioxide in metal active gas welding shielded by that gas and in the incomplete combustion of flux materials containing carbonates and/or cellulose in all or almost all processes. The amounts of carbon monoxide generated by fluxed arc welding processes are small and, generally, the risk of overexposure is low.

**SHIELDING GASES**

Shielding gases used in processes such as TIG, MIG/MAG and flux-cored arc welding (FCAW) may be inert, such as argon, helium or nitrogen, or active argon-based mixtures containing carbon dioxide, oxygen or both. Helium may be added to argon/carbon dioxide mixtures to improve productivity. Carbon dioxide may be used on its own. None of the gases can be seen and none has a smell — although a method for odorization was described two decades ago. Their presence in hazardous concentrations is difficult to detect without prior knowledge or measuring equipment. The main hazard arising from shielding gases is asphyxiation (see under Asphyxia, p. 432).

**INFLUENCE OF COATINGS AND CONTAMINANTS ON EMISSIONS**

The composition and amount of fumes and gases produced may be influenced significantly in complexity and potential to cause harm when the metal to be welded has a surface coating applied, e.g. by galvanizing, electroplating, painting on primer, thermal coating, or is contaminated by materials such as oil, degreasers or the products/byproducts of manufacturing processes, e.g. lead, manganese.

It is becoming increasingly common, particularly with resistance welding in the auto and white goods industries, to weld through or close to organic materials, such as shop primers, other coatings, adhesives, etc. This can generate a wide range of degradation products. Their composition may be difficult to predict even if knowledge of the composition of the product is available.

Chlorinated hydrocarbons, such as trichloroethylene, may still be found in use for degreasing. These may present as vapour particles in the ambient air having passed from an adjacent tank or remain on metal parts which have just been cleaned but have not yet dried. The radiation from welding arcs may cause chlorinated hydrocarbons to decompose in the air or on the parts. The very toxic gas phosgene may be formed.

In many cases, the risk assessment will indicate that it would be best for the surface coatings and contaminants to be removed before welding. An exception may be made when the coating is classified as ‘weld-through’ and sufficient is known about it to conduct and act upon a properly informed risk assessment. With these coatings, fume composition and thus the risk of harm may be dependent on welding method as some processes produce more volatile organic compounds and less particulate than others when used on metal coated with the same primer.

**SAMPLING AND ANALYSIS**

Air samples should be collected and analysed by qualified people using approved standardized methods and devices. The dynamism of the fume and the variation in gas emissions can present challenges to meaningful sampling. When assessing exposure, it is best to collect the fume in the breathing zone behind the welder’s helmet – although this may not be possible with modern close-fitting helmets. If there is a national or international standard for sampling, this should be followed. Even with care, standardized methods and long experience, it can prove difficult to get reproducible results.

The content of the fume measured in the breathing zone may include significant contributions from neighbourhood activities, such as grinding and, as mentioned earlier, degreasing, indicating the wider than perhaps expected range of exposure the workers may be experiencing. There
are so many variables at work that often it will be imprudent to extrapolate results obtained in one situation, or even from one welder, to another.

**CONTROL OF WORKPLACE EXPOSURES IN WELDING**

The hazards associated with welding and its allied processes are largely the same all round the world, yet the standards set for precautions to be taken to control the risks of harm vary greatly between countries. Local enquiries must be made to determine the minimum levels to be achieved.

The multiplicity of situations in which welding and allied processes are used, the variations between and within them, and in legislation in many countries, make it obligatory for measures for control of workplace exposures to be selected following risk assessment of all relevant aspects of the individual work situation – including when this is off-site, e.g. at the customer’s premises.

Accurate risk assessment of exposure to welding emissions can be a difficult task. The assessment must consider not only the operators, but also the people working in the vicinity of welders. It should include the workers involved in the processes in discussions from the outset if at all possible. Guidance on assessment is available. Means have been suggested to remove the requirement for expensive analysis of every fume sample. The extent and method of health surveillance required must be included. This is considered under Health surveillance, p. 435.

The basic traditional occupational hygiene hierarchical approach must be taken to achieve adequate control of exposure:

- prevent emission by selection/substitution of process; improve working practices by modification of process, process parameters or consumables to lower fume and gas emission rates or toxicity of the constituents;
- prevent exposure by natural ventilation and/or engineering controls, including isolation or segregation, control of pollutants at the source by local exhaust ventilation; and finally,
- prevent exposure by wearing respiratory protection equipment (RPE).

It is not appropriate to go directly to or rely solely on personal respiratory protection equipment. Although much guidance is available, specialist advice may be required at any or every stage.

Selection of the process at the outset should include consideration of health risks alongside technical suitability, product quality, productivity and cost. In the last 25 years, technological improvements designed primarily to give better welds and improve productivity have also provided opportunities to reduce emissions. For example, enhanced control of power sources has allowed finer control of electrical parameters giving the potential to reduce emissions sensitive to such changes. Process automation should be considered as this may greatly improve the possibilities for control of welding exposures in the welding environment.

Selection, substitution and process modification require knowledge of emissions of alternative processes and the effect of selected process parameters (such as weld speed, current and voltage), shielding gas or other consumables to allow meaningful comparisons to be made. In practice, process or parameter substitution or modification may be limited to situations where the product quality and overall production costs (including the cost of control measures) are not significantly adversely affected by the proposed changes. Experience has shown that opportunities for substitution lie in the selection of consumables using fume data provided by suppliers. It is important to ensure that hazards are not removed only to be replaced by others of equal or greater concern.

Isolation or segregation is often appropriate for automatic or semi-automatic processes, perhaps using remote control and/or an enclosure closely surrounding the source. It should be applied to the full range of manual processes in both stationary and non-stationary workplaces by reducing the number of people who are in the area of emissions to an absolute minimum and separating them from others by exclusion instructions and screens.

Local extraction ventilation (LEV) is usually required for welding and often provides the necessary control. It should be designed to capture the particulate fume and gases at source before these enter the breathing zone of the operator. It may be fixed, flexible or portable, or integrated in the welding equipment and should introduce air movement sufficient to capture and transport the pollutants away from the breathing zones of welders and those working with them. General ventilation is usually required as a supplement to LEV to supply fresh air and dilute pollutants. Guidance is available for self-help. It may be prudent to seek specialist advice on the design and selection of extraction and general ventilation systems in all but the most straightforward situations.

Use of personal respiratory protection equipment is essential where previous steps cannot provide sufficient protection against exposure to fumes and gases. There are two aspects to be considered: (1) the selection and care of a suitable device and (2) the human aspects of achieving the expected level of respiratory protection. Both can present challenges.

The requirement may be met by filtering or air-fed respirators or helmets. These should be fitted and supplied to the individual welder. All apparatus used should be marked with the appropriate nationally-used protection classification and quality scheme logo. Filters must protect against gases, as well as fumes – or alternative arrangements made for removal of gases. This should have been achieved by arrangements for ventilation. There must be adequate support arrangements (including education and training, cleaning and maintenance) and for supervision over such matters as length of use of filters.
ADVERSE HEALTH EFFECTS OF EMPLOYMENT AS A WELDER

Sudden deaths

Though fortunately rare, welders and allied workers are killed in the course of their work by electrocution, explosion or fire, and, as discussed below, asphyxia or acute chemical exposures. It would be hard to argue that these deaths were not entirely avoidable had a safe system of work based on sound risk assessment been followed. Much excellent guidance and direction are available from national and other health and safety agencies to assist in avoiding these and other potentially fatal hazards and how appropriate safe systems of work should be designed and operated.1,31

Other injury accidents

The Health and Safety Executive estimates that there are over 1000 work-related accidents to welders reported in the United Kingdom each year with around 300 classified as major accidents, such as fractures and amputations.31 The three most common types of reported accidents to welders in the UK are related to handling, slips and trips, and being hit by a moving or falling object – which may be a foreign body heading for the eye!

BURNS AND OTHER NON-MALIGNANT SKIN LESIONS

Welders suffer a high incidence of burns and other skin lesions from hot metal, UV and IR radiation burns of unprotected areas of skin. UVR and IR radiation from electric arc welding processes commonly cause ‘ray burn’ (erythema) and, ultimately, persistent pigmentation in unprotected areas of skin, neck and chest exposed at the V-opening of an unbuttoned shirt or overall, the wrists due to stretching over-head, forehead and the fronts of the ankles in welders who squat to weld and allow their trousers to ride up.32,33 The back of the ears may be affected by reflected radiation, e.g. when welding within an aluminium container. Almost all welders have been burned by sparks, spatter and droplets of molten metal or slag and bear the scars of these repeated injuries. The occupational stigma of ray burn and multiple small burn scars found on many welders can cause difficulties in ‘blinding’ controlled studies as it is so easy to distinguish the welders from others. Rarely, such burns occur inside the ear. These are particularly painful and may give rise to serious complications including perforation of the tympanic membrane with deafness and facial paralysis and unusually high rates of residual and recurring perforations.34–37

High velocity metal projectiles causing deep penetrating injuries with residual foreign body material may be emitted during spot or resistance welding, probably due to poor cleaning and maintenance of the equipment.38,39

Arc welding has been reported as affecting the exposed skin in other ways, including siderosis40 and contact dermatitis due to chromium and nickel.41 Atopic dermatitis has been exacerbated by UVC radiation from the arc42 and the much rarer photodermatitis has been reported in a resistance welder.43

MALIGNANT SKIN LESIONS

Exposure to UVR, whether solar or of artificial origin, carries potential risks to human health. It is a known carcinogen. Excess exposure to solar radiation increases the risk of cancer of the lip, basal cell and squamous cell carcinoma of the skin and cutaneous melanoma, particularly in fair skin populations. Artificial UVR from welding torches may also contribute to the burden of disease from UVR.44 It is possible that welders are at greater risk of developing these skin cancers than the general population, but there is a dearth of case reports or well-designed studies of that question.

The first of only two case–control studies found no excess of skin tumours in the welders45 but, as has been remarked,46 the welders examined were all well protected (so the dose level may have been unusually low) and young so the length of their exposure was relatively short compared to long-serving career welders and, moreover, they may not have had time to develop skin cancers as a response. The second case–control study found no persuasive evidence of occupational risk factors for melanoma.47

Reports have been published of basal cell carcinoma occurring after frequent episodes of cutaneous erythema and peeling induced by welding,48 a group of five welders with non-melanoma skin cancer,49 a welder with five squamous cell carcinomas on his hands46 and a woman who had presented with numerous squamous cell carcinomas on her hands and commented that she had frequently experienced ‘sunburn’ on her hands after assisting her son with his welding business.50 Interestingly, in regard to this last case, a case–control study of uveal melanoma has shown an increased risk associated with ‘welding burn’.51

EYES

Welders normally require stereoscopic vision with good acuity to strike the arc and produce high quality joints. Their eyes should be especially precious to them, yet the eye is the part of the body most commonly injured by welding and related processes in industrial settings. It has been reported from the United States that, as a group, they sustain a higher number of eye injuries than most other types of workers52 and that eye injuries account for 25 per cent of insurance compensation claims by welders.53 In a survey of consumer product-related eye injury trauma treated in emergency rooms in hospitals across the United States in the period 1998–2000, welding equipment was estimated to be the product most commonly associated with eye injuries,54 perhaps reflecting the increasing
availability and unprotected use of that equipment by DIY amateurs, in addition to professional workers.

Foreign body eye injuries relate, in the main, to spatter during welding and to associated processes, such as chipping slag from the formed weld, or grinding metal in preparation for welding or after the joint has been made. The foreign body ‘missile’ may be set in flight by the actions of the injured welder or someone working closely adjacent. The particles may be carried on the wind or fall into the eye from the hair or skin or a protective goggle as it is moved from its perch on the welder’s brow to cover his eyes; the process is completed by the welder rubbing his eye.

The high risk of injury makes it essential for the welder and those working around him to wear well-fitting goggles or spectacles with side pieces all the time in the workplace – including when the protection of the helmet or handheld shield is added before the arc is struck.

When a patient has a history of a known intraocular or periorbital foreign body or of occupational exposure to potential metallic ocular injury, as do welders, grinders and metalworkers, it is necessary to screen them with plain radiography before they have a magnetic resonance (MR) scan to ensure the latter is not undertaken during the continued presence of intraorbital metallic foreign bodies.55

Despite the periodic welding flashes from the arc, when the appropriate protection is worn, the UV radiation exposure levels reaching the eye are below those needed to cause permanent damage to the corneal endothelium and long-lasting eye damage is reported only very occasionally.56,57 In contrast, the acute injury ‘arc eye’ is frequently recorded as the most commonly occurring eye injury of welders.

In that injury, the UV rays from the arc irritate the superficial corneal epithelium of the inadequately protected eyes provoking an inflammatory response which includes oedema, congestion of the conjunctiva and stipling of the corneal epithelium (superficial punctuate keratitis (SPK)), the latter characterized by small pinpoint defects in the superficial corneal epithelium which stain with fluorescein. If SPK is severe, it may be followed by total epithelial desquamation with conjunctival chemosis, lacrimation and blepharospasm. Re-epithelization occurs within 36–72 hours and long-term sequelae are rare.58

This is the classical ‘arc eye’. It may occur in the welder who is actually producing the harmful emissions. It is often said to occur more commonly in neighbouring welders, other workers and in onlookers who are in the UV radiation area, but are not wearing appropriate eye protection. A recent report showed that whereas 85 per cent of cases received their overexposure from welding, only 3.8 per cent were professional welders with the remainder other occupations with occasional use of welding.59

Typically, arc eye is characterized by increasingly intense eye pain, photophobia, a feeling of grittiness, excess lacrimation and reduced visual acuity beginning some 4–12 hours after the exposure, by which time the damaged epithelial cells have sequestered. Symptoms usually resolve spontaneously within 48 hours of exposure.

Although the history may appear to make the diagnosis obvious, care must be taken to examine the eye carefully under local anaesthetic, such as proparacaine 0.5 per cent58 to exclude trauma (including foreign body), conjunctivitis, corneal ulceration and ulcerative keratitis, and iritis and uveitis. The cornea must be stained with fluorescein to demonstrate the characteristic lesions. A full clinical record should be kept and this should include a note recording that other diagnoses, especially foreign body injury, were positively excluded.

As a first aid measure, some relief may be gained by flushing the eyes for several minutes with water or saline solution. Medical treatment involves administering a short-acting cycloplegic drug,58,60 such as 1 per cent cyclopentolate or 2 per cent homatropine to relieve the pain of reflex ciliary spasm, a single drop being all that is usually necessary. It is essential to check for glaucoma as these drugs may induce acute glaucoma – though the risk may be small. The use of topical antibiotics in the absence of infection remains controversial but, as a secondary infection is a rare but devastating consequence of a corneal abrasion, their use has been said to be ‘a very reasonable course of action’ in that situation.60 An eye patch is not recommended as routine treatment, but may give relief in those with large corneal abrasions.60 These patients and others with extensive damage should be seen by an ophthalmic specialist without delay.

Patients should not leave the medical facility after treatment until the effects of the local anaesthetic have worn off and must be advised not to drive while the cycloplegic agent is still acting (it is usually safe after about 8–12 hours). They should be told to return if symptoms persist without steady diminution or are unresolved in 48 hours. They should not be given local anaesthetic to reapply as this introduces risks of further injury and may delay healing.

Retinal injuries attributed to radiation in the visible and near-infrared spectrum emitted by a range of arc welding processes have been reported in the literature under several titles,61–72 but are all the same basic pathology. The radiation penetrates the eye to be absorbed by the retina and rarely causes clinically apparent photochemical or thermal damage. This may be permanent and sight-threatening. It has been reported that the prescription anti-psychotic medication fluphenazine may render workers particularly susceptible to retinal photic damage.71

Early diagnosis of the maculopathy may be difficult because it can be masked in the first few days by ‘arc eye’. Multifocal electroretinography (ERG)73 and automatic perimetry have been shown to be useful tools for the detection and quantification of the functional defects.66 In most cases, retinal injuries heal spontaneously without loss of vision, but severe burns of the macula may lead to permanent complete or partial loss of central vision. They need to be seen by an ophthalmologist without delay.
After a controlled study of a group of welders, it was concluded that the usual protective measures prescribed in professional welding to guard against radiation from the arc are sufficient to prevent an occupational risk of maculopathy and that its occurrence seems to be rather the result of a sequel of occupational accidents and neglect of safety regulations.

Ocular melanoma is the most common primary malignancy of the eye. A rare disease, it usually develops in the uveal tract, most commonly in the choroid which underlies the retina. Diagnosis tends to be late as it is quite literally ‘out of sight’. It tends to metastasize before diagnosis, often to the liver, and this makes it a usually fatal disease. The first large case-control study seeking occupational links with melanoma found no persuasive evidence in their data or the scientific literature to link this neoplasm with welding – or any other occupation. At about the same time, a large and more focused case-control study for intraocular melanoma found a significantly increased risk for occupations with welding exposure. This view found some support from a study in France where the investigators considered that they had demonstrated an elevated risk of ocular melanoma in welders, increasing with job duration, and suggested that exposure to ultraviolet light was the likely causal agent. A study in Australia found the risk of choroid and ciliary melanomas increased with increasing duration of welding exposure, although the trend was not significant overall. A meta-analysis soon followed showing that there was evidence implicating welding as a possible risk factor for ocular melanoma. The most recent and largest case-control study covering nine European countries found an excess risk for welders in only one, France.

Accounts of contact lenses adhering to the cornea following exposure to UV and IR radiation from welding circulate periodically. None has been substantiated and there is no evidence to support the contention that welders should not wear contact lenses. Welders may do so, provided they observe the normal rules for their care and limitation on wear.

HEARING

The high sound pressure levels which can be found as background in some welding shops and are emitted by some welding and cutting processes may cause noise-induced hearing loss. That injury may be seriously disabling to a welder as they use their hearing to detect changes in the sound of the welding arc which reflect what is going on at the weld.

PROTECTION OF SKIN, EYES AND HEARING

Care must be taken to protect the skin, eyes and hearing of arc welders and those working with them. Those within 2–3 metres of the arc should wear spark-, fire- and UV-proof protective clothing, without cuffs or pockets that catch sparks. This should be worn closed at the neck and be of a size which allows all exposed skin to be covered, even when the wearer is stretching or squatting.

A broad-spectrum high factor, e.g., 50, sunscreen could be a useful adjunct affording extra protection against UVA and UVB in solar radiation should the welder be working outside, but reliance should not be placed on such a preparation to protect against the high intensity of UVC from arc welding as they are usually formulated to be effective between the wavelengths of 297 to 400 nm – with UVC being those wavelengths below 270 nm.

Welders should also wear fire-resistant gauntlet gloves, a helmet or handheld shield and suitable footwear. The headgear should be chosen to give protection from direct and reflected UV and incorporate a filter selected to counter the expected emissions. The welding helmet filter may be ‘passive’ (constantly dark), in which case the helmet or shield will have to be lifted repeatedly to allow the worker to see the workpiece, or ‘auto-darkening’ with a light or other sensor to trigger lenses to automatically darken to the correct level of protection. Footwear must have insulating rubber soles which will not melt if hot spatter or metal splashes are stood upon. The uppers must also be impervious to these hot materials. Ankle boots with anti-crush toecaps are advised for all processes. Shoes with protective toecaps may be adequate for use with TIG.

Appropriate hearing protection should be added when working in a noise hazard area. Other additional protection may be needed in particular situations, e.g. a flame-retardant hood, cape with sleeves, chaps and leggings, bib and waist apron, and spats. Comfortable clothing and equipment is more likely to be used, so modern lighter-weight materials should be used whenever possible, provided these give adequate protection.

Because much time at risk is spent with the welding helmet raised or shield discarded, welders should also wear protective goggles or eyewear to guard against non-radiation hazards and arc radiation from neighbouring workers.

Prevention of arc eye requires more than eyewear alone and should follow the full gambit of risk assessment and control from elimination or substitution of the process through to improved personal protection. For example, MIG produces more UV than MMA and TIG. UV radiation also varies within the same process and with the metal being welded. Factors which increase UV emission such as arc energy, arc duration, electrical current and using argon as the shielding gas offer an opportunity to reduce the risks by process modification. Welders working on aluminium, and those in their vicinity, are at the greatest risk of heavy exposure to UV radiation and need the greatest protection, including from reflected rays.

Those in the vicinity of, but not involved in, the welding processes, and this includes passers-by in the street, should be protected from emitted radiation by containing it within the work area by strategically placed screens or curtains. These should absorb the radiation rather than reflect it back at the welder and those working with him/her.
MUSCULOSKELETAL SYSTEM

Manual welding involves a combination of high muscular strain, high precision demands and static muscle loads for the whole body, and especially for the arms and shoulders. Irrespective of position, the high precision demands of the work require postural stabilization, particularly of the hand and arm, which means that the stabilizing muscles of the shoulder are active to a high degree for as long as welding continues.81,82

Steps should be taken to minimize the physical stresses welders may experience should they have to lift, carry or manoeuvre heavy workpieces and welding or ventilation equipment; negotiate difficult worksite access or egress; work in confined spaces, such as in pipes or the double bottoms of ships, or in uncomfortable positions such as kneeling, leaning over the workpiece or straining to reach the weld line, always supporting the weight of the gun (electrode holder) and the cables connecting it to the welding unit. The welding gun plus cable may weigh between 1 and 7 kg or more, depending on the process being used.82

Musculoskeletal wear and tear injuries and disorders sustained by shipyard welders can render a significant proportion of them incapable of or motivated against work in the full range of normal tasks at the workplace or until the prescribed retirement age.83-84 Welders were found to have a significantly higher prevalence of musculoskeletal pain than the rate in the general population in Sweden.85 In the United Kingdom, the rate for those in the welding trade diagnosed with work-related musculoskeletal disorders by specialists in recent years was about twice that of all skilled workers, and 7 kg or more, depending on the process being used.82

Musculoskeletal wear and tear injuries and disorders sustained by shipyard welders can render a significant proportion of them incapable of or motivated against work in the full range of normal tasks at the workplace or until the prescribed retirement age.83,84 Welders were found to have a significantly higher prevalence of musculoskeletal pain than the rate in the general population in Sweden.85 In the United Kingdom, the rate for those in the welding trade diagnosed with work-related musculoskeletal disorders by specialists in recent years was about twice that of all skilled trades taken together. All this information invites the conclusion that the stresses of manual welding are causing undue wear and tear to the welders' musculoskeletal system. There is evidence of particularly increased risk for shoulder pain and to a lesser extent for disorders in the neck, hand, lower back and lower extremities.86-88

Welders have been found in different studies to have significantly higher rates of problems in the shoulder and neck than controls. In one, almost a fifth of welders were affected87 and it began at an earlier age than in workers in other arduous trades.88 Much of the shoulder pain is due to inflammatory reactions in the rotator cuff, mainly tendonitis – a condition found ten times more often in those who commonly worked above shoulder level than in the overall study.89 The supraspinatus muscle in the shoulder is particularly overloaded when the welder is working at or above shoulder level.90-94

Development of neck pain may be influenced by the individual welder’s posture and static muscle load and in some cases by the dynamic biomechanical loading of the helmet/visor.93 This is most likely if that equipment is heavy, not fully adjustable and has to be nodded down each time the welder arcs and both his hands are occupied.

Experience suggests that there can be early benefits if priority is given to correcting the intensity of work, the weight of the equipment and workpiece to be handled and the strain induced by the working position. Designing hazards out of the workplace from project conception to completion should proceed in parallel, in consultation with workers, and with improvements being made without delay. Automation should be sought and introduced wherever practicable.

In the workshop, physical strains would be reduced by providing welding tables and workholders which allow welders to set their preferred working height and angle. They may then optimize the hand position between waist and shoulder – without requiring twisted or bent postures – without involving any heavy lifting during adjustment and to choose whether they stand or sit.94 The risk of shoulder strain should be reduced by designing out the need for overhead welding as far as possible and providing tool and arm support by suspension devices to reduce muscle loading.92 Returning to neck pain, advantage should be gained by adjusting the welders’ work so that less stressful postures can be adopted and equipping them with a lightweight, automatic darkening visor with adjustments for height and angle.

RESPIRATORY SYSTEM

Adverse effects on the respiratory system which have been related to employment as a welder include asphyxia; metal fume fever; perforation of the nasal septum; increased pulmonary infections in terms of severity, duration and frequency; parenchymal diseases such as siderosis; chronic bronchitis and emphysema; chronic obstructive pulmonary disease; occupational asthma; and an apparent increase in the risk of developing lung cancer.

A cause–effect relationship is seldom a matter of contention for the more acute effects of exposure to emissions from welding processes on the respiratory system. In contrast, the possibility and nature of chronic effects of exposure have long been the subjects of research studies with, in general, inconsistent or inconclusive results. This may be due to the absence of such a causal link, the variety of exposures (and thus effects) welders may experience, and/or deficiencies in the study designs. The latter may include healthy worker and survivor population effects operating within the study populations, i.e., workers who become welders or remain in that occupation over the long term may be healthier than the employed population in general.

ASPHYXIA

Asphyxia is a fortunately rare, but sometimes fatal, work-related acute condition suffered by welders through working in inadequately ventilated confined spaces, where the oxygen has been displaced by inert shielding gas or depleted by combustion or, reportedly, rusting of ferrous structures.

Shielding gases are supplied at a flow rate of some 15L/min. The inert portion passes unchanged from the area of the arc into the workplace. They may leak from
connections in supply pipes. Argon is heavier than air so tends to collect in low areas displacing oxygen-bearing air. Inhaling such a gas mixture, which contains little or no oxygen, can cause rapid loss of consciousness. A classic scenario is the welder welding with a gas-shielded process in a confined space with inadequate ventilation and, as he bends down, e.g. to retrieve a dropped object, his head enters the deadly concentration of argon, he loses consciousness, he falls into the gas – and asphyxiates. A Safe System of Work devised before the welding task is begun with inert gases in confined spaces, and followed during the work, should avert the risk of such tragedies. Workers should not enter an atmosphere that contains less than 18 per cent oxygen.

Great care must be taken to consider a diagnosis of pneumonitis during the initial assessment and observation.\textsuperscript{107,108} Discussing more detail under Inhalation fevers, p. 436.

Metal fume fever

Metal fume fever\textsuperscript{97–103} is one of the most common acute harmful effects of exposure to welding fume. It is usually an unpleasant, but short-lived, self-limiting flu-like toxic illness beginning some hours after welding has ceased. It may mimic other more serious diseases\textsuperscript{104} and have been associated with development of symptoms of welding-related asthma\textsuperscript{105} and other serious long-lasting health consequences.\textsuperscript{106} It may well be that other effects remain to be identified, particularly in those who have had repeated attacks. Metal fume fever and other ‘inhalation fevers’ are discussed in more detail under Inhalation fevers, p. 436.

Great care must be taken to consider a diagnosis of pneumonitis during the initial assessment and observation.\textsuperscript{107,108} Lest they actually have as-yet undeveloped and undetected chemical pneumonitis – which can progress to serious and even fatal consequences – before sending them home to recover, it is essential to warn workers thought to have metal fume fever to seek further medical assistance without delay if they develop worsening respiratory symptoms. Be especially cautious when cadmium is or may be involved. If this is the case, initial and monitoring investigations should include measuring urinary cadmium concentration and seeking evidence of renal damage.

Pneumonitis and adult respiratory distress syndrome

Rarely, freshly formed oxides of metals, notably zinc or cadmium, produced by welding on coated or plated metal\textsuperscript{107,109,110} or using allied processes, such as flame cutting,\textsuperscript{111,112} brazing with cadmium-containing solder\textsuperscript{113} or metal spraying with an arc process,\textsuperscript{114} cause chemical pneumonitis or adult respiratory distress syndrome. These conditions may have a fatal outcome due to respiratory failure. Survivors may be left with persistent pulmonary function abnormalities.\textsuperscript{107} In the initial stages, these conditions may mimic metal fume fever. Sufficient investigation to allow an accurate differential diagnosis to be made is essential. It is better to err well on the side of caution, should there be any doubt.

Lobar pneumonia

National statistics of occupational mortality for England and Wales over two,\textsuperscript{115} then three,\textsuperscript{116} decades suggested that welders have an excess risk of dying from pneumonia attributable to exposure to metal fumes – and that this was not pneumonitis, but rather an excess of pneumococcal and unspecified pneumonia. There was no excess in men over retirement age adding weight to the conclusion that this was a work-related effect. It was suggested that metal components of welding fume, or possibly ozone or oxides of nitrogen, might reversibly increase the susceptibility of the lung to pneumonic infection\textsuperscript{116} and, after case–control studies, that this may be attributable specifically to ferrous, and possibly other metal, fumes.\textsuperscript{117}

Animal studies first showed that pre-exposure to fumes from MMA welding of stainless steel might result in suppression in immune response and an increase in susceptibility to infection\textsuperscript{118} and more recently have demonstrated that short exposure to these fumes caused significant lung damage and suppressed lung defence mechanisms to bacterial infections.\textsuperscript{119} Investigations on experienced welders, fresh from exposure at the workplace where they had received a high iron challenge from welding, found a ‘note-worthy’ absence of an inflammatory response.\textsuperscript{120} The conclusion was drawn that chronic exposure to metal fume blunts responsiveness to inhaled particulate matter by an as-yet-undefined mechanism.

Chronic obstructive pulmonary disease

It might be expected from the nature of the mixture of fumes and gases arising from welding processes that, given sufficient time and concentration of exposure, the
respiratory system would be irritated sufficiently for there to be a work-related excess risk of COPD and emphysema. This hypothesis has been investigated in many studies – though less so in recent years.

Although excess prevalence of both these diseases and/or adverse changes in lung function has been demonstrated in some studies, this has not been the case in all of them. There is insufficient consistent and statistically convincing evidence of a causal relationship between prolonged exposure to the concentrations of fumes and gases from arc welding processes found in industry and the development of COPD for these to be considered occupational diseases of welders. That said, for the purposes of risk assessments, worker protection and health surveillance, but not for purposes of legislation or litigation, the prudent occupational healthcare worker or employer will not wait for such evidence, but rather will act as if the link had been established – as logic demands that it must be there – and seek out those who may be susceptible and need special protection or are being affected adversely.

To clarify the situation, there is a need for epidemiological studies of sufficiently large cohorts of workers engaged only in welding, preferably mainly ‘new starts’, and appropriate controls in sufficient numbers to give the required level of statistical power, thoroughly and appropriately assessed at the baseline and thereafter over, perhaps, a decade or two, and with concurrent records of work processes and measurement of exposures.

**Occupational asthma**

Asthma is characterized by variable airflow limitation and airway hyper-responsiveness. Once sensitized, exposure to very small concentrations of the causative agent will cause a reaction. The long-term effects can be significant in terms of employability. Symptoms include wheezing, coughing, chest tightness and/or shortness of breath. These can come on immediately after exposure or be delayed for several hours. Other associated conditions are rhinitis and/or conjunctivitis.

The incidence of occupational asthma appears to be generally low in welders. Most cases are attributed to exposure to hexavalent chromium in fume emitted from welding on stainless steel. There may be no apparent difference in prevalence in surveyed employed welders working on stainless steel compared to those welding mild steel, but this may be due to a survivor effect in the stainless steel welders studied as in most cases it is impossible for the patient to return to and continue with welding work after a diagnosis of occupational asthma.

Employers should assess their workplace for known asthma agents, the risk of exposure, minimize exposure, inform their employees of the findings and precautions and conduct health surveillance, as under Health surveillance, p. 435.

**Siderosis**

Siderosis is a radiologically apparent pulmonary nodulation exhibited by varying proportions of arc welders of ferrous materials as a result of inhaling and retaining in their lungs a proportion of the iron oxide from the welding fume. It is seen more often after 15 years’ exposure, the prevalence then increasing over time. Reports of siderosis being a fibrotic condition are unusual given the huge number of welders exposed to iron compounds in fume. With one exception, such proposals have arisen from individual case reports or small series, some with gross overexposure. The fact that iron clears from the lungs and radiological nodulation regresses after ferrous welding has ceased support the alternative conclusion which may be drawn safely from the many studies undertaken that siderosis alone is a benign condition without related fibrosis or pulmonary dysfunction.

**Parenchymal fibrosis**

There is, however, no doubt that siderosis and parenchymal fibrosis may coexist in the lungs of welders. Materials in their mixed exposure to which the fibrosis has been attributed include oxides of nitrogen, zinc, silica, hexavalent chromium, nickel compounds, aluminium and asbestos.

Aluminium and asbestos merit further attention as the first is becoming increasingly used and the second is a well-proven cause of parenchymal fibrosis in certain groups of arc welders.

**ALUMINIUM**

This metal merits attention because it is becoming increasingly used and welded. Emissions from refining aluminium, manufacture of certain abrasives with the use of aluminium-containing powders are causally associated with specific chronic respiratory diseases. Increased activity of the small airways and reduced expiratory flow through the airways have been noted in aluminium welders. In contrast, the existence of interstitial lung disease caused by exposure to aluminium in general, let alone from aluminium welding, has been the subject of unresolved controversy. There are a very few published individual clinical cases. Additionally, two cases of pulmonary granulomatous reactions, one of desquamative interstitial pneumonia, and one of severe non-reversible obstructive lung disease have been reported in men employed as welders of aluminium. In each, alternative explanations are offered. No epidemiological evidence has been found in support of the hypothesis of there being a causal relationship between aluminium welding and development of chronic interstitial pulmonary disease. A well-designed and implemented cross-sectional controlled survey of clinical findings and lung function tests, albeit limited by small sample size, published in 1985, did not
detect any evidence of pulmonary fibrosis in the study group of 64 aluminium welders. The welders had a higher prevalence of chronic bronchitis than their controls and it is reported that these respiratory symptoms were related to ozone concentrations.

**ASBESTOS**

Parenchymal fibrosis due to asbestos is found in arc welders, especially those who were employed in shipbuilding or repair yards, locomotive works and similar workplaces, where there was heavy use of crocidolite and amosite — and no adequate protection from exposure. Historically, in such places, they worked among the asbestos during lagging, broke into it to gain access to metal on which to weld, were exposed during delagging and, probably of least importance, used it for their protection — tearing sheets to size, thus maximizing dust emission! They had high and sustained exposures to airborne fibres and have been shown to be affected by the whole range of asbestos-related diseases, including mesothelioma.

**Lung cancer**

Welding fume has been classified as ‘possibly carcinogenic to humans’. National statistics and international epidemiological studies have shown that employment as an arc welder is associated with a sustained higher risk of developing lung cancer than is found in the general population. Welding fume from some welding processes contains compounds which are proven carcinogens in other work processes, e.g. hexavalent chromium. The evidence to link the increased risk of lung cancer to these substances or even to processes is not sufficiently strong or consistent to draw firm conclusions regarding specific processes or materials, or even to differentiate between them.

Surveys have shown that, on average, the proportion of welders who smoke or have smoked is likely to be higher than in the general working population. As tobacco smoke is a known lung carcinogen, it must be a strong candidate for at least contributing to causation, but it is also thought likely that the work environment contributes to the excess risk of lung cancer.

A history of working in asbestos-contaminated environments may be an important occupational factor in the excess risk of lung cancer in welders, especially those who smoke or smoked, as people who have been exposed to both asbestos and tobacco have the highest risk for lung cancer. This risk reduces over time since they stopped smoking, emphasizing the importance of smoking prevention and smoking cessation programmes.

Action is needed to control recognized risk factors, such as smoking (by assisting welders to cease), ending all exposure to asbestos (paying particular attention to developing countries), and reducing exposure to the fume and gas emissions from welding processes to at least the nationally defined occupation limits.

**ADVERSE EFFECTS ON REPRODUCTION**

Investigation of reproductive dysfunction requires wide-ranging evaluation and enquiry, including defining occupation and exposures to environmental and industrial toxins. Welders’ reproductive health has attracted much research interest, more than most occupations, perhaps because they may be exposed to a combination of agents which have been linked in other circumstances to reproductive dysfunction, such as ionizing radiation, heat, lead, cadmium, chromium, copper and organic solvents. It has been said that the evidence for welding having an adverse effect on male reproduction is strongly supported in well-designed epidemiological studies.

There can be no doubt that several studies present evidence that being a welder carries risks of adverse effects on sperm quality, fertility and rate of spontaneous abortion. A minority have presented contrary conclusions on some of these matters. Also, no adverse effect on the probability of implantation nor increased risk of spontaneous abortion in in vitro fertilization (IVF) have been demonstrated. Statistically significant associations have been described between spina bifida and paternal exposure to welding fumes and UV. The only reproductive disorder which has been associated with maternal employment as a welder is a possible association with low birthweight, but, importantly, this finding did not survive adjustment for key confounding variables.

Should a welder suggest that his reproductive health is being compromised by his work as a welder, and the quality or quantity of his semen is shown to be subnormal, the several factors mentioned as possible ‘causes’ should be checked. He should stop smoking. Steps should be taken to reduce his exposure to fumes and/or excessive radiant heat.

**HEALTH SURVEILLANCE**

Welders should be under a health surveillance programme designed primarily to detect especially susceptible or sensitized workers with regard to occupational asthma, and, to a lesser but probably still worthwhile extent, to monitor and seek to prevent the development of COPD. It also offers opportunities for education and to encourage self-referral for non-respiratory conditions. It has been recommended or prescribed from time to time in regulations and guidance, but the methods to be adopted are rarely defined clearly other than that they are to be in line with the outcome of the risk assessment. An exception is the abundance of good guidance available to help when exposure includes an agent or agents known to cause occupational asthma.
The necessity and design of such health surveillance of welders should be determined after a formal risk assessment has been completed. Surveillance should be undertaken by appropriately trained healthcare workers. Other personnel may be used for monitoring specific aspects or possible effects. Personal records must be kept. These should allow easy analysis of group health. A basic scheme would start with a baseline assessment for each worker, initially before they started work, with the programme being rolled out to encompass all welders and others identified by the risk assessment. This would include an occupational history and record of current work circumstances (place, process, exposures, protection, etc.); completion of a standardized, previously validated, respiratory questionnaire enquiring about work-related upper and lower respiratory symptoms including pre-existing sensitization to substances they might be exposed to in their (new) job; and standardized assessment of lung function (peak expiratory flow and/or FEV₁ and FVC). There should then be periodic review at intervals determined by the risk assessment and the health of the individual worker and an annual formal expert review of absence said to be due to ill health or injury. The workers should be given information, advice and education about the risk, how it should be controlled, recognizing and reporting symptoms, and stopping smoking tobacco. To this may be added an interview on return from absence and special tests, such as audiometry and biological monitoring, as indicated by the risk assessment.

INHALATION FEVERS

Inhalation fevers are related to many occupations other than welding, but are discussed here because the most common is metal fume fever – and welding is the activity most frequently associated with that disorder.

The term ‘inhalation fever’ collectively describes a group of acute, non-allergic, usually benign and, importantly, self-limiting flu-like illnesses, some with colourful names, which may follow shortly after exposure to any one of a disparate range of inhalable occupational and environmental pollutants. The attack rate is usually higher in those with the highest exposure. Unlike allergic response disorders, there is no discrimination between those with and without previous exposure. Putative pollutants may be grouped, in order of overall population incidence, as metal fumes; pyrolysis products of polymers, principally polytetrafluoroethylene; and bioaerosols. Each of these groups is considered separately below.

There is often a latent period between exposure and the onset of clinical features of an inhalation fever, so the worker may have left the workplace when the illness first becomes apparent. Features may include undulating low-grade – but sometimes high – fever, chills and difficulty keeping warm, shivering, muscle aches and joint pains, headache, malaise and nausea – even vomiting, thirst, chest pain and difficulty breathing and/or breathlessness – the latter ringing alarm bells.

Diagnosis depends largely on pinpointing the cause by way of an appropriately focused and analysed occupational and environmental history – and excluding more serious illness. Physical examination of the chest may be unremarkable or reveal rales and rhonchi. Pulmonary function is commonly unaffected. Although there is likely to be an inflammatory lung infiltrate of polymorphonuclear leukocytes, the chest radiograph should be clear. There is a peripheral blood leukocytosis.

Management of the uncomplicated case of inhalation fever is conservative and supportive. It is usual for the disorder to resolve within two to three days. Of course, the best management is by prevention – seeking to anticipate and control the exposure before cases result, and protecting others who may be at risk of exposure to the damaging pollutant by investigating occupational and environmental sites from which cases arose.

Inhalation fevers may closely mimic or, by their similarities, mask another lung disorder which may be progressive, potentially fatal and result from exposure to pollutants which arise in similar circumstances. It is vital to differentiate specifically between inhalation fever and much more serious conditions. The principal differential diagnosis relevant to inhalation fever includes acute lung injury, infection, hypersensitivity pneumonitis and other immunologic responses.

An alternative diagnosis is likely if improvement does not begin early in the course of the illness and is not completed within two to five days, if at any stage respiratory function is compromised, and/or if infiltrates or other changes are apparent on the chest radiograph. While in inhalation fever occasionally there may be transient acute impairment with reduced lung volume and transfer factor and rarely an asthma-like response, these features should be treated with special suspicion.

Before sending those thought to have an inhalation fever home to recover, it is prudent to consider these alternative diagnoses – and record that this process has been completed and why the decision has been made. Be especially cautious when cadmium is or may be involved. If this is the case, the patient should be kept under observation and initial and monitoring investigations should include measuring urinary cadmium concentration and seeking evidence of renal damage. If the patient is sent or left at home, it is essential to warn them to seek further medical assistance without delay if they develop worsening respiratory symptoms. If recovery does not occur as expected, the diagnosis must be reviewed and the possibility of pneumonitis reconsidered.

The pathogenesis of inhalation fever has yet to be elucidated. The symptoms cannot be engendered by ingestion or intravenous injection of the causative agent, only by inhalation. It is, however, apparent that the lung is not only the sole entry portal and principal target organ, but also the source of whatever substance or substances the inhaled pollutant stimulates to initiate the typical adverse pulmonary and systemic clinically apparent responses.
Research indicates the likelihood of pro-inflammatory cytokines playing a pivotal role.

### Metal fume fever

Metal fume fever is one of the few ancient occupational diseases still encountered in modern industrial practice in developed countries. Caused by inhaling freshly formed fumes, and perhaps very finely divided dusts, of some metal oxides, most commonly zinc oxide, it is the most frequently encountered of the inhalation fevers and rejoices in a wide range of names including ‘Monday morning fever’, ‘Monday ague’ and ‘welder’s shakes’. Sometimes, quite moderate concentrations of the pollutant can provoke an attack, especially if the exposure time is prolonged over the working period. Clinical features typical of an inhalation fever (see under Inhalation fever, p. 436) tend to begin some hours after exposure began and often after work has ceased. Symptoms include thirst, chills, muscle aches, shivering and fever, headache and nausea.

If asked, the affected worker will often admit to welding or being in the vicinity of welding on zinc-containing material, galvanized metal being most commonly involved, but the oxides of several other metals have been implicated. These include magnesium, copper, cadmium, chromium, antimony and iron, but the evidence for these is sparse.

A worker with straightforward metal fume fever requires only conservative and supportive treatment while he recovers over one to three days (five days at most). Rarely, he or she will develop pneumonitis when the concentration of fumes has been unusually high or when the situation is complicated by specific acute metal toxic damage, e.g. due to cadmium. As previously mentioned, it is vital to seek to exclude this initially and to advise the patient of this risk, how to recognize that all is not well and to seek further medical aid promptly.

Some welders believe that an attack of metal fume fever early in the working week confers temporary immunity or resistance. There is no scientific evidence for this view, and it may be that the affected welder is more cautious about minimizing his exposure in the days following such an unpleasant illness!

In common with all inhalation fevers, the pathology of metal fume fever is poorly understood. It may mimic other more serious diseases and has been associated with development of symptoms of welding-related asthma and other serious long-lasting health consequences. It may well be that other effects remain to be identified, particularly in those who have had repeated attacks. It has been concluded in a prospective study that it could be a predictor for the development of respiratory symptoms, but not functional abnormalities, in welders.159

Treatment is conservative and supportive. Before sending those thought to have metal fume fever home to recover, it is prudent to consider the diagnosis lest they actually have as-yet-undeveloped and undetected chemical pneumonitis – which can progress to serious and even fatal consequences (see under Polymer fever). If the decision is made to send them home, it is essential to warn them to seek further medical assistance without delay if they develop worsening respiratory symptoms. Be especially cautious when cadmium is, or may be, involved. If this is the case, on referral of the individual to hospital, initial and monitoring investigations should also include measuring urinary cadmium concentration and seeking evidence of renal damage.

For completeness, it should be noted that inhalation of zinc chloride, as distinct from zinc oxide, while not precipitating an ‘inhalation fever’ can cause serious lung injury. Exposures can occur through the use of zinc chloride-containing smoke bombs in military or police training exercises. It is important not to confuse the effects of these two different exposures.

### Polymer fever

First described in 1951, this fever has the general clinical characteristics of an inhalation fever. It may occur within eight hours or so of the inhalation of pyrolysis products of fluorocarbon polymers or copolymers, the most commonly reported being polytetrafluoroethylene (PTFE) or Teflon®, exposed to temperatures between 250/300 and 750°C. Under normal usage, Teflon is among the most inert non-toxic and non-inflammable substances, but if it is heated in excess of 750–800°C, it will decompose to form hydrogen fluoride, tetrafluoroethylene, hexafluoropropylene and octofluoroisoo-butylene. Other common pyrolysis products include organic fluorides, carbonyl fluoride and perfluoropropane, depending upon the fluorocarbon polymer and the temperature and humidity at which it is burnt.

Outbreaks of polymer fever have been described in workers in an aircraft repair shop and in factories moulding or extruding PTFE, welding on PTFE-coated metal, testing electronic equipment, using mould release sprays and shoe sprays containing fluoropolymers, and in the manufacture of synthetic fabrics, plastics and chemicals, paint and rubber stamps.

Cigarettes rolled or smoked at the workplace and contaminated with particles of polymer may be a source of the fever, pyrolysis products being inhaled with the smoke. A no-smoking rule should be enforced and employees instructed to wash their hands before rolling or smoking cigarettes in permitted areas. Smoking immediately after using a waterproofing spray is thought to have caused an acute respiratory illness in a young man in Japan.160

Higher temperature breakdown of PTFE and related polymers produces highly irritant fumes that can cause acute lung injury, rather than inhalation fever. Severe, acute non-cardiogenic pulmonary oedema has been reported after such exposures, e.g. after overheating a Teflon-coated cooking pan.161 This may have been the situation in a reported case of a syndrome resembling polymer fever, but with chest radiographs consistent with
pneumonitis, occurring in the patient shortly after the inhalation of pyrolysed spray.\textsuperscript{163} It appears that pyrolysis is not always necessary as four cases of toxic pneumonitis with chronic alveolar changes due to direct inhalation of industrial fluorocarbon used as a waterproofing spray for horse rugs has been reported.\textsuperscript{163}

### Bioaerosols

Inhalation fever may be a response to exposure to a range of bioaerosols, including mouldy organic dust (hay, grain, silage, wood and bark in trimming at sawmills and used as garden mulch); dust from flax, cotton, kapok or hemp; or mould or bacteria-contaminated water mists from humidifiers, air conditioning systems, showers and even jet bath tubs.

Organisms causing inhalation fever may also cause more serious pulmonary and systemic illness. \textit{Legionella pneumophila} contaminating the water in these situations causes the inhalation fever called Pontiac fever and may also cause the more serious Legionnaires’ disease (\textit{Legionella pneumophila}). In contrast to the latter, in Pontiac fever the attack rate is high, the incubation period short at between five and 66 hours, and the illness is benign and self-limiting with resolution in one to five days. Cytophaga, an endotoxin-producing bacteria, was shown to be the cause of both humidifier fever and hypersensitivity pneumonitis in a nylon-producing plant.\textsuperscript{164} This further emphasizes the importance and challenge of thorough differential diagnosis in cases of inhalation fever.

**Key points**

- The work of the welder is widely perceived by those in the occupation, often justifiably, as ‘dirty and dangerous’.
- Adverse health effects of most concern include eye, skin and musculoskeletal injuries, acute and chronic respiratory disease, and malignancies of the skin and lung. Occupational injuries are common.
- It is essential to control the risk of exposure to a wide range of potentially harmful particle, gas and radiation emissions, which may vary between and within welding processes.
- A wide range of control and protection measures is available, but their implementation can be a challenging task. Good education and training gives a high return on investment.
- Welders generally warrant pre-employment and periodic health surveillance.
- Metal fume fever is the most common inhalation fever and is most prevalent in welders.

The semiconductor industry

DAVID KOH AND JUDY SNG

INTRODUCTION

The semiconductor industry has developed rapidly over the past few decades and is expected to continue expanding. In 1965, Gordon E Moore, cofounder of Intel (currently the world’s largest silicon supplier), predicted that the number of transistors on a chip would double every two years. This has come to be known as ‘Moore’s Law’, which reflects the increasing complexity and performance of the devices and rapid progress of the industry. The sales volume of the electronics industry could comprise about 10 per cent of the gross world product if current growth trends continue. The electronics industry is heavily dependent on the semiconductor industry, thus both can be expected to grow together. According to the Semiconductor Industry Association, worldwide semiconductor sales totalled US$232.7 billion in the first 11 months of 2008.

A July 2007 press release from the Semiconductor Industry Association stated that in the United States, the chip industry employs a domestic workforce of 232,000 people. In 2001, in the United Kingdom, about 10,000 people were employed directly within the semiconductor industry, and 5000 within the supply base, and a further 30,000 engineers were involved in research and development for the industry.

In its early days, semiconductor manufacturing was mostly located in California (Silicon Valley) and Texas. However, since the 1960s, the industry has spread to many other countries such as Taiwan, Japan, Korea, Singapore, China and India. Taiwan alone is responsible for 70 per cent of total worldwide production of CD-ROM (compact disc read-only memory) devices, as well as 50 per cent of world production of light-emitting diodes with integrated circuit products. In a 2004 evaluation, more than 30,000 people were employed in Taiwan’s semiconductor industry in 350 companies located in the Hsinchu science-based industrial park. In 2006, in India, the semiconductor and embedded design industry generated a revenue of approximately US$4.6 billion and employed almost 102,000 people. By 2015, this is projected to increase to a revenue of US$43 billion and a workforce of 780,000.

The industry is now growing most rapidly in the Asia Pacific region. Previously, this rapid growth was mainly due to demand from countries in the west resulting in a move of their manufacturing bases to Asia. Today, growth in production in this region is mainly a result of increasing domestic demand.

SEMICONDUCTOR MATERIALS

At the heart of the industry is the unique electrical property of substances that are neither conductors nor insulators. A semiconductor is a material whose conductivity is normally between that of a metal and an insulator. In addition, altering temperature or chemical composition can change the conductivity of a semiconductor material.

There are essentially three classes of semiconductor materials:

1. Elemental semiconductors, such as silicon and germanium
2. Compound semiconductors, such as gallium arsenide and indium phosphide
3. Alloy semiconductors, such as silicon germanium and aluminium gallium arsenide.
Silicon is currently still the most widely used material. Gallium arsenide and aluminium gallium arsenide have been used in recent years in the development of quantum-effect semiconductor devices.\textsuperscript{9}

**SEMICONDUCTOR DEVICES**

The term ‘semiconductor device’ usually refers to an integrated circuit (IC or chip). This is a tiny electronic circuit that is created on the surface of a semiconductor substrate, such as a wafer of silicon. The world’s first integrated chip was demonstrated by Texas Instruments in 1958.\textsuperscript{10}

Integrated chips are now used in many home and office items, including personal computers, mobile phones and household appliances, such as washing machines and televisions. Diodes and transistors are also semiconductor devices. These are frequently seen in applications such as light emitting diodes (LEDs) and laser diodes which are used in digital video devices (DVDs) and compact disc read-only memory devices (CD ROMs).\textsuperscript{11}

**WORK PROCESSES IN SEMICONDUCTOR MANUFACTURING**

In semiconductor device fabrication, electronic circuits are built on to a wafer of pure semiconductor material in a series of intricate processes. It takes several weeks to complete the entire manufacturing process from raw materials to packaged chips.

There is a high degree of automation in semiconductor fabrication factories and much of the work processes are enclosed and take place in clean rooms. In a typical semiconductor manufacturing clean room, the humidity is kept low and the air is recirculated through high efficiency particulate absolute filtration units to ensure a dust-free environment (Figure 45.1). These measures are for the protection of the highly sensitive products, where a single speck of dust or spot of condensation could cause profound damage and malfunction. In such an environment, workers are also required to wear special protective gowns, caps, facemasks and boots to prevent them from unintentionally contaminating the materials.

Briefly, the manufacturing process comprises front end processing, which involves production of wafers from pure silicon ingots and fabrication of integrated circuits on to the wafers, and back end processing, which involves assembly and testing, of the finished products (Figure 45.2). The work processes vary widely depending on the desired final product.

**Front end processing**

**SILICON WAFER PRODUCTION**

Sand is used to obtain purified polycrystalline silicon which is then melted. A pure silicon crystal ingot is grown...
from a ‘seed’ – a small piece of pure silicon placed in the molten silicon bath. The seed is gradually drawn up from the bath to form the ingot.

The ingot is sliced into thin wafers by a diamond blade, ground smooth and chemically polished. These wafers are the base for the manufacture of integrated circuits. Some companies list another step known as epitaxy, in which another 0.5–20 micron-thin layer of ultrapure silicon is grown over the wafer to enhance subsequent processes and overall performance of the wafer. The techniques for epitaxy vary from chemical vapour deposition to the newer molecular beam epitaxy.

**PRODUCTION OF MASKS**

The required patterns for the integrated circuits are drawn on to chromium-plated quartz glass plates to form reticles or stencil-like instruments. The chromium plating is removed by lasers or electron beams to form a negative image of the pattern. This plate will subsequently be used as a mask or stencil in photolithography to imprint the patterns on to the silicon chips.

**FABRICATION**

This is a key step in any semiconductor manufacturing, and takes from 1.5 to more than 4 weeks to complete, all within the highly controlled clean room environment.

The wafers are rinsed with deionized water and chemicals (such as diluted hydrochloric/hydrofluoric acid) and then exposed to high temperature and oxygen concentration to induce thermal oxidation – the growth of a uniformly thin insulating film of silicon dioxide on the surface.

Next, the wafers are coated with photoresist – a light-sensitive polymer film which becomes soluble when exposed to ultraviolet light (Figure 45.3).

In a process known as photolithography, ultraviolet light is passed through a patterned glass mask (a stencil) on to the wafer. Thus the pattern is transferred from the glass mask to the wafer. The exposed areas of photoresist become softened by the ultraviolet light and are subsequently washed away with a solvent. The areas of exposed silicon dioxide are etched away with chemicals such as hydro-fluoric acid (wet etching) or plasma etching/reactive ion etching (dry etching). The rest of the photoresist is then removed and the wafers are visually inspected for accuracy of image transfer before being transferred to the next step.

Doping or ion implantation is the next process, where impurities (dopants) are introduced into the exposed areas of the wafer to alter the electrical conductivity of the silicon. Arsenic, boron, antimony and phosphorus are some commonly used dopants.

The above steps are repeated many times to achieve multiple differently patterned layers on the wafer. Atoms of metal (usually aluminium or copper) are deposited into windows created in the wafer, interconnecting the individual devices. This process is known as ‘metalization’. Dielectric films (insulators) are also inserted to separate the components. The circuit is then coated with another protective insulating layer (passivation).

Hundreds of microprocessors are created on one wafer. Every wafer is inspected both macroscopically and with the use of a microscope for scratches and defective patterns. Every single microprocessor is also tested to ensure it is functioning properly. Defective chips are marked for automatic rejection.

At the back end processing factory, a diamond saw cuts the wafer, separating the individual microprocessors (dicing). The chips are mounted on lead frames (‘lead’ as in ‘leader’, not the metal Pb) and connected to the frame by wire bonding. Either gold, aluminium or copper is used to connect the chip to the package. The chips are then inspected again before being encapsulated in resin for protection.

The substances used in the manufacturing process are presented in Table 45.1. This is by no means an exhaustive list, but serves to illustrate the large number of chemicals involved.

**Recent advances**

New techniques and substrates are frequently being tried and introduced in the race to find more precise techniques to produce smaller and faster devices. As a result, the work processes in the semiconductor industry are continually changing. The implications of the substrates and equipment used in new work processes remain to be seen with time.

Shorter wavelength light produced using krypton fluoride or argon fluoride is gradually replacing ultraviolet light for more accurate transcription of miniaturized circuit patterns.

Laser beams are also increasingly being used for more precise dicing of the wafers at the start of back end processing.

An interesting new development is the flexible thin film transistor which can be applied in novel ways, such as paper-like roll-up displays and conformable x-ray

HAZARDS IN SEMICONDUCTOR MANUFACTURING

Chemical hazards

Numerous chemicals are used in semiconductor wafer fabrication, many of which present either safety, corrosion or health hazards. Two issues arise from this. First, multiple concurrent chemical exposures from daily operations and maintenance work are likely to cause health issues that are very different from those resulting from single chemical exposure. There are few data on this issue. Second, possible health effects of other chemicals which might be overlooked (such as byproducts from the reactions between various process chemicals, as well as chemicals used for maintenance and cleaning) need to be considered.

Fortunately, most of these chemicals are used within contained systems in the high-tech environment of semiconductor factories, and thus typically exposure to employees would be minimal. Many companies have sophisticated
engineering control measures to ensure that workers are protected from exposure during normal production runs. Common engineering control measures used include maintaining the processes under reduced pressure, purging of chambers with inert gas before products are removed by workers and monitored process exhaust systems.

However, when maintenance work needs to be performed, some of the engineering controls may need to be either bypassed or shut down. It is then that the possibility of workers coming into contact with the hazardous chemicals is higher. This would be less likely during routine scheduled maintenance work and more likely when the maintenance work is unscheduled, such as in the event of system malfunction. Additional exposure prevention measures need to be preplanned and communicated to the relevant workers.17

Hydrofluoric and hydrochloric acid are used in wet etching and to rinse the silicon wafers prior to thermal oxidation. Both are highly corrosive mineral acids which can cause severe chemical burns. Hydrogen fluoride can also cause hypocalcaemia, hypomagnesaemia and death if systemic absorption occurs.18 Chromic acid used in etching and cleaning can ignite on contact with alcohol. The International Agency for Research on Cancer (IARC) has also designated chromic acid as a confirmed human carcinogen.19

Some etching processes also involve the use of strong alkalis such as sodium hydroxide and potassium hydroxide.

Arsine, phosphine and diborane gases used in doping are flammable or potentially explosive. These gases also carry a health risk: arsine is a potent haemolytic agent, while phosphine reacts with moisture to form phosphoric acid which can cause acute respiratory irritation. Gas detectors for toxic materials are commonly found in clean rooms. (Figure 45.4).

The thermal oxidation of pure silicon wafers requires high concentrations of oxygen coupled with high temperatures of about 1000°C. There is a potential fire and explosion hazard if any reactive or combustible material is accidentally included in the chamber.20

Some of the metals used to generate dopant atoms, as well as alloy and compound semiconductors, are health hazards. Inorganic arsenic causes hyperkeratosis, peripheral neuropathy and anaemia, and has been classified by the IARC as a confirmed human carcinogen. Antimony causes both acute effects of respiratory and mucous membrane irritation, as well as chronic effects of pneumoconiosis, pustular dermatitis and nasal septum perforation.21 Antimony is a suspected human carcinogen.

Many organic solvents are used in semiconductor manufacturing to clean, rinse or dry the chips. The commonly encountered ones are isopropyl alcohol, n-butyl acetate, xylene, acetone, methanol, methoxy ethanol, petroleum distillates, trichloroethane, methylene chloride, tetrachloroethylene, ethylene glycol and methyl ethyl ketone.

Ethylene glycol ether used in photolithography has been linked to prolonged menstrual cycles22 and prolonged time to pregnancy.23 Although the use of ethyl and methyl glycol ethers appears to have been phased out since 1992 in the United States,24 they may still be used in factories in other countries, and can still be found on the waste inventories of some semiconductor manufacturing companies (Figure 45.5).

**Physical hazards**

Ionizing and non-ionizing radiation are used for testing, quality control inspection and curing. Ionizing radiation
(such as x-rays) is used in ion-transfer processes and in quality-control inspection of wafers. Non-ionizing radiation like ultraviolet light, infrared light or microwave is used in photolithography to harden the photoresist layer and to transfer the required patterns from the mask to the wafer. Shorter wavelength light or ‘extreme ultraviolet light’ is used if even greater precision is required.

Some workers may be exposed to high noise levels, although it is not usually considered to be a major issue within semiconductor factories. Vertical laminar flow hoods and ceilings normally create a background noise level of about 75–78 dBA in clean rooms. Core building areas which house the equipment for running the factory operations (for example, air-conditioner compressors, chillers or boilers) are usually the noisiest areas of the factory – often at about 85 to >95 dBA. The main group of workers at risk of noise exposure here would be the maintenance personnel. However, the total duration of work in the core building areas may not be sufficient to cause noise-induced hearing loss.25

The relative humidity level in clean rooms needs to be kept low to protect the components from corrosion. The levels are generally kept at or below 40–50 per cent relative humidity. Low humidity has been linked to skin disorders, such as physical irritant contact dermatitis.26,27 Relative humidity of less than 35–40 per cent can induce pruritus and skin changes related to xerosis, especially in susceptible individuals.28 Workers exposed to relative humidity of 2.5 per cent in an ultradry clean room of a high-tech device-developing laboratory had significantly higher prevalence of skin complaints, such as itch, dryness, rash and pain.29

Psychosocial

Shift work is common in the semiconductor industry, as most factories run continuously. Rotating shifts are a well-documented source of psychosocial stress. Monotonous and repetitive work at a fast and unvarying pace also contributes to psychosocial stress in the semiconductor industry.

This industry also has sizeable numbers of non-production workers. Sales and marketing staff are usually required to travel frequently, and are often under high stress levels due to intense competition between companies to promote their products.

Research and development engineers in the semiconductor industry are also under pressure to design smaller and faster chips with wider capacities and applications, within tight time lines.

Ergonomic

An increasing degree of automation may find ergonomic problems progressively being phased out. However, while automation reduces the physical strain on workers, they are often still required to lift the wafer cassettes in and out of the machines and monitor the running of multiple machines. The Semiconductor Health Study indicated a dose–response relationship between the numbers of hours spent on fabrication work and distal upper extremity pain.30 A study conducted in 2004 on 906 female semiconductor workers from different factories in Malaysia found that 80.5 per cent of the workers had experienced pain in the past year in at least one part of the body, including the neck, shoulders, back, upper and lower limbs. The Malaysian factories studied dealt mostly with back end processing.31

Workers who are required to inspect the chips visually with the use of microscopes at various stages of the manufacturing process may be subject to visual fatigue and other ergonomic problems, such as prolonged or repeated neck flexion. However, much of this work can and has been automated.

Administrative and research and development staff may be subject to the ergonomic issues of office workers from prolonged work at the computer terminal.

Biological

Although biological hazards are not routinely encountered in semiconductor manufacturing work processes, the recycling of air in clean rooms may aid the spread of communicable diseases, such as upper respiratory tract infections.

The risk cannot be overlooked, especially with the experience of the severe acute respiratory syndrome (SARS) epidemic and concerns with influenza outbreaks and pandemics. During the 2003 SARS crisis in Singapore, a worker in an electronics company was diagnosed to have SARS. This resulted in a temporary shut down of the entire electronics line, as all 305 workers on the same shift as the infected worker had to be quarantined.32

An outbreak of conjunctivitis in a microelectronics factory resulted in a temporary plant shut down after safety glasses and routine hand-washing instructions failed to curb the spread of the infection. A total of 145 workers had been affected by that time, and the mode of disease transmission was believed to have been via the sharing of microscopes among workers.33

HEALTH ISSUES IN THE SEMICONDUCTOR INDUSTRY

Cancer incidence

Workers in semiconductor manufacturing facilities are exposed to known and suspected carcinogens. Commonly cited are arsenic and its compounds, antimony and ionizing radiation. These have all been linked with lung cancer occurrence. In addition, some researchers have suggested
that prolonged night shift work increases the risk of breast cancer in women. As previously mentioned, night shift is common in the semiconductor industry, especially among female line workers.

A study conducted in two major semiconductor companies in Taiwan found that the workers were exposed to high levels of arsenic, as well as to gallium and indium. The arsenic level in inhalable air for operators ranged from 5.26 to 106.12 μg/m³. This was above the permissible exposure limit set by the United States Occupational Safety and Health Administration (OSHA). The levels for gallium and indium were between 0.34 to 101.26 μg/m³ and 0.14 to 100.62 μg/m³, respectively. Mirroring these results were the high metal levels in the urine of exposed workers, with a mean level of 39.35 μg/L of urinary arsenic, 10.15 μg/L of gallium and 6.98 μg/L of indium. Cancer risk was calculated by the US EPA Carcinogen Assessment Group’s multistage model to predict dose–specific cancer risk associated with inhalation of inorganic arsenic. The workers were found to have a cancer risk higher than the allowable risk-based US EPA’s acceptable risk limits.4

In a large retrospective study of over 100 000 staff working in IBM factories, the mortality rates and causes of death were noted. No conclusive evidence of causal association between work and increased mortality from any form of cancer was found, although there was some suggestion of increased rates of central nervous system cancer in process equipment maintenance workers in one plant and prostate cancer among facilities/plant engineers and laboratory workers in another plant.35

A retrospective study was conducted based on 4388 workers in a Scottish semiconductor manufacturing facility. Fifty per cent of the male workers and 79 per cent of the female workers were recorded to have been involved in fabrication work in this factory. Although total cancer registrations were close to expected levels for both males and females, the authors identified increased rates of cancers of the respiratory tract, stomach and breast in females, and mortality from cancer of the brain among males. In females, the standardized registration ratio (SRR) for malignant neoplasms of the trachea, bronchus and lung was 273, for malignant neoplasms of the stomach the SRR was 438 and the SRR for breast malignancies was 134. For males, the main finding was a standardized mortality ratio (unadjusted) of brain cancer of 401.36

Another retrospective study published in 2005 that focused on 1807 workers from a semiconductor factory in the United Kingdom found significantly elevated standardized registration ratios for malignant melanoma (SRR, 217) and rectal cancer (SRR, 199) in males and females, and pancreatic cancer (SRR, 226) in females. Detailed work history was not analysed in this study. A case–control study conducted in 1993 found increased risk of cutaneous melanoma (odds ratio, 2.03) in individuals who had previously worked in the electronics industry.38

The current data on cancer experience among workers in the semiconductor industry is patchy and inconclusive. Other studies are currently ongoing in an attempt to establish more clearly the relationship between occupational exposures and cancer incidence.

Reproductive problems

The association between semiconductor work and reproductive disorders remains a controversy. The main reason for this is the inherent difficulty of obtaining sufficient sample sizes of pregnancy-related epidemiological studies. In a United States retrospective cohort study, the spontaneous abortion rate of 904 female workers with eligible pregnancies was studied. The risk of spontaneous abortions was slightly higher in fabrication-area workers (adjusted risk ratio, 1.43) compared with non-fabrication workers. Further analysis of specific work exposures showed a dose–response association of spontaneous abortions with photoresist and developer solvents. The main constituent of these would be ethylene-based glycol ethers.39 A later study that was conducted by the Health and Safety Executive in the United Kingdom found no evidence of increased risk of spontaneous abortion among female workers in the British semiconductor industry who were also exposed to ethylene glycol ethers. This was a nested case–control study that was based on a retrospective cohort of 2203 females. From these, 116 were selected as cases or controls. The adjusted odds ratio for spontaneous abortions was 0.58 for fabrication workers.40

In Taiwan, 292 pregnancies from 173 female workers from a wafer manufacturing company were studied and the relative fecundability as reflected by the fecundability ratio (FR) was calculated. The waiting time to pregnancy was prolonged (FR, 0.77) among female workers in the photolithography area compared to non-fabrication workers. In addition, among fabrication workers, those who worked in areas where they were potentially exposed to ethylene glycol ethers had longer time to pregnancy (FR, 0.59) compared to those who were not likely to be exposed.23

Another Taiwan-based study of 606 female workers compared workers in the fabrication areas with those working in non-fabrication areas. Fabrication workers had a 2.0 odds ratio for long menstrual cycles (defined as cycles that were more than 35 days long) compared to workers in non-fabrication areas. Fabrication workers in the photolithography areas, who were likely to be exposed to ethylene glycols and isopropyl alcohol had the highest odds of long cycles (5.0, compared to non-fabrication workers).22 However, this is in contrast to other earlier studies that found shortened menstrual cycles in relation to ethylene glycol ether exposure, underscoring the need for further, more conclusive evidence.41

Male fertility was also assessed during the Semiconductor Health Study in 1990 to 1991, comparing men working in fabrication rooms with those in non-fabrication areas. Men who worked in the furnace, thin-film or ion implantation
areas of fabrication sections were more likely to report previous difficulty conceiving (defined as needing one or more years to achieve conception; relative risk, 1.79) and to have lower past fertility (adjusted fertility ratio, 0.79). However, contraception data were not collected in this study.\textsuperscript{42}

**Decreased white cell counts**

Male fabrication workers in a Taiwan semiconductor plant who were involved in photolithography and implantation work were found to have significantly lower white cell counts than male office workers in the same company. The office workers had a mean white cell count of 7350/mm\textsuperscript{3}, while male workers in photolithography and implantation areas had mean counts of 5870 and 6190/mm\textsuperscript{3}, respectively. The prevalence of leukopenia, defined for the purpose of the study as a white cell count of 5 \times 10\textsuperscript{3}/mm\textsuperscript{3} or less, was also significantly higher in male photolithography workers (30 per cent) compared to male office workers (5.6 per cent). The authors suggested the risk of intermittent short-term peak exposures to glycol ethers, ionizing radiation, arsenic and other toxins in these male workers to be the possible cause of lower white cell counts.

Female workers in the photolithography section had marginally elevated liver enzyme levels. The fabrication processes in this company were automated and workers had no direct contact with the chemicals under normal working circumstances. Previous studies had also found the estimated exposure concentrations of solvents to be below the permissible exposure limit. The control systems within the plant were found to be in good order, with careful attention paid to the prevention of toxic chemical leaks.

Thus, the finding of a biological effect on the workers, despite maintaining seemingly adequate environmental control, suggests that adverse health effects may occur at levels below the permissible exposure limit.\textsuperscript{43}

**Genotoxicity**

In a 1991 German study, the genotoxic effect of exposure to chemicals including boron compounds was assessed by looking for the formation of micronuclei in lymphocytes. Twenty workers who had contact with open plasma etching processes had significantly higher mean frequency of micronuclei (9.2 micronuclei per 500 billion cells) than a control group of 21 workers who were not exposed (5.7 micronuclei per 500 billion cells). This was despite the fact that environmental levels of boron trifluoride and boron trichloride were under the detection rate. Urinary boron fluoride measurements also did not indicate significant chemical exposure. A second survey was conducted in 2004, 12 years after the implementation of numerous control measures. The levels of micronuclei in exposed workers had decreased to 3.2 per 500 billion cells. The conclusion drawn by the authors was that the workers could have been exposed to intermediate products formed by a variety of chemicals during the plasma etching process. These intermediate products were not individually identifiable, but had the potential to cause genotoxicity.\textsuperscript{44}

**IMPACT ON THE ENVIRONMENT**

There has been concern about the discharge into the environment of toxic and persistent waste material by semiconductor manufacturing facilities. In early 2002, the Silicon Valley in the United States had more than 150 polluted groundwater sites.\textsuperscript{45}

In a 2004 Taiwan survey, groundwater from around the semiconductor industrial park was tested for arsenic, gallium and indium levels. The average arsenic concentration in the well water samples was 34.19 \mu g/L. This far exceeds the level set by the Environment Protection Agency for drinking water of 10 \mu g/L. Average gallium and indium levels in the water were 19.34 and 9.25 \mu g/L respectively.\textsuperscript{5} Gallium, arsenic, indium and thallium were also found in high concentrations in the kidney, liver and lung tissues of squirrels captured from a county adjacent to Taiwan’s main semiconductor industry site. Squirrels of the same species that were captured from Japan had much lower levels of the elements tested. In particular, renal thallium concentrations were two to three times higher in the Taiwanese squirrels compared to the Japanese specimens.\textsuperscript{46}

On the positive side, the industry has been able to find environmentally safer alternatives to the ozone-depleting chlorofluorocarbons (CFCs). In the 1970s to early 1980s, CFCs were being used in massive amounts in the Silicon Valley and in Japan as they were thought to be safer than trichloroethylene. When it was realized that CFCs were damaging the ozone, the semiconductor industry moved to develop alternatives. By the end of 1992, many electronics companies worldwide had stopped using CFCs.\textsuperscript{47}

**CONCLUSION**

The semiconductor industry is large and rapidly growing in many aspects. The industry employs millions of people worldwide, and is an important driving force behind the economies of many countries. Cutting-edge research and development is a cornerstone of the industry, designing smaller yet faster and more complex products within a short time and finding more efficient ways to manufacture them.

The work processes within the industry are diverse, varying from country to country, and depending on consumer demand. Many hazardous chemicals and agents are used, albeit within enclosed and automated processes. The potential for exposure still exists, and occupational health personnel need to be aware of this and understand the unique work experiences of each set of workers under their care.
Key points

- In many countries, the semiconductor industry is an important employment sector.
- Work processes within the industry and resultant worker exposures vary greatly.
- While many highly toxic substances, such as arsine and hydrofluoric acid, are used, most processes in this high-tech industry are enclosed and automated.
- Work processes and materials used are continually changing as research and development progresses towards greater precision, smaller and more powerful devices, that consume less energy.
- Occupational health problems associated with semiconductor work are dermatitis, and issues related to shift work and work-related musculoskeletal disorders. Currently, there are insufficient data on cancer risk in semiconductor workers.

Noise

46 Sound, noise and the ear
   Richard T Ramsden and Shakeel R Saeed
INTRODUCTION

There has been an awareness for several centuries that exposure to high levels of sound may be detrimental to an individual’s hearing. The objectives of this chapter are to review the response of the ear to normal and hazardous sound levels, examine the issues of assessment and management of patients presenting with possible noise-induced afflictions of the ear, and discuss the legal provisions available for such individuals.

THE PHYSICS OF SOUND

The application of a mechanical force to an elastic medium, such as air, results in the displacement of the particles or molecules that constitute that medium. The energy in the displacing force effectively overcomes the mass or inertia of the molecules. This displacement is resisted by a force that tends to return the molecule or particle to its resting position, that is the elasticity. In effect, the displacing force sets up an oscillation or vibration in that medium, which is essentially sound. This oscillation would continue indefinitely if it were not for the frictional resistance that is also inherent to any vibrating system. As a result of this frictional resistance, the energy in the initial displacing force is dissipated as heat and the vibration ceases. The transfer of kinetic energy between vibrating molecules, however, leads to a propagation of the sound through the medium. This generates alternating areas of condensation (with a rise in ambient pressure) and rarefaction (with a fall in ambient pressure) within the medium (Figure 46.1). There is no net movement of the medium as such, but rather the movement of changes in pressure in the medium, which is a sound wave and takes the form of a sine wave when the pressure changes are plotted against time. A sound wave thus has two fundamental properties: its intensity (amplitude of the peak of the wave form), correlating subjectively with loudness, and its frequency, which has the subjective correlate of pitch.¹

Sound wave intensity

By definition, the intensity of a sound wave is its power per unit area (expressed in watts per metre squared) and depends on the peak pressure of the sound wave and the peak velocity of the air molecules. The peak pressure and peak velocity are proportional to each other, the constant of proportionality being the impedance of the medium through which the wave is being propagated. The ambient pressure of a sound wave depends on the point on the sinusoid wave form at which it is measured and therefore the relationship between the intensity and the peak pressure will also vary in this manner. In order to overcome this during quantification, the average or root mean square (RMS) value of the pressure is calculated from pressure measurements at points along the waveform. This allows the intensity of the sound to be calculated from the RMS pressure for a medium with a known impedance. Unlike intensity, sound pressure can be readily measured with a
microphone and is expressed in newtons per square metre (N/m²) (pascals (Pa)). The auditory system, however, is sensitive to a vast range of sound pressures: $2 \times 10^{-5}$ N/m² for the threshold of hearing to around $1 \times 10^5$ N/m² next to a jet aircraft at take off. With such a wide numerical range, the impracticalities of quantification and calculation are obvious. Second, the ear does not respond in a linear manner to linear changes in sound pressure. In fact, the ear perceives changes in intensity more closely to logarithmic changes in power or sound pressure. The use of the logarithm of the ratio of the measured pressure to a reference pressure or ratios of intensity or indeed power overcomes the two difficulties cited.

Logarithms to the base 10 of these ratios are termed 'bels' after Alexander Graham Bell, as the scale was first used in telephony. In practical terms, one-tenth of a bel or decibel (dB) is more convenient for the sizes of the numbers involved. Thus:

\[
\text{Sound pressure level in bels (SPL)} = \log_{10} \left( \frac{\text{RMS measured sound pressure}}{\text{Reference sound pressure}} \right)
\]

\[
\text{Sound pressure level in dB (SPL)} = 10 \log_{10} \left( \frac{\text{RMS measured sound pressure}}{\text{Reference sound pressure}} \right)
\]

To express the sound intensity which varies as the square of the pressure:

\[
\text{Intensity (dB SPL)} = 20 \log_{10} \left( \frac{\text{RMS measured sound pressure}}{\text{Reference sound pressure}} \right)
\]

Using this decibel scale for measuring sound pressure levels (SPL), the reference sound pressure is $2 \times 10^{-5}$ N/m² (20 μPa), 0 dB SPL corresponds to the threshold of hearing and 130 dB SPL the threshold of pain. Audiometrically, however, the reference pressure is frequency dependent as the threshold sensitivity of the human ear is frequency dependent (see Sound wave frequency, p. 461). These reference pressures have been defined by the International Standards Organization (ISO 389: 1991) and are the same as those of the British Standards Institution (BS 2497: 1992). Using these reference pressures, an audiometric sound level of say 30 dB is written as 30 dB hearing level (HL) and if this corresponds to the threshold of hearing of an individual's ear then the threshold is said to be 30 dB HTL (hearing threshold level) for that ear. Conveniently, the minimum detectable change in intensity is 1 dB SPL and an increase of 10 dB SPL gives a subjective sensation of doubling the loudness of a sound, although the intensity of the sound has increased ten-fold.

Table 46.1 shows the internationally agreed reference levels for the calculation of decibels of sound with respect to power, sound pressure and intensity. One other relevant consideration relating to sound intensity is the effect of distance from the sound source. For a theoretical point sound source in a homogeneous medium, the intensity of the sound is a function of the power per unit area. Since the area increases as the square of the distance from the source, the intensity is inversely proportional to the square of the distance from the source of the sound. In reality, the presence of physical obstructions with the resultant reflection, diffraction and absorption effects tend to confound this relationship.
Sound wave frequency

The number of complete cycles of a sound wave per second is its frequency, expressed in hertz (Hz). At sea level with an ambient temperature of 15°C, the velocity of sound waves is 330 m/s in free air. Therefore, a sound wave with a frequency of 330 Hz has a wavelength of 1 m and as the frequency increases, the wavelength decreases. The human ear in a child or young adult has a frequency perception range between 20 Hz and 20 kHz. The high frequency sensitivity diminishes with age such that few adults over the age of 30 years can detect sound with a frequency greater than 16 kHz.

The frequency of a sound broadly correlates with the subjective sensation of pitch. The threshold of human hearing, however, varies with frequency with maximum sensitivity between 2 and 3 kHz which encompasses the important speech sounds. This necessitates the use of a correction factor or weighting when measuring sound pressure levels or hearing thresholds and several such weighting curves exist. Of these, the ‘A’ weighting scale (low and extremely high frequencies weighted less heavily) is commonly utilized as it best correlates with measured and perceived sound. A statement of a sound pressure level should also, therefore, indicate the weighting utilized by means of a suffix, e.g. 30 dB (A) SPL.

As with sound intensities, the ear subjectively responds to incremental changes in frequency ratios, rather than in a linear manner. Hence, doubling the frequency of a tone produces a perceived change in pitch of one octave. Conventionally therefore, tuning fork tests and audiometric testing is undertaken in multiples of 256 Hz (middle C) though among musicians, middle C corresponds to a frequency of 261 Hz. Everyday sounds, of course, are more complex than those of a simple sinusoid (sine wave). Analysis of a complex waveform by breaking it down into its component sinusoids (Fourier analysis) allows the relative contribution of the components to be determined by frequency and relative amplitude. Periodic sounds (waveforms in the same time interval) are shown to have components that are multiples of the fundamental frequency or harmonics. These in part give a musical note, for example, its particular timbre. For non-periodic sounds, such as the spoken voice, analysis shows that rather than discrete component frequencies, there is a continuous range of frequencies or spectrum.

**Noise**

The preceding discussion examines sound in terms of its physical properties. Physically, noise is a complex sound whose characteristics are not easily amenable to analysis and has little or no measurable periodicity. Physiologically, noise is an uninformative signal with variable intensity. Psychologically, any sound that is unpleasant, noxious or unwanted is noise irrespective of its waveform. Noise may be classified as continuous (steady-state or fluctuant) or intermittent (impulse or impact). Impulse noise, such as the noise generated from a gun blast, is characterized by its short duration and shock-front pressure waveform. Impact noise, such as in pile driving, is characterized by little or no shock-front, but considerable reverberant sound. The characteristics of intermittent noise merge into those of continuous noise if the former is repeated very rapidly.

**ANATOMY AND PHYSIOLOGY OF THE EAR**

Structurally and functionally, the human ear is divided into three parts, namely the outer ear, middle ear and inner ear (Figure 46.2). Together with the central connections of the ear in the brain, each part plays a role in the process of hearing and therefore merits further consideration.

**The outer ear**

The outer or external ear comprises the auricle (pinna) and the external auditory canal. Collectively, these serve to modify incoming sound in two specific ways. First, the combination of the auricle behaving as an ear trumpet, concentrating sound from a large area to the smaller area of the external canal and the natural resonances of the external canal itself serves to increase the sound pressure level at the tympanic membrane by about 10 dB over a frequency range of 2–7 kHz. Second, based on the above phenomenon and the fact that a proportion of incident sound is reflected off the head in a manner dependent on the direction of the sound, the outer ear provides some information about sound localization.

**The middle ear**

Embryologically derived from the outer and middle ear, the tympanic membrane (drumhead) constitutes the major component of the lateral or outer wall of the tympanic cavity. Within this cavity are the three ossicles, the malleus, incus and stapes, linking the drumhead to the inner ear. The middle ear cavity communicates with the pharynx at the back of the nose by the Eustachian tube and with the mastoid air cells by the aditus ad antrum. The fundamental function of the middle ear is mechanically to couple acoustic energy to the cochlea. To do this effectively, the middle ear has to match the impedance of air to
the considerably higher impedance of the inner ear fluids, that is, function as an acoustic sound pressure transformer. The effect of this, in combination with the effects of the outer ear already described means that up to 50 per cent of the incident sound energy is transmitted to the inner ear as opposed to the expected 1 per cent in the absence of the transformer. This is achieved by two mechanisms. The leverage of the malleus and incus about their axis of rotation gives a \( \frac{1}{1003} \) mechanical gain. The difference in the functional surface area between the drumhead and the stapes footplate which sits in the oval window gives rise to a 14-fold hydraulic effect. Combining the two provides an increase in pressure at the oval window by a factor of around 18.

The second consideration is that the cochlear fluids, like any fluid, are incompressible. The ossicular chain preferentially directs acoustic energy to the stapedial end of the cochlear compartment. The other end of this compartment is closed by the round window membrane which is able to deform in response to the pressure change in the cochlear fluids. Relative to the oval window, the incident acoustic energy at the round window is very small due to the effect of the ossicular chain and the presence of air (via the Eustachian tube) in the middle ear cavity (Figure 46.3).

The inner ear

The inner ear consists of two parts: the osseous labyrinth and the corresponding membranous labyrinth which lies within it. Descriptively, the labyrinth comprises the semicircular canals and vestibule which house the sensory end organs of balance and the cochlea within which is the hearing organ (Figure 46.4). Lying in the medial wall of the middle ear, the cochlea is shaped like a snail’s shell with two and three-quarter turns, 5 mm in height and 9 mm across the base. The central bony axis of the cochlea (modiolus) has a spiral bony lamina projecting from it along its length which is completed by the basilar membrane. On this lies the cochlear duct (membranous labyrinth) effectively dividing the cochlear lumen into three compartments, the scala vestibuli (in continuity with the vestibule, containing perilymph), the scala tympani (in continuity at the apex of the cochlea with the scala vestibuli and closed by the round window membrane) and the scala media (containing endolymph), within which is the organ of Corti (Figure 46.5). The organ of Corti is a specialized area of the lining of the cochlear duct that runs the whole length of the cochlear spiral and is around 35 mm long.
The sensory cells of the organ of Corti are arranged in one inner row and three to five outer rows. Microfilaments (stereocilia) from the sensory cell surface have given rise to the descriptive term sensory hair cells (Figure 46.6). This represents the interface where mechanical energy is converted to electrical energy; the organ of Corti is thus a specialized transducer. From the sensory cells, afferent nerve fibres pass together as the cochlear nerve to the brainstem and ultimately to the auditory cortex of the brain.

The incident mechanical energy at the oval window sets up a series of waves in the perilymph of the scala vestibuli which in turn distort the membranes of the cochlear duct.
In the 1940s, Békésy introduced the concept of the travelling wave (Figure 46.7) following a series of experiments in which he observed the movements of cadaveric basilar membranes in response to high intensity sounds at different frequencies. The travelling waves for higher frequencies peaked at the basal end of the cochlear, while the lower frequencies produced a peaked wave towards the apex. He correctly concluded that the basilar membrane had the property of frequency selectivity. More recent work has shown that the mechanical response of the basilar membrane (by way of tuning or frequency-threshold curves) and indeed the tuning curves for hair cells and the auditory neurons is very narrow. There is thus a sharp band pass frequency for a given point on the basilar membrane, the hair cells in the organ of Corti at that point and the auditory neurons from those sensory cells. The deflection of the basilar membrane results in deflection of the stereocilia of the sensory cells in the organ of Corti. Depending on the relative movements of the stereocilia, ion channels in the sensory cell membrane are either opened or closed. The resultant movement of potassium and calcium ions from the endolymph into the hair cells and change in their relative electrical potentials leads to the release of neurotransmitters in the synapses at the base of the hair cells giving rise to action potentials in the auditory nerve fibres. This then completes the process of transduction as the inner hair cells are in contact with 95 per cent of the afferent fibres of the auditory nerve.

**OCCUPATIONAL NOISE-INDUCED HEARING LOSS**

**Historical aspects**

One of the earliest descriptions of the adverse effects of noise on hearing was by Francis Lord Bacon in 1627. He wrote, 'A very great sound, near hand, hath strucken many deaf.' He relates his own experience of what was a temporary threshold shift, ‘… myself, standing near one that lured (whistled loudly to call back a falcon) loud and shrill, had suddenly an offence, as if somewhat had broken or been dislocated in my ear; and immediately after a loud ringing (not an ordinary singing or hissing, but far louder and differing) so I feared some deafness. But after some half quarter of an hour it vanished'.

Nearly a century later, a report by Ramazzini recognized the relationship between copper hammering and hearing impairment and in 1782, Admiral Lord Rodney was deafened for two weeks following the firing of 80 broadsides from his ship HMS Formidable. In 1831, Fosbroke accurately described noise-induced hearing loss in blacksmiths and coined the phrase ‘blacksmith’s deafness’. It was the
arrival of the Industrial Age, however, that led to a more widespread recognition of the deleterious effects of intense or prolonged noise on hearing: Roosa and Holt in the United States of America, Bezold in Germany and Barr in Great Britain.5

The work of Thomas Barr merits further consideration. He undertook field studies comparing the hearing in 100 boilermakers, 100 ironmoulders and 100 postmen.19 He wrote, 'It is familiarly known that boilermakers and others who work in very noisy surroundings are extremely liable to dullness of hearing. In Glasgow, we would have little difficulty in finding hundreds whose sense of hearing has thus been damaged, by the noisy character of their work. We have therefore in our city ample materials at hand for investigation on this subject'. Barr found that 75 per cent of the boilermakers had difficulty in hearing at church or at a public meeting compared with 12 per cent of the ironmoulders and 8 per cent of the postmen. Four years later, in 1890, the pathology of noise-induced hearing loss was described by Habermann. Partial loss of the organ of Corti with destruction of the hair cells, particularly in the basal turn was noted.20

Following the introduction of audiometry, Fowler in 1929 observed the characteristic 4-kHz dips and the first systematic audiometric studies were reported in 1939 by Bunch and by Larsen.21–23 The technological advancements seen after the Second World War were paralleled by ever-increasing noise levels in the workplace. While loss of earnings due to hearing loss caused by acute trauma at work was compensatable from the early part of the last century, it is only in the last 35 years that the legislative bodies of developed countries have recognized occupational noise-induced hearing loss, put into place mechanisms to confer responsibility on the manufacturing industries and compensate those individuals deemed to suffer this disorder.

Epidemiology

Occupational noise-induced hearing loss is considered one of the most common occupational disorders in industrial countries. Apparently, between 1 and 4 per cent of the population are exposed to harmful or potentially harmful noise levels and the presence or effectiveness of hearing conservation programmes will dictate the proportion of these individuals who do not have a noise-induced hearing deficit.4 The paucity of hard data on hearing impairment in the adult population prompted the Medical Research Council to fund a multicentre epidemiological study which was carried out in the 1980s. This rigorous study (UK National Study of Hearing) found that 12 per cent of adults in the United Kingdom had a sensorineural hearing defect. Around one-third of these was accounted for by age and 5 per cent by noise.24 This would imply that around 1 in 200 of the adult population has noise-related sensorineural hearing impairment. Putting aside principal factors, such as the level and nature of noise exposure, its duration and hearing conservation programmes, adjunctive factors are also recognized. Variations in individual susceptibility are now considered to be multifactorial, but nonetheless a real entity.25 The evidence for differences in susceptibility between men and women or between dark- and fair-skinned individuals is conflicting.25,26 Indeed, a recent pilot study showed that in view of their ambivalence to their disorder, women with noise-induced hearing loss are less likely to be reported than men in studies examining noise-induced hearing loss.27 With regard to children, a study that screened over 14 000 Swedish schoolchildren found a greater than 20-dB, 4-kHz dip in 2.3 per cent with nearly two-thirds having an identifiable noise exposure factor, such as firearms and crackers.28 Perhaps the greatest area of concern, however, is that while developed countries are slowly bringing noise under control, the developing nations are witnessing an ever increasing level of urban and industrial noise.

Effects of sound stimulation and hazardous noise

ADAPTATION (PERSTIMULATORY FATIGUE)

This is an immediate physiological phenomenon that occurs when a sound is presented to the ear. For sound pressure levels up to 80 dB, the greatest elevation in threshold occurs at the same frequency of the stimulating tone. There follows an exponential recovery which occurs within 1 second. Electrophysiological animal studies have shown that adaptation correlates with a reduction in auditory nerve action potentials.29 For higher stimulating sound intensities, true temporary threshold shift sets in though the intensity of stimulation required varies from individual to individual and depends on the frequency of the stimulating tone.

TEMPORARY THRESHOLD SHIFT (POST-STIMULATORY FATIGUE)

The magnitude of a temporary threshold shift is proportional to the intensity and duration of the stimulus and the recovery, unlike adaptation is slow. Recovery usually occurs within 16 hours, but may take several days with higher intensities. The risk of developing permanent threshold shift has been studied by Mills and is complex.30 Interactions between the level, nature and number of noise exposures, their duration and frequency and the susceptibility of the individual are all factors (Figure 46.8). Classically, there is a high frequency rise in threshold with a characteristic notch at 4 kHz (Figure 46.9), though the notch may centre at 3 or 6 kHz. This is often accompanied by tinnitus and after a short rest period, the rise in threshold recovers. With repeated exposure, there is a tendency to acquire resistance to the auditory effects in that the degree of temporary threshold shift lessens31 though at
some arbitrary point, continued exposure leads to a permanent threshold shift.

PERMANENT THRESHOLD SHIFT

This is characterized by irreversible audiometric effects and pathological changes in the cochlea. The 4-kHz notch tends to deepen but also insidiously widens, encompassing adjacent high frequencies (Figure 46.10). Once the audiometric changes encroach upon the speech frequencies (2 and 3 kHz in particular), the affected individual becomes aware of the diminished acuity in his or her hearing. Speech discrimination with background noise becomes difficult and the associated tinnitus (which is highly variable in character) may become intrusive. The rate of progression again depends on the noise parameters cited previously and on individual susceptibility. Generally, progression at 4 kHz is initially rapid, but slows down after 10–12 years. Progression to involve the lower frequencies is associated with a flattening of the audiogram in the highest frequencies (Figure 46.11) such that the characteristic notched audiogram is not a prerequisite for a diagnosis of occupational noise-induced hearing loss. At this stage, the impaired speech discrimination in noise is accompanied by the complaint of sound generally being too quiet.5

With the progression of time, the increasing effects of ageing on auditory function come into play and this aspect assumes importance in the evaluation process of those being assessed with possible occupational noise-induced hearing loss (see below).

Pathology

As mentioned previously, the correlation of occupational noise-induced hearing loss with cochlear pathology was first described by Habermann in 1890. He reported that it
was the organ of Corti, particularly the sensory hair cells and occasionally the spiral ganglion cells of the auditory nerve fibres that were affected. Studies by Igarashi and colleagues and Bredberg showed that the site of predilection in the organ of Corti was 11 mm and 10.5–14 mm, respectively, from the beginning of the basal turn of the cochlea. This corresponds to an area that is responsive to sound frequencies around 4 kHz.

The work of Békésy in the 1940s not surprisingly led to attempts to tie in his mechanical travelling wave theories with pathological changes in the cochlea. If the maximal excursion of the basilar membrane in response to a travelling wave is in its central relatively unsupported part, then the shearing stress is exerted maximally at this point and would explain why the supporting cells of the inner hair cells and the first row of the outer hair cells are the structures that sustain most injury. As the limitations of the Békésy model were realized and technological advances, such as electron microscopy, became available, the ultrastructure and function of the hair cells themselves has become the focus of attention.

Progressive degrees of stereocilial damage and hair cell death correlate with temporary and permanent threshold shifts (Figure 46.12). The sensitivity of the afferent inner hair cells depends in part on the function of the efferent outer hair cells and it is postulated that dysfunction of the latter has an adverse effect on the function of the former. The time-honoured belief that the pathological site correlated with the threshold shift has also been challenged as there is a variation in the distribution of the hair cell loss and loss of cochlear sensitivity, related perhaps to the response of the middle ear muscles to different types of hazardous sound stimulation. In addition to these mechanical factors, metabolic and vascular factors have been postulated.

It is becoming increasingly apparent that the damage to the cochlea caused by excessive noise is the result of cellular injury from reactive oxygen species (ROS). ROS are ions or small molecules that include oxygen ions, free radicals (hydroxyl radical OH, peroxyxinitrite radical ONOO) and peroxides (e.g. hydrogen peroxide, H$_2$O$_2$) and are produced in the mitochondria. They are a natural product of oxygen metabolism and have an important role in cell signalling. They may, however, be produced in excess in response to stress and are then capable of causing serious damage to cell structures, a condition known as 'oxidative stress'. They have a role in programmed cell death (apoptosis), and also have some beneficial effects in the induction of host defence genes. The damaging effects of ROS include damage to DNA, oxidation of fatty acids and amino acids and inactivation of enzyme systems. Normally, there are enzyme systems that protect the cell from damage from ROS, such as superoxide dismutase, catalases, glutathione peroxidases. In addition, antioxidants, such as ascorbic acid (vitamin C) and tocopherol (vitamin E), have a major role in scavenging free radicals.

The cochlea is metabolically highly active and produces ROS which are in normal circumstances neutralized by endogenous antioxidant mechanisms. There is evidence that oxidative stress can be responsible for cochlear impairment as a result of an accumulation of harmful free radicals. Noise exposure is the most common cause of this stress, but similar mechanisms are at play in cochlear injury from ototoxic medication. One factor which seems to play a significant part in causing these metabolic changes is the role of reduced cochlear blood flow following stimulation with loud noise.

There is a body of animal work to support the ROS theory. During acoustic overstimulation, there is a change in cochlear homeostasis with an increase in the uptake of glucose and an increase in the perilymphatic oxygenation. Superoxide anions and hydroxyl radicals build up in the scala media after excessive exposure to noise. Ohlemiller et al. demonstrated a two-fold increase in hydroxyl radical in the cochlea after a one hour exposure to broadband noise of 112 dB. The process of lipid peroxidation consists of a series of reactions through which free radicals and ROS can break down lipid molecules, such as cell membranes. There is evidence of increased lipid peroxidation after noise exposure. Noise-induced changes in the sensory cells of the cochlea may also be mediated through the Src-protein tyrosine kinase (PTK) signalling cascade. It is clear that there is much laboratory animal work being done and many points in the homeostatic pathway are being identified at which injury from noise may occur. It is interesting that the changes in the cochlea are not all immediate and that there is a significant late formation of free radical as late as seven to ten days following noise exposure.
The effects of middle ear disease

The widely held belief that a conductive hearing loss due to middle ear disease serves to protect the inner ear from hazardous noise is open to debate as the literature is somewhat conflicting. Alberti and colleagues studied a group of individuals with otosclerosis and presumed occupational noise-induced hearing loss and found that there was no difference in the bone conduction threshold curves between the operated and non-operated ear, even though the individuals concerned had continued to work in a noisy environment after their surgery. Similarly, Simpson and O’Reilly could not demonstrate a protective effect on the inner ear in a worker with chronic middle ear disease.

In contrast, a study by McShane and colleagues examined the hearing in workers with unilateral unoperated otosclerosis and demonstrated a small protective effect (around 4 dB) in the affected ear at 4 kHz.

Hinchcliffe has discussed the reasons for such disparate findings and reduces them to two main factors. First, the two most common causes of adult conductive hearing loss, otosclerosis and chronic inflammatory middle ear disease, may be associated with sensorineural hearing loss – the former as cochlear otosclerosis and the latter as a complication of the disease. The pathological status of the middle ear in terms of extent, nature and activity also has a bearing on inner ear function. Ossicular fixation (whether due to otosclerosis or otherwise) alters the middle ear resonance and may give rise to the 2-kHz Carhart notch in the bone conduction threshold. Second, the temporal relationship between the onset of the conductive hearing loss and noise exposure is also relevant. Clearly, the interaction between middle ear disease and inner ear function is complex and one cannot draw the intuitive conclusion that a conductive hearing loss acts as some form of hearing protective device.

Figure 46.12 Change in the stereocilia of guinea pigs. (a) Exposure to 110 dB for 30 min; half an hour after exposure, there is swelling of the cuticular plate (arrow) ×2800. (b) Exposure to 110 dB for 30 min; 80 days after exposure, 9.5 mm from the round window. The inner and outer hair cells appear normal as was the hearing threshold (×1900). (c) Exposure to 120 dB for 150 min; half an hour after exposure, there is total loss of the stereocilia on the outer hair cells (×4300). (d) Exposure to 120 dB for 150 min; 80 days after exposure, 9 mm from the round window. The surface is devoid of both stereocilia and hair cells, correlating with a 30–35 dB permanent threshold shift at 2 and 4 kHz. Reproduced with permission from Ref. 5.
Diagnosis of occupational noise–induced hearing loss

The process of establishing a diagnosis of occupational noise–induced hearing loss should be no different from the process of reaching a diagnosis when faced with any other clinical problem. The fundamental principles of taking a comprehensive and pertinent history, conducting a thorough examination and undertaking appropriate investigations are just as applicable. However, certain factors cloud this process and as a result the diagnosis is usually circumstantial. When faced with an individual with hearing loss and a history of occupational noise exposure, the clinician has to make a decision as to whether the former is a result of the latter. This gives rise to the first problem. Of the 12 per cent of adults found to have a sensorineural hearing loss in the Medical Research Council study cited earlier under Epidemiology (p. 465), only 40 per cent of these could be accounted for by the effects of age or noise exposure. Some of the remaining 60 per cent were no doubt due to the myriad of less common or rare disorders (in population terms) that cause a sensorineural hearing loss, but a significant proportion were idiopathic (cause unknown). If the diagnostic process is one of exclusion of known causes, Williams has put forward the argument that attempting to exclude that which cannot be identified defies logic. However, appraisal by an appropriately trained clinician remains paramount as there is no reason why the prevalence of other otological disorders should be any different in the individual with noise–induced deafness than in the general population. The Department of Health and Social Security publication ‘Occupational deafness’ states that apart from the characteristic audiometric changes, there are no signs or symptoms specific to noise–induced deafness. This implies that the diagnosis of occupational noise–induced hearing loss is an audiometric one. However, the characteristic audiogram with its 4-kHz notch is not a pathognomonic feature of noise–induced deafness. The notch may lie between 3 and 6 kHz (a notch centred at 6 kHz is considered to be an artefact), and with progression over time the notch may widen and be lost as the thresholds at the higher frequencies rise. Additionally, noise exposure is not the only cause of a 4-kHz notch and the hearing loss may not necessarily be symmetrical.

The history must include not only audiovestibular symptoms, but also details of previous and intercurrent focal and systemic disorders that may affect the ear. This includes the administration of potentially ototoxic drugs. The history of noise exposure, whether occupational, military or otherwise, can be difficult to construct in temporal terms as individuals may have difficulty in recalling past events and employment accurately. Increasing recognition of non-syndromic familial sensorineural deafness and the familial nature of otosclerosis and some cases of Menière’s disease underline the importance of obtaining a good family history. Autoimmune deafness may be associated with systemic symptoms and these should be enquired about. The examination of the ear, nose and throat must be complete. Much information regarding the health of the external and middle ear can be gleaned from pneumatic otoscopy and if the clinician is in any doubt, microscopic examination of the ear should be readily available, if nothing else, to clear the external meatus of wax that precludes a view of the drumhead. Aside from the audiometric evaluation, additional investigations are dictated by the clinical assessment and include haematological, serological and relevant immunological laboratory tests, in addition to radiology if indicated. Evaluation of the historical, clinical and investigative evidence usually allows, if present, the causal relationship between hearing loss and noise exposure to be established, but as there is currently no single clinical or investigative feature unique to noise–induced hearing loss, the diagnosis remains one of clinical probability and audiometric compatibility.

ACOUSTIC TRAUMA AND BLAST TRAUMA

The preceding discussion has primarily focused on the auditory effects of prolonged exposure to hazardous noise. The term ‘acoustic trauma’ describes permanent hearing loss following brief exposure to a single very loud noise. This encompasses, for example, the effects of gunfire, but also includes the effects of industrial impulse noise associated with drop forging and riveting. Gunfire noise in particular has the potential to be extremely hazardous. Peak sound pressure levels of 160 dB for hand–held weapons to 190 dB for field weapons have been recorded and therefore permanent injury to the inner ear may arise from the first exposure. It is worth bearing in mind that with rifle fire, the forward ear (left ear in a right–handed individual) is closer to the muzzle, thereby bearing the greater brunt of the acoustic trauma than the opposite ear and this is often discernible audiometrically. Second, occupational noise–induced hearing loss and acoustic trauma may coexist in the same individual.

Blast trauma (otic blast injury) is due to the effects of an explosion such as a bomb blast, but may also be a component of the acoustic trauma from large calibre weapons. It is characterized by a greater severity and may be associated with damage to the tympanic membrane and the middle ear structures. The shock wave from an explosion is longer than that of hazardous sound and consists of a short (5 ms) positive pressure followed by a longer (30 ms) negative pressure. Clinically, there may be a history of bleeding from the ear following the injury and examination shows a spectrum of tympanic membrane changes ranging from hyperaemia to frank perforation of the pars tensa which may be ‘clean’ or ragged. It is the initial positive pressure that perforates the drumhead and the subsequent negative pressure that leads to the characteristic everted edges of the perforation. The resultant deafness and tinnitus is immediate and severe but recovery, though
incomplete for the higher pitches, is not uncommon and over three-quarters of drumhead perforations heal spontaneously.52

**ASSESSMENT OF HEARING DISABILITY**

**Impairment, disability and handicap**

These consequences of disease are differentiated by the World Health Organization.53

- **Impairment** relates to a loss or impairment of the structure or function of an organ or system. Within the auditory system, there are a number of impairments of function which could be measured. The one which has most relevance for the assessment of hearing disability is the alteration in the pure tone threshold.

- **Disability** is an index of the loss of an individual’s functional performance as a consequence of impairment to the diseased organ or system. It thus represents a disturbance at the level of the individual. Hearing disability has been described as the restriction or lack of ability to perceive everyday sounds in the manner that is considered normal for healthy young people.54

- **Handicap** encompasses the disadvantages experienced by an individual as a consequence of impairments and disabilities. It thus reflects interactions between the individual and his social and working environment. Hearing handicap is the disadvantage to an individual resulting from a hearing impairment or disability, that limits or prevents the fulfillment of a role that is normal for that individual. Disability and handicap are thus seen to be multifaceted. A given degree of hearing impairment could represent a much greater handicap for a professional musician than for a sculptor for example. The complex picture of disability and handicap that may result from occupational noise-induced hearing loss has been painted by Hetu et al.55

In 1981, a working party of members of the British Association of Otolaryngologists (BAOL) and the British Society of Audiologists (BSA) was set up to address the problem of assessment of hearing disability for the purpose of compensation. Up to then, there was a plethora of conflicting recommendations, from a number of different sources. The results of the working party’s deliberations were published in the so-called ‘Blue Book’ of 1983.56

Because of some misgivings about its conclusions, a new group called the Inter-Society Working Group was established in 1986 with a wider membership including representatives of the British Association of Audiological Physicians (BAAP), and the British Association of Audiological Scientists (BAAS).

The results of this group’s efforts are published in ‘Guidelines for medicolegal practice’, although the BAAP did not sign up to the final document because of problems on the definition of disability and on agreeing the scale of degrees of disablement. The group considered every aspect of hearing disability and its assessment. They stated that, ‘hearing disability assessment should provide an accurate quantitative assessment of the actual disability suffered by the individual, appropriately weighted according to the way he uses his auditory facilities and the extent to which difficulties in hearing interfere with those activities’. The authors recognize, however, that the ideal is impossible to attain in an easily measurable, scientific and quantitative way because of the subjective nature of disability and handicap and the great variability between individuals. They identify instead a typical (median or average) individual and relate disability to that notional individual, and they recognize that such a concept may underestimate disability in some people and overestimate it in others. They also recognize the need to identify an audiometric surrogate (i.e. a measure of impairment) as a means of quantifying disability.

Several studies have been carried out to identify the audiometric descriptors which best relate with disability including those by Atherley and Noble,57 Lutman et al.58 and the Medical Research Council’s National Study of Hearing from the early 1980s. These studies, by and large, looked at the different patterns on pure tone audiometry which were the best predictors of disability. It was concluded that the three-frequency average of 1, 2 and 3 kHz was the best predictor. Errors were introduced by the inclusion of 0.5 Hz and 6 kHz.59 It may seem strange that 4 kHz is excluded from this formula, when one considers that this is the frequency most likely to be affected by occupational noise; however, the notches at 4 kHz may be narrow but quite deep, so that there is a danger of obtaining an inflated average hearing threshold measurement which does not truly reflect the degree of disability. Furthermore, it is convenient not to include 4 kHz in the estimate because of the difficulty in obtaining accurate bone conduction thresholds above 3 kHz. Finally, the three-frequency average coincides with the UK statutory hearing loss criteria, even though the fence values of the latter may be subject to some criticism.

**Fence values**

The low fence is that notional point on the continuum of elevation of the hearing threshold level at which disability is deemed to commence. It has never been satisfactorily identified, and indeed cannot be seen as anything other than an artifice erected for administrative convenience, with little relevance to the individual case. Robinson et al.60 identified a 30 dB hearing threshold level averaged over 1, 2 and 3 kHz as the threshold of disability, and this coincides with British Standard BS 5330 (1976).61 A low fence as high as 50 dB HL (1, 2, 3 kHz average) is employed
in the UK statutory compensation scheme. Even the much lower value of 26 dB (0.5, 1, 2 kHz) that prevailed under the American Academy of Otolaryngology and Ophthalmology (AAOO) scheme underestimated the disability of those individuals who began life with hearing that was 'normal'. The high fence is that point in the continuum of elevation of hearing threshold level at which disability is deemed to be total. High fence values have been judged to be any level from 70 dB upwards, and are just as arbitrary as low fence values.

AGE-ASSOCIATED HEARING LOSS

Ageing is associated with a progressive loss of auditory function, a condition which has been described in the past as 'presbyacusis'. It is recognized that most of the impairment arises as a result of progressive cochlear dysfunction with loss of hair cells from the organ of Corti, affecting the higher frequencies first, but advancing through the cochlea to affect eventually the whole frequency range to some extent. Other structures may also undergo degenerative change, for example the auditory nerve and the central auditory pathways. There may also be a central loss of cognitive function. It is clearly important to be able to make some allowance for the effects of 'natural' ageing on the hearing of those middle-aged and elderly individuals who have also been exposed to the harmful effects of noise during their working lives.

Data on this subject are available from many sources. International Standard ISO 7029 (1984) gives values of age-associated hearing loss as deviations relative to the median thresholds of young otologically normal subjects. The data are available for sex, for the age range 20–70 years, for frequencies ranging from 125 Hz to 8 kHz, and for percentiles of the population from the 5th to the 95th. They are available in table form for ease of reference so that allowance can be made in the individual case for the effects of ageing.

The International Standard ISO 1999 (1990) 'Determination of occupational noise exposure and estimation of noise-induced hearing impairment' assumes a direct additive effect between noise and age effects, although that is not true at profound levels of deafness. A word of caution is necessary, however. Burns and Robinson and Robinson have drawn attention to the complicated interrelationship of occupational noise-induced hearing loss and ageing. The former tends to produce an elevation in threshold which is initially rapid, but slows down with subsequent exposure. Age-related hearing loss takes a progressively accelerating course with time. Thus, the contribution of occupational noise-induced hearing loss to the total sensorineural hearing loss decreases with age, and by the age of 80 it would make virtually no difference what the noise had been.

HEARING CONSERVATION PROGRAMMES

There are several areas in which employers may help to minimize the risks to the hearing of employees from the harmful effects of industrial noise:

- noise measurement and reduction;
- provision of personal ear protection;
- audiometric testing;
- education.

Noise measurement: the relationship of hearing loss to noise exposure

With the development of accurate methods of measuring both the sound stimulus and the hearing level, more precise determination of the relationship between hearing loss and noise exposure has become possible. Burns and Robinson reduced the number of significant parameters to two: the noise level and the duration of exposure. Daily personal noise exposure (\(L_{\text{EPd}}\)) can be determined by wearing a personal sound dosimeter over a given period. A more accurate picture may, however, be established from the measured values of A-weighted sound pressure levels and the duration of exposure at work using a Noise Exposure Ready Reckoner as recommended in the 2005 Health and Safety Executive document 'Controlling Noise at Work'. This employs a noise exposure points system relating average sound pressure levels (\(LA_{\text{eq}}\) dB) with duration of noise exposure in hours. It is a simple way of working out the daily personal noise exposure especially in situations where the noise exposure is variable throughout the day, for example, if an employee spends part of a day in a very noisy environment and part of the day in a less noisy activity (Table 46.2). In the noise exposure points scheme, the upper exposure action value is 100 points (equivalent to an \(L_{\text{EPd}}\) of 85 dB) and the lower exposure action is 32 points (equivalent to an \(L_{\text{EPd}}\) of 80 dB) (Table 46.3). For a worked example of this scheme, the reader is referred to the original document. The 'first action level' of 80 dB is the level at which ear protectors should be available on demand. The 'second action level' of 85 dB is the level at which the use of ear protectors is mandatory. These values have each been reduced by 5 dB since the previous 1989 document. A similar scoring system can be used to work out weekly exposure and is of particular value if there is significant variation in noise exposure from day to day during the working week.

There are also occasions when one wants to establish the \(L_{\text{EPd}}\) caused by repeated 'single event' noise produced for example by impact or cartridge-operated tools. Peak pressure meters provide rapid information and are easy to use. If the reading exceeds 125 dBA, more accurate measurements should be made. An integrating sound level meter (BS 6693: IEC 804) is the most convenient instrument for general use. It calculates the equivalent continuous sound pressure level.
Table 46.2  Noise level and duration of exposure are combined to give ‘noise exposure points’.

according to the equal energy principle. A peak sound pressure level of 140 dB is defined as the ‘peak action level’. At this level, the use of ear protectors is mandatory.

It is clearly the responsibility of employers to ensure that all measurement equipment is accurately and regularly calibrated.

Employers in the music and entertainment industries were given an additional period of two years to comply with the 2005 regulations, while continuing to comply with the 1989 regulations.67,68

Noise reduction

This can be helped, inter alia, by the enclosure of noisy machines, the use of mufflers, damping, silencers and anti-vibration mountings, the treatment of reflective surfaces with absorbing materials, the limitation of the use of noisy equipment to times when it is actually required, and the distancing of workers from the areas of maximum noise. There are many more suggestions for the reduction of noise in the workplace in the consultative document ‘Prevention of damage to hearing from noise at work’ published by the Health and Safety Commission in 1987.69 The publication ‘Sound solutions’ published by the Health and Safety Executive in 1995 provides employers with many examples of techniques to reduce noise in the workplace.70

ACTIVE NOISE CONTROL

The principles of active noise control (or active cancellation) have been known for 60 years, but the techniques remain rather experimental. One sound is cancelled by the introduction of a second sound of equal amplitude but reversed phase, derived electronically from the first sound. There are considerable difficulties in designing and commissioning these systems, but the technique does show considerable promise in the reduction of low frequency noise where control by passive measures can be difficult. Commercial interest in the technique is increasing.

EAR PROTECTION

Ear protection provides a system of attenuation of the incoming sound and thus minimizes the sound arriving at the tympanic membrane. Various types of protector are available.71,72

Ear muffs

Ear muffs (Figure 46.13) fit over the ears and are sealed to the side of the head by soft cushion seals filled with soft plastic foam or a viscous fluid. They are usually held in position by means of a headband, but may alternatively be attached to a safely helmet. Attenuation may be ‘frequency selective’, protecting some frequencies more than others,
Hearing conservation programmes

particularly the higher frequencies rather than the speech frequencies. ‘Amplitude selective’ devices are designed to provide attenuation that increases with sound level. Such a device usually has a small hole which acts as a mechanical filter, allowing low sound pressures to pass but offering more resistance at high pressures. ‘Active devices’ incorporate electronic circuitry which limits the transmission of sound at high intensity, and are of value when workers are exposed to short bursts of high intensity sound or impulsive sounds. ‘Anti-noise’ devices incorporate circuitry which cancels out incident noise especially at low frequency. These devices are still largely experimental. Many of the newer muffs incorporate an inbuilt communication system.

While ear muffs usually provide an effective level of attenuation, their value may be limited by any effect which decreases the efficiency of the seal, for example spectacle frames, goggles, beards and long hair, or scarves worn under the muffs. Furthermore, wear and tear may decrease the efficiency of the seal. It should also be emphasized that if protection is removed in noisy areas, even for a short period, the amount of protection will be severely limited. For example if a protector with an ‘assumed protection’ of 20 dB(A) is removed for 30 minutes per day the actual reduction in noise dose received by the wearer will be only 12 dB(A).

Ear plugs

Ear plugs are generally thought to be less efficient attenuators of sound than muffs, but have the advantage that they are easy to use. They may be disposable or permanent. Disposable plugs are made of a compressible or conformable material and fit most people without individual fitting. They are readily available commercially, but have a finite ‘life expectancy’ after which their effectiveness decreases. Permanent and custom moulded plugs have a longer survival, and are usually comfortable if made by an experienced technician. One of the main disadvantages of plugs is the increased propensity to otitis externa, although this too can occur with muffs.

Dual protection with the use of both muffs and ear plugs may be indicated when the noise levels are extremely high (e.g. when LEPd exceeds about 115 dBA).

Noise-excluding helmets

At extremely high levels of sound (e.g. in tunnelling), the protection offered by muffs and plugs, either alone or in combination, may be insufficient. Sound may still reach the ears through the nose, mouth, eye sockets and the skull itself. Experimental studies with helmets to protect the whole skull are at present under evaluation.

The attenuation provided by a protector should comply with British Standard BS 510866 (ISO 4869),25,26 and the basic design features should comply with BS 6344.26 The ‘assumed protection’ of a device will vary with frequency and most will attenuate higher frequency sound better than low frequency sound. The ‘assumed protected level’ of noise exposure is obtained by subtracting the assumed protection of the device at each octave band frequency from the sound pressure level at each frequency.

Conversion should then be made to A-weighted sound levels (dBA). All this sounds complicated. Attempts to simplify the rating of devices by using a ‘single number’ rating which does involve frequency analysis, tends to sacrifice accuracy in the cause of simplicity. It is important that ear

protection zones be identified within which use of ear protectors are advisable or mandatory.

**Measurement of hearing: Audiometry in the workplace**

Measurement of hearing using electroacoustic devices is generally referred to as audiometry. Pure tone audiometry records the threshold for each ear separately, at a series of test frequencies at octave intervals covering the frequencies most commonly encountered in everyday life and in particular in everyday speech. The frequencies usually tested in the clinical setting are 125 Hz, 250 Hz, 500 Hz, 1 kHz, 2 kHz, 4 kHz and 8 kHz. In the medicolegal and compensation fields, 3 kHz is always tested, and 6 kHz may be. Air and bone conduction thresholds are measured to establish the presence or absence of a conductive component of the overall hearing loss. Bone conduction thresholds are inaccurate above 3 kHz. Audiometry may be carried out by an audiometrician (manual audiometry) or using a self-recording audiometer.

Hinchcliffe has pointed out the possible shortcomings of manual audiometry. Two different audiometricians might obtain significantly different thresholds at 3 and 4 kHz on the same patient on the same day. Test–retest reliability on the same patient by the same audiometrician may yield differences of up to 25 dB. Self-recording audiometry eliminates the variability due to the audiometrician. By utilizing a combination of continuous and pulsed test tones, there is a greater likelihood of picking up a spurious (non-organic) hearing loss. A permanent record is obtained without the need for transcription with the risk of errors. Sweep frequencies are used because this technique may pick up notches at intervals not tested on fixed frequency audiometry. Thus, the preferred technique is sweep frequency audiometry using both continuous and pulsed tones. An audiometry programme ideally should consist of a pre-employment test followed by tests at regular intervals. Important side issues include the calibration of equipment, the acoustic requirements of the test area, instructions to the subject and the format and storing of records. These are all covered in detail in the discussion document, ‘Audiometry in industry’, published by the Health and Safety Executive for full details, but certain salient points can be highlighted here.

- **Regulation 5.1.** An employer who carries out work which is liable to expose any employees to noise at or above a lower exposure action value shall make a suitable and sufficient assessment of the risk from that noise to the health and safety of those employees, and the risk assessment shall identify the measures which need to be taken to meet the requirements of these regulations.
- **Regulation 6.1.** The employer shall ensure that risk from exposure of his employees to noise is either eliminated at source or, where this is not reasonably practicable, reduced to a low a level as is reasonably practicable.
- **Regulation 7.1.** Without prejudice to the provisions of regulation 6, an employer who carries out work which is likely to expose any employees to noise at or above the lower exposure action value shall make personal hearing protectors available on request to any employee who is so exposed.
- **Regulation 7.2.** Without prejudice to the provisions of regulation 6, if an employer is unable by other means to reduce the levels of noise to which an employee is likely to be exposed to below an upper exposure action value, he shall provide personal hearing protectors to any employee who is so exposed.
- **Regulation 8.1.** The employer shall (a) ensure as far as is practicable that anything provided by him in compliance with his duties under these regulations to or
for the benefit of an employee, other than personal hearing protectors provided under regulation 7.1 is fully and properly used, and (b) ensure that anything provided by him in compliance with his duties under these regulations is maintained in an efficient state, in efficient working order and in good repair.

- Regulation 9.1. If the risk assessment indicates that there is a risk to the health of his employees who are, or liable to be, exposed to noise, the employer shall ensure that such employees are placed under suitable health surveillance, which shall include testing of hearing.

- Regulation 9.2. The employer shall ensure that a health record in respect of his employees who undergo health surveillance in accordance with paragraph 9.1 is made and maintained and that the record or a copy thereof is kept in a suitable form.

In addition, the regulations define the responsibilities of the employer in the provision of ear protection zones, in the maintenance and use of equipment and the provision of information, instruction and training to employees. The employees’ obligations under the regulations are also emphasized. The document also deals with the legal obligations of designers, manufacturers, importers and suppliers of plant and machinery for use at work to provide noise information and control the noise emission of machinery.

**MANAGEMENT**

With the exception of the transient phenomenon of temporary threshold shift, the hearing loss caused by noise exposure is permanent and is due to the loss of or damage to the organ of Corti and neuronal structures in the inner ear. There is, as yet, no medical or surgical treatment that can reverse the damage to these structures. Management of occupational noise-induced hearing loss is therefore based on prevention of further damage, suitable amplification with hearing aids, and the provision where indicated of other assistive devices. It is generally felt that the process of injury to the inner ear ceases when the subject is removed from, or protected from, his noisy working environment, but subjects should be warned of further possible damage from other sources, such as recreational noise exposure.

These effects on the inner ear are, as has been previously stated, most marked in the high frequencies commencing at 4 kHz, but spreading downwards across the frequency range. The early effects, therefore, are most marked for the high frequency components of speech, the consonants, the siblants and fricatives. It is these elements which convey most of the meaning in speech. Neuronal damage causes a further loss of speech discrimination which may not be correctable by simple amplification. In addition, there are other psychoacoustic deficits which may come into play and for which hearing aids cannot compensate, such as impaired frequency discrimination, frequency selectivity or temporal acuity. Furthermore, the phenomenon of recruitment, a feature of cochlear deafness, may limit the usefulness of amplification. This is characterized by a disproportionately great increase in the perceived loudness for a small increase in the actual sound pressure level. This is a major factor in causing distortion with hearing aids, and may limit their use. The ability to discriminate speech in the presence of background noise is lost early in the evolution of sensorineural deafness, and involves factors other than a simple elevation of the hearing threshold. It is not restored by fitting a hearing aid and it remains one of the main grievances of hearing aid users who find it impossible to converse with one individual in a noisy environment, such as a bar, cocktail party, or if the television or a stereo system is on.

Despite these shortcomings it is, however, clear that individuals with noise-induced hearing impairment can derive appreciable benefit from hearing aids provided that careful attention is given to the type of aid and the design and engineering of the ear mould.

Different hearing aids have different frequency responses. Some preferentially amplify the higher frequencies and this would intuitively seem a sensible type of device for a subject with a high frequency hearing loss. The prescription of an aid with a customized frequency response for an individual hearing loss is beguiling and has commanded much attention in recent years. It is, nevertheless, a much more challenging problem than the prescription of spectacles for a simple refractive error, for reasons mentioned earlier in this section. Different hearing aids have different gain or amplification (i.e. some are stronger than others), and again it is clearly important to have the appropriate aid for the severity of the deafness. Hearing aids, like car engines, have a point or a range at which they function best. If one attempts to get more performance from an underpowered aid, there is a marked fall off in the efficiency of the device. It is better to get a stronger aid and have it working at its most efficient level. Compression aids incorporating automatic gain control, attempt to overcome the problem of the loud sound which exceeds the discomfort level of the listener.

Systems which address the problems of understanding speech in the presence of background noise have been developed and in the UK are at present only available in the private health sector, where they cost considerably over £1000.

The other factor of considerable importance is the design and fitting of the hearing aid mould. The aid must fit comfortably in the ear, but must be secure enough to prevent acoustic feedback problems – the whistling that one often associates with hearing aids is usually the result of a poorly fitting mould or an underpowered aid with the volume setting too high. The effect of occlusion of the ear canal may be to cause otitis externa in susceptible individuals. Some wearers develop an allergic reaction in the skin of the meatus to the mould material. Hypoallergenic alternatives are available to overcome such problems.

The physical properties of the mould have an effect on the acoustic output of the aid and modifications to the
mould may influence the performance of the device. Venting entails the creation of a second hole next to the existing sound tube. This has a considerable effect in increasing the low frequency responses of the aid. It also incidentally may decrease the tendency to otitis externa by decreasing the greenhouse effect within the ear canal. Funnelling of the outlet tube where the sound leaves the mould may increase the high frequency response. Acoustic filters can be introduced into the tube. These may alter the shape of the frequency response curve. All of these facilities are available in the United Kingdom on the standard ear level hearing aids. The National Health Service does not, at present, provide small in-the-ear aids.

In addition to hearing aids, there are other assistive devices or environmental aids that can be used with or independent of conventional hearing aids including amplifying devices, alerting and alarm systems, telephone modifications and speech-to-text transcription. They are not necessarily expensive and may provide significant personal benefit. They include induction loop systems, television listening aids, tactile and visual devices activated by sound stimuli (door bells, fire alarms, alarm clocks, telephone). Inductive coupling between coils in the hand-piece and the hearing aid greatly helps telephone conversation. Text telephones using a computer link, or a relay service via an operator may help the very deaf. Speech-to-text transcription, such as Palantype, is a major help at public meetings, but is expensive and the system operators are relatively few. A simple overview of the devices available is given by Martin.

Cochlear implantation

The cochlear implant is an electric device inserted into the inner ear of certain profoundly deaf individuals to take the place of a severely damaged organ of Corti and convey to the brain a processed sequence of electric stimuli which the brain perceives as sound. Cochlear implants have now reached such a level of sophistication that the best implantees can converse almost effortlessly even over the telephone. To ‘qualify’ for an implant, a subject must have a degree of deafness that cannot be aided with any conventional hearing aid. Pure occupational-induced hearing loss very rarely if ever produces deafness of that degree of severity, and with the present selection criteria for implantation, cochlear implantation is not a treatment option for such individuals. There are indications, however, that selection criteria may become less strict in the future.

Antioxidant treatment: a possibility for the future

With the new insights outlined earlier in this chapter into the cellular events that result in noise-induced deafness comes the possibility of prevention and treatment of the condition. Glutathione has been shown to limit noise-induced hearing loss in the guinea pig both on auditory evoked brainstem response audiometry and on histological studies of cochlear hair cell loss. Kopke et al. looked at three strategies for enhancing the cochlea’s intrinsic stress defences in a chinchilla model. Acetyl-L-carnitine is an endogenous mitochondrial membrane compound that helps maintain mitochondrial function in the face of oxidative stress. Carbamathione is a glutamate antagonist. Glutathione levels are reduced in the noise damaged cochlea. Kopke and co-workers administered acetyl-L-carnitine, carbamathione and a glutathione repletion drug D-methionine to three groups of chinchillas and demonstrated protection from cochlear damage by showing significant reduction in hearing threshold elevation and significant reduction in cochlear hair cell loss at post-mortem examination. The same team demonstrated a strong protective effect on the chinchilla model of the antioxidants acetyl-L-carnitine (ALCAR) and N-L-acetyl cysteine (NAC). Hight et al. administered a combination of two antioxidants, glutathione monoethylester and R-PIA, to chinchillas subsequently exposed to impulse (145 dB SPL) or continuous (105 dB, 4 kHz) noise and demonstrated a significant protection from both. They also demonstrated raised glutathione levels in the perilymph. Other workers have looked at the effect of magnesium administration on the susceptibility to damaging noise levels in the guinea pig and found that there was a protective effect if the magnesium was administered immediately after noise exposure. The magnitude of the effect lessened with the length of time that elapsed from the noise exposure and the administration of the drug. It seems that there may be a synergistic effect between magnesium and free radical scavengers, such as vitamins A, C and E in reducing noise trauma.

How these animal observations relate to the protection of the ear from noise in human beings in an industrial environment is not yet clear, but they are a very encouraging pointer to future developments in the field. Human trials have not yet commenced, but the animal results would suggest that they cannot be far off, assuming safety factors have been addressed. Early clinical trials with the antioxidant N-acetylcysteine (NAC) are anticipated.

Another phenomenon to attract increasing interest is that of ‘cochlear toughening’. A sound of sufficient mid-intensity produces a temporary threshold shift (TTS) following exposure. If the same exposure is repeated on a daily basis the TTS gets progressively less compared with the original shift. The cochlea has become conditioned by the so-called toughening exposures. Again it is not yet clear if and how this observation can be put to practical use in humans.

NON-ORGANIC (OR EXAGGERATED, OR FUNCTIONAL) HEARING LOSS

In the medicolegal context, with the attendant lure of financial gain from compensation, the doctor assessing an
The cochlea and eighth nerve give rise to near field potentials of very short (or no) latency, such as the cochlear microphonic (CM), the summating potential (SP) and the eighth nerve action potential (AP). The components of the auditory brainstem response (ABR or BSER) have a latency of up to 7–8 ms, and arise from structures in the lower to mid brainstem. The middle latency response (MLR) takes origin higher in the brainstem and at higher subcortical levels. The slow vertex response (SVR), recorded on cortical ERA (CERA), is thought to take origin from the highest levels in the auditory pathways and naturally has the longest latency (50–300 ms).

Most of these responses are recorded through simple disc electrodes located on the skin of the scalp and are thus non-invasive. The exception is the recording of cochlear potentials by the process of electrocochleography (ECoChG, ECoG), which entails the siting of a recording electrode deep in the ear canal on the surface of the ear drum, or sometimes from the medial wall of the middle ear by means of a transtympanic needle electrode. The potentials recorded are of very low voltage and are difficult to differentiate from random background electrical activity. They have to be extracted by the process of ‘time domain averaging’ of the responses to a series of stimuli, then amplified for display on a visual display/computer unit where they can be studied, manipulated and stored for future recall. The better the signal-to-noise ratio of the response the fewer stimulus repetitions will be required to produce a reliable recording. Near field responses, such as ECoChG, therefore, require fewer stimuli that far field responses, such as the ABR. A greater number of stimuli are needed to produce a response as the threshold is approached.

Electric response audiometry is employed in the neuro-otological diagnosis of certain disease states. For example, ECoChG, yields typical patterns in Menière’s disease. The ABR frequently demonstrates latency abnormalities in tumours of the cerebellopontine angle or brainstem of which vestibular schwannoma is the most common example. The other main use for ERA is to help establish the true hearing threshold when it is difficult to obtain reliable thresholds using conventional techniques. In addition to its role in the case of suspected non-organic hearing loss, it is used to test very young children, or children or adults with multiple handicaps who are unable to cooperate in the performance of standard hearing tests. The great advantage of the technique is that the patient cannot influence the generation of the potentials.

There are, however, certain disadvantages with ERA, some of which are common to all techniques, and some of which are specific to the individual test. Subjectivity on the part of the tester remains, in that it is not always easy, when tracing an ever-decreasing response to a stimulus of decreasing intensity, to determine at exactly what point the response disappears (the end point). Thus, the threshold estimation is not always as precise as one might wish. All ERA techniques tend to give more accurate information about high frequency thresholds than about thresholds at frequencies below 1 kHz. In the industrial deafness case, this is not always such a problem as in pure clinical work, because most of the desired information is in the higher frequencies anyway. One misconception about ERA needs to be corrected. It is not a better test of hearing than conventional hearing tests. The best estimate of hearing is a pure tone audiogram carried out on a willing and cooperative subject; ERA is used when that ability or willingness are absent. The preferred technique in the evaluation of a subject suspected of exaggerated hearing loss is CERA, but two other techniques (ABR and ECoChG) are occasionally employed and will also be described.

**Auditory brainstem response**

The ABR comprises a series of five potentials (N1–N5) which occur in the first 7–8 ms after acoustic stimulation.
The generators of these potentials are still the subject of debate, but have been suggested to be:

- N1, cochlear nerve/nucleus;
- N2, cochlear nucleus;
- N3, superior olivary complex;
- N4, lateral lemniscus;
- N5, inferior colliculus.

Of these, the largest component and the one most usually employed in the estimation of hearing threshold is N5 (Figure 46.14). Stimuli are presented initially at a moderately high intensity, say 70 dB, and if an N5 response is observed, the stimulus intensity is decreased stepwise. As threshold is approached, the latency of the N5 response increases and the amplitude decreases, until it is no longer recordable. In a subject with normal hearing, the N5 response can usually be recorded down to stimulus intensities of 25–30 dB. The reason it cannot be recorded at lower intensities is largely due to the small voltage of the response and distance of the recording scalp electrodes from the generators in the brainstem. Most workers in this field would state that if responses are recordable down to 25–30 dB, the hearing is likely to be close to normal.

The advantages of ABR are that in the hands of an experienced audiologist, it produces clear and reproducible waveforms, is non-invasive and carries no risk to the subject. It is also unaffected by general anaesthesia, which is of value in the assessment of the young and uncooperative. There are certain disadvantages. It is quite time-consuming because as the threshold is approached many hundred stimuli may be required to produce a good response, and in order to demonstrate reproducibility, the test may have to be repeated several times. The information it yields is greatest in the high frequencies, although as stated above this may be less of a problem in the industrial deafness case.

Electrocochleography

The most important component of the ECochG is the eighth nerve action potential. The signal–noise ratio is much more favourable than with ABR, so large and reliable responses can be obtained after very few stimuli, even at quite low stimulus intensities, at which the response again decreases in amplitude and increases in latency. Threshold estimation is usually more accurate than with ABR (probably to within 10–15 dB), but as with ABR the higher frequency responses are more reliable than the low. The main disadvantage is the fact that the recording electrode has to be sited in the ear. An ear canal electrode may be satisfactory, but the best responses are obtained from a transtympanic electrode which has to be passed through the tympanic membrane to lie on the cochlea. This is performed under topical anaesthesia using EMLA® (eutectic mixture of local anaesthetics) cream, and the tiny perforation created nearly always heals rapidly. Nevertheless, the invasiveness of the technique means that it is not the technique of first choice, although there are occasions when its reliability might be desirable.

Figure 46.14 Auditory brainstem response. The stimulus intensity is marked on wave N5. Note that the latency of the N5 response increases and the amplitude decreases as the hearing threshold is approached.
Cortical evoked response audiometry

CERA records a response, the slow vertex response (SVR) which occurs between 50 and 250 ms after the delivery of sound to the ear (Figure 46.15). This long latency suggests that it is not a primary response. It is best recorded from scalp electrodes placed at the vertex. The precise generators of the response are unclear, but it is known to arise from cortical structures. It thus has the theoretical advantage over ABR and ECochG of getting closer to recording 'hearing' than the other techniques which record events lower in the auditory pathway. The components of the waveform are two vertex positive waves and one vertex negative wave (the P1, N1, P2 complex).

Although frontal lesions do not affect the waveform, extensive temporoparietal lesions may eliminate the N1 component, but not P1. The SVR is influenced by general anaesthesia and to a lesser extent by sedation, so it is of little value in children. It is also influenced by EEG alpha activity, so is best tested with the subject’s eyes open. In about 5 per cent of subjects, high levels of alpha activity make it very difficult to obtain an accurate SVR threshold. In such a situation, ABR or ECochG might be preferred. The test is carried out with the subject reclining, perhaps reading. The scalp electrodes are non-invasive. In most cases, an audiogram at 500 Hz, 1 kHz, 2 kHz and 3 kHz can be obtained in an hour. In adults, it is usually accurate to about 10 dB of the true threshold and furthermore its frequency specificity is better than that of ABR and ECochG. It is the technique of choice for verification of the pure tone audiogram in cases of suspected NOHL. If the pure tone threshold and the SVR threshold agree to within 10 dB, the behaviour threshold is confirmed. If the pure tone threshold exceeds the SVR threshold by 15 dB or more, exaggerated hearing loss should be strongly suspected.

Otoacoustic emissions: the possible use as a predictor of noise-induced hearing loss

Otoacoustic emissions (OAE) are sounds that are produced by the outer hair cells of normal ears. They are an epiphenomenon that seem to be the result of non-linearities in the way that the cochlea functions in response to acoustic stimulation. Spontaneous otoacoustic emissions (SOAEs) occur in about 40–50 per cent of normally hearing people. Transient otoacoustic emissions (TOAE) are the most useful clinically. These are low intensity sounds that are produced instantaneously by the cochlea in response to an acoustic stimulus. They are transmitted through the middle ear to the outer ear canal where they can be recorded using a small hand-held probe that delivers the test tone and records the response. TOAEs usually arise in frequency bands where hearing is normal so are fairly frequency-specific responses. They are very sensitive to changes in the cochlear hair cells. The technique is the basis for the newborn hearing screening programme. In general, the presence of a TOAE is a good indication that the hearing in that frequency band is within 30 dB HL of normal. The question arises as to whether the test or a modification of it could have any value in detecting preclinical changes in the hearing in individuals exposed to...
OCCUPATIONAL NOISE-INDUCED TINNITUS

Many individuals have experience of the tinnitus that occurs after exposure to loud music, such as that of a rock concert or discotheque. This temporary tinnitus may be short-lived or last for days, depending on the duration and intensity of the exposure and may be associated with a measurable temporary threshold shift. Similarly, tinnitus is reported often to accompany industrial noise exposure and while initially it is temporary, over a period of years it may become permanent in as many as 60 per cent, particularly in those exposed to impact noise. There is some debate, however, regarding the importance of tinnitus in the assessment of occupational noise-induced hearing loss: Hinchcliffe and King suggest that tinnitus is often a symptom of those seeking compensation. Another study looked at 135 ship engine room workers and concluded that, although TOAE changes after one year showed a high sensitivity (88 per cent) in predicting noise-induced hearing loss (NIHL) after two years of exposure, the test was a very poor screening tool because of the very low specificity (33 per cent) with an unacceptable false-positive rate. The case for adoption of the technique for screening workers with noise exposure has not therefore yet been made, but it does seem likely that the test can be improved in the future using mathematical modifications of the technique, such as Volterra Slice techniques.

OCCUPATIONAL NOISE-INDUCED VERTIGO

Temporary vestibular disturbance in response to loud noises is referred to as the Tullio phenomenon. In a state of health, high sound intensities are required to evoke this response. In various otological disorders, however, lesser sound levels may have a similar effect in certain individuals. Firm evidence that occupational noise-induced vertigo is a real entity is lacking. However, three more recent studies merit consideration. Shupak and colleagues demonstrated a reduced vestibulo-ocular reflex and reduced caloric response of the inner ear in 22 individuals with occupational noise-induced hearing loss compared with 21 controls, although all those evaluated were subclinical in terms of vestibular complaints. Manabe and colleagues evaluated 36 patients with occupational noise-induced hearing loss cases, half of whom complained of vertigo. In the symptomatic group, a reduced caloric response was also shown, as were electrophysiological changes suggestive of endolymphatic hydrops. Histopathological evidence of endolymphatic hydrops in two patients with late onset vertigo and noise-induced hearing loss was provided by Kemink and Graham. Thus, there is some evidence to substantiate a link between acoustic trauma and delayed endolymphatic hydrops, but further investigation into this aspect of hazardous noise exposure is required.

INFRASOUND AND ULTRASOUND

Evidence that excessive sound above or below the normal human auditory range may have an adverse effect on inner ear function remains scant.

Infrasound (conventionally sound below 20 Hz) is commonly felt as vibration rather than heard and is a component of natural phenomena such as earthquakes and thunder. Heavy industrial machinery, high speed car travel with open windows and ship’s engine rooms are potential sources of infrasound. More specifically, Pyykkö and colleagues examined 203 lumberjacks over a six-year period, compared the hearing in those with and without vibration-induced white finger syndrome and found a statistically significant difference in thresholds at 4 kHz in those with the syndrome than those without. They postulated that the higher thresholds in the lumberjacks with vibration-induced white finger was due to reflex sympathetic vasoconstriction in cochlear blood vessels in response to vasospasm of the hands rather than a direct mechanical effect on the cochlea (see Chapter 47, Hand-arm vibration syndrome, p. 489).

The auditory effects of ultrasound (sound above 20 kHz) have been reviewed by Acton. These include a full feeling in the ear, tinnitus and headaches. Utilizing low frequency ultrasound (10–28 kHz) in guinea pigs, Ishida and colleagues noted auditory electrophysiological effects, including alteration in the cochlear microphonic and increased thresholds. Currently, the adverse auditory effects of hazardous levels of both infrasound and ultrasound in humans remain to be defined.
Systemic Effects of Noise Pollution

Recently, the World Health Organization Noise Environment Burden of Disease (BoD) Working Group has identified environmental noise (as distinct from occupational noise) as a stressor in the evolution of cardiovascular disease. In addition, there is increasing concern about the burden of sleep disturbance, of annoyance, of hearing impairment, of tinnitus and of cognitive impairment from environmental noise. It has been estimated that the severe annoyance due to noise from traffic, trains and aircraft may account for approximately 3 per cent of coronary heart disease deaths in Europe each year (or about 210,000 deaths). Chronic noise exposure has been incriminated in elevation of systolic blood pressure in workers in the metal manufacturing industry, and in shipyard workers. Risk tends to be associated with nighttime noise exposure and the noise threshold for cardiovascular disease has been stated to be a night-time exposure of 50 dBA. The mechanism is thought to be the high levels of stress hormones, such as cortisol, adrenaline and noradrenaline, released into the circulation at times of stress at a subcortical level in the amygdala. This mechanism may be active during sleep and there are several reports in the literature that indicate that exposure to traffic noise and aircraft noise during sleep may cause autonomic changes, leading to hypertension and myocardial infarction. It has been suggested that the neuroendocrine changes associated with noise stress may modify immune function. Willich et al. reported that the risk of myocardial infarction from chronic noise burden appears more closely associated with sound levels than with subjective annoyance.

As a means of further assessing the noise-related disease burden, the WHO Working Group have devised disability adjusted life years (DALY). These allow one to quantify the amount to which life expectancy is reduced by premature death or disease-related disability. It was estimated that in 2002, Europeans lost 880,000 DALYs to coronary heart disease related to road traffic noise. The group also recognized the possible interaction between traffic noise and air pollution in the increased BoD. Outdoor air pollution represents approximately 2 per cent of cardiopulmonary disease mortality, and it is not clear whether the impact of noise on ischaemic heart disease is independent, additive or synergistic to the impact of outdoor air pollution.

It is also suggested that sleep disturbance caused by environmental noise (noise-induced insomnia) can be a contributory factor to loss of performance and predispose to accidents at home, at work and when driving. The deleterious effects of noise on cognitive function are also under scrutiny. There are four components of cognitive impairment (reading, recall, recognition and attention) which appear to show a consistent relationship with noise exposure. It must be emphasized, however, that there are immense difficulties in acquiring robust data to establish a causal relationship. There are uncertainties in quantifying noise exposure, in separating the effects of noise from other variables, and in agreeing and in quantifying outcome measures. Pooling of data for meta-analysis is fraught with hazard because of differences in the assessment of exposure and outcome.

In 2004, the World Health Organization published a guide for occupational health professionals aimed at the provision of a tool for carrying out detailed disease burden estimates of the hearing loss from occupational noise. In Europe, environmental noise is becoming a major health concern for policy-makers. The European Directive related to the assessment and management of environmental noise (Directive 2002/49/EC) addresses the action plans to reduce harmful effects of noise exposure.

The summary policy implications of these initiatives are:

- Estimates of the incidence of occupation-related NIHL in a given country or study population will provide quantitative information on the importance of the problem and help motivate interventions to reduce the risks and impact on health.
- While incurable and irreversible, NIHL is nevertheless preventable and it is essential that preventative programmes are implemented.
- Hearing conservation programmes should be integrated into the overall hazard prevention and control programme for the workplace.

On this basis, the WHO publication stipulates that such programmes require political will and decision-making, high-level management and workforce commitment, adequate human and financial resources, technical knowledge and experience, communication and monitoring mechanisms and continuous programme improvement. The WHO also recognizes the importance of local sociocultural aspects and financial climate, and that in developing countries a large proportion of the population works in the informal sector – a group that represents a major challenge in terms of occupational hazard prevention.

In an attempt to provide a common basis for tackling the environmental noise problem across the European Union (EU), the European Parliament and Council have adopted Directive 2002/49/EC of June 25, 2002 which encompasses the following environment policy directives:

1. Monitoring the environmental problem through member states drawing up strategic noise maps for major roads, railways and airports.
2. Informing and consulting the public about noise exposure and measures considered to address it.
3. Addressing local issues whereby competent authorities will need to devise action plans to reduce environmental noise.
4. Developing a long-term EU strategy to reduce the number of affected individuals.
The deadlines relating to the implementation of this Directive spanned from 2004 to July 2009, by which time the member states should have set up a database of information on strategic noise maps at which point the Commission must submit a report on the implementation of the Directive to the European Parliament and Council.

Key points

- Industrial noise exposure remains a significant cause of hearing impairment, disability and handicap in the Western world, and a major cause in developing countries.
- Permanent threshold elevation cannot yet be treated medically or surgically. Management is with hearing aids. The condition is best prevented.
- In the future, there may be therapeutic possibilities in the use of antioxidants in protecting the ear from the damaging effects of noise.
- Legislation places strict requirements on employers to reduce sound levels in the workplace and to provide adequate hearing protection at levels of noise defined by statute.
- Evidence is emerging that environmental noise pollution can have serious long-term effects on health in general, particularly heart disease.

INTRODUCTION

The prolonged use of vibrating tools and equipment can lead to a number of pathological effects primarily in the peripheral neurological, vascular and musculoskeletal systems. The resulting symptom complex is now internationally known as the hand–arm vibration syndrome or HAVS.1 The relative importance of the two main components, vascular (a Raynaud’s phenomenon) and sensorineural (a peripheral neuropathy), has shifted since the condition was first recognized at the beginning of the last century. In Alice Hamilton’s biography,2 in a chapter entitled ‘Dead fingers’, she described the presentation in limestone cutters working in Bedford, Indiana in 1918:

The men call the condition ‘dead fingers’ and it is a good name, for the fingers do look like those of a corpse, a yellowish-greyish white and shrunken. There is a clear line of demarcation between the dead part and the normal part.

These early reports did not reach a conclusion as to the cause of this condition, but presumed cold and tight gripping of tools to be responsible. It was the work of Seyring on vibration exposure in iron foundry workers in 1931 which made it clear that vibration transmitted to the hand–arm system was the underlying cause of the condition, and cold the trigger to the attacks of vasospasm.3 Towards the end of the twentieth century it became generally accepted that disability associated with the syndrome resulted from the effect of vibration on the peripheral nervous system rather than the visible presentation of whiteness. Presciently in Hamilton’s original work she reported, ‘they could not tell a dime from a nickel without looking at it’. Epidemiological evidence suggesting that the sensorineural and vascular components could develop independently emerged at a landmark workshop in Stockholm in 1986, and led to a new classification system, the Stockholm Workshop Scale (SWS).4,5 The legacy term vibration white finger (VWF), which neatly encapsulates the cause and presentation, now tends to be confined to legal circles in the United Kingdom. A series of multiparty litigation cases in the early part of the twenty-first century in the United Kingdom, led to the examination of large volumes of claimants under standardized conditions.6 Systematic reviews and international workshops have attempted to standardize the clinical assessment, testing and management of the syndrome.7–9 However, the use of specialized tests remains confined to a limited number of centres of excellence in most countries.

An acceptance that the sensorineural component of the syndrome causes disability has been slow to receive recognition. It was only in 2004 in the United Kingdom, that the Industrial Injuries Advisory Council recommended the assessment of isolated sensorineural symptoms for the...
purposes of industrial injuries disability benefit. This led to amended regulations in 2007.

Exposure to hand–arm vibration (HAV) from hand-held vibrating tools and equipment is common, particularly in construction and engineering. The number of workers exposed to HAV varies significantly between countries. A national survey estimated that approximately 4.9 million workers are exposed in the United Kingdom alone. An estimated 350 000 workers are regularly exposed in Sweden, 6.7 million in Germany, and 1.5 million in the United States. A European Working Conditions Survey 2005 (EWCS) suggested usage was five times more common in men. Sources of HAV that can lead to HAVS are numerous and varied, including both electrically and pneumatically powered percussive and rotary tools, such as fettling tools, impact wrenches, needle guns, hammer drills, chipping hammers, nibblers, hand-held polishers, sanders, grinders, pedestal grinders, rock drills, road breakers, tampers, chain saws, brush saws, strimmers and concrete scarblers. Foundry workers, construction workers, metal workers, miners and forestry workers are at greatest risk.

Prevalence studies in HAVS have mostly considered finger blanching and may be confounded by differences in climate. One prevalence study in the United Kingdom reported 670 000 men and 104 000 women with episodes of finger blanching in response to cold. These types of study have been mostly from developed countries, but other regions are now adding to the literature.

The occupational health professional needs to have some understanding of vibration measurement and its implications when assessing individual cases. Vibration is an oscillatory motion that can be represented by a simple harmonic sine wave with the properties of displacement, velocity and acceleration. In practice, the wave is a complex, of differing frequencies and acceleration. Vibration can move in three orthogonal directions (x, y and z axes) and it is the vector sum that is normally calculated (ISO 5349). The measurement of interest, in terms of a biological effect, is the magnitude of vibration or ‘A(8)’ which incorporates intensity, duration and direction.

The daily exposure to vibration of a person is ascertained using the formula:

\[ A(8) = a_{10} \sqrt{\frac{T}{T_o}} \]

where \( a_{10} \) is the vibration magnitude, in metres per second squared (m/s²); \( T \) is the duration of exposure to the vibration magnitude \( a_{10} \) and \( T_o \) is the reference duration of eight hours (28 800 seconds).

A frequency weighting up to 16 Hz is factored into calculations to take account of the supposedly more damaging lower frequencies suggested by laboratory studies. The validity of this frequency weighting and whether damaging frequencies extending from 6.3 to 5000 Hz should be adopted by unweighted measurement continues to cause controversy.

Inaccuracy in both measurement of vibration and assessment of clinical effects has meant that a robust dose–response model has been elusive. The most frequently cited is in ISO 5349. This model bases the prediction of vascular symptom prevalence on groups of workers who use tools with vibration predominantly above the 30–50 Hz range such as grinders, rock drills and chain saws. Other factors thought to affect the severity of an individual’s condition include temporal exposure patterns, intermittency of exposure, direction of vibration transmitted to the hand, including push and other ergonomic factors that may ultimately affect the transmission of vibration into the hand–arm system. Recent studies suggest that even low level vibration may lead to HAVS. Individual susceptibility, particularly those with pre-existing Raynaud’s phenomenon, peripheral neuropathy and nerve entrapment, also plays a part.

An understanding of the relationship between the onset of symptoms and first exposure can be assisted by a general understanding of the group prevalences at given vibration magnitudes. It was accepted at an international workshop that the first onset of finger blanching in relation to exposure (the latent interval) might range from a few months after the start of vibration exposure to approximately one year after vibration exposure ceased and can be 20 years or more. In turn, reversibility depends on age of the subject, the severity of symptoms, duration of exposure to vibration and the type of vibration tool used.

### CLASSIFICATION

The vascular and sensorineural components of HAVS are graded separately in the SWS (see Table 47.1). The scale is a clinical grading and not a disability scale. It has, however, been used to make recommendations on employability. Limitations in definitions used in the scale has led to suggested modifications (see Table 47.3). It has been difficult to carry out powerful prospective studies because of the diminishing levels of manufacturing, and from younger employees more readily choosing to seek job alternatives.

### PATHOPHYSIOLOGY

There is uncertainty as to the exact pathogenesis of hand–arm vibration syndrome. The vascular and neurological components of the hand–arm vibration syndrome may, however, share a common pathogenesis. Vasospasm may be initiated by nerve fibre dysfunction in the vessel wall, or conversely numbness and tingling may be due to damage to the intraneural vessels. In addition, nerve injury, carpal tunnel syndrome and Dupuytren’s contracture can all be associated with vascular dysfunction.
Normal physiology of the skin

The skin regulates body temperature, stores blood and provides protection from uncontrollable fluid loss and sepsis. Cutaneous sensation allows an awareness of the environment. Sweating and the adjustment of blood flow are part of the homeostatic regulation of body temperature. Thermoreceptors in the skin provide local temperature control and neurons in the pre-optic area of the anterior hypothalamus contribute to central control. Local skin temperature reflexes help prevent excessive heat exchange from locally cooled or heated portions of the body. These reflexes are weak in comparison with hypothalamic control. Moderate cooling or a brief exposure to severe cold leads to constriction of arterioles (resistance vessels) and venules (capacitance vessels) and arteriovenous anastomoses (AVA). The radial and ulnar arteries divide into the deep and superficial palmar arches. The ulnar artery is the main arterial input to the superficial palmar arch usually receiving a branch from the radial artery, but which may be small. The digital arteries, one of which lies on each side of the finger, are derived from the superficial palmar arch for the little, ring and middle fingers. The radial artery supplies the deep palmar arch and this produces the digital arteries to the thumbs and the index fingers. The deep arch also gives anastomotic arteries to the digital arteries from the superficial arch. The digital arteries may anastomose with each other in the digits, more especially at their tips. Acting together, the digital arteries are effectively end arteries: in digital arterial vasospasm the blood supply is effectively cut off and the finger skin becomes diffusely white. Acute injury to both digital arteries may result in loss of the digit unless microvascular repair can be carried out.

The arterial blood supply anatomy can be variable and the relative contribution of radial and ulnar arteries may be different from one person to another. An absent ulnar pulse reflects no more than an innocuous variant from the normal: it does not necessarily reflect pathology.

The cutaneous circulation is controlled by sympathetic vasoconstrictors and vasodilator nerves. Sympathetic vasoconstrictor and vasodilator nerves innervate all areas of hairy skin (non-glabrous), whereas hairless (glabrous skin) is innervated by sympathetic vasoconstrictor nerves only. In glabrous skin, arteriovenous anastomoses are numerous and opening and closing of AVA can cause substantial change in blood flow. Secondary Raynaud’s phenomenon related to functional changes in blood flow would be expected more often to present in glabrous skin, for the second to the fifth digits and in relation to cold. In practice, the phenomenon is often circumferential.

Cutaneous sensation entails a variety of modalities including tactile (touch, pressure, vibration), thermal (heat and cold) and pain sensations carried through the peripheral nerves for interpretation in the central nervous system.

Pathogenesis of neurosensory dysfunction

Manifestations of neurosensory dysfunction can include reduced or absent sensibility, symptoms of pain or dysaesthesia and changed perception of cold (cold sensitivity). Disturbances of central nervous integration may be implied by reduced hand coordination and manual dexterity. Investigations on the sympathetic and parasympathetic autonomic activity have demonstrated an altered balance, with increased sympathetic drive in vibration-exposed subjects. It is postulated that neurosensory pathogenesis may occur at multiple levels. These include changes to sensory receptors, compression or changes in nerve fibres and intrinsic muscles, and to the somatosensory and motor cortex.
Takeuchi et al.\textsuperscript{28} analysed finger biopsies from 30 patients with vibration-induced white fingers, and conducted electron microscopy biopsies from three additional patients with VWF.\textsuperscript{29} The impairment of large myelinated fibres has been documented in both morphologic studies and nerve conduction studies. Histological assessments of patients with VWF revealed an increase in the thickness of the perineurium, and a decrease in the number of myelinated nerve fibres and thick lamellar fibrosis of the perineurium.\textsuperscript{28,29} The nerve fibres were often reduced in size with an increase of collagen with fibroblasts in the endoneurium. The impairment arising from small diameter nerve fibres (A-delta and C-fibres) is documented in disturbed thermal perception studies. Ultrastructural studies using different neural markers for small diameter nerve fibres showed a significant reduction of epidermal nerve density (END) over the forearm among vibration-exposed subjects.\textsuperscript{30}

Sensory and motor dysfunction could also be due to changes in cortical somatotopic mapping of the hand in the brain.\textsuperscript{31} Here, Lundborg et al. conducted an fMRI study to compare the somatotopic cortical representation of the hands of workers exposed to vibration with controls. Cortical activation did not differ significantly between patients and controls, thus favouring a peripheral mechanism. The findings did show some shift in cortical activation suggesting a possible cortical remodelling.

Several different experimental animal models have been used to study vibration-induced neuropathy. Most studies have been conducted on rats. Early experiments often used the paws and assessed the results with light microscopy, while more recent studies use a rat-tail model,\textsuperscript{32} and electron microscopy with immunostaining. Long-time exposure of a rat limb induces swelling (intra-neural oedema) and permanent damage to the sciatic nerve.\textsuperscript{33} Ultrastructural changes (such as detachment of myelin sheath from the axolemma at the nodes of Ranvier, axonal loss, and constriction of the axon) increase with the dose of vibration.\textsuperscript{34} Axonal damage is seen both in myelinated and non-myelinated axons. Non-myelinated axons have also been found to be oedematous.\textsuperscript{35} Rat tails exposed to vibration also exhibit elevated nitrotyrosine immunoreactivity indicative of free-radical damage.\textsuperscript{36} Short-term vibration exposures have been associated with disrupted axoplasmic transport, and the experimental results indicate a cumulative effect.\textsuperscript{37} Vibration and cold generate similar percentages of myelinated axons with disrupted myelin. Cold with and without vibration caused intraneural oedema, whereas vibration alone did not.\textsuperscript{38}

### Pathogenesis of vibration-induced Raynaud’s phenomenon

Raynaud’s phenomenon (RP) denotes an exaggerated vasospastic response to cooling. The aetiology of the phenomenon can be either primary (idiopathic) or secondary, where secondary RP relates to a number of different conditions, including vibration exposure. The phenomenon may be triggered or modified by emotion and stressors. The pathogenesis varies between the underlying conditions. From physical principles (Poiseuille’s law) alone, three general mechanisms can be identified that influence peripheral microcirculation:

1. perfusion pressure
2. the luminal radius of the digital artery
3. blood viscosity.

Abnormalities in all three mechanisms have been described among vibration-exposed subjects. The vascular dysfunction may be due to functional or structural abnormalities or both.\textsuperscript{39,40} Some dysfunction is better understood, while others are speculative.\textsuperscript{41} The pathogenesis of Raynaud’s phenomenon either primary or secondary remains uncertain.

### Perfusion Pressure Abnormalities

Both sympathetic vasoconstrictor and vasodilator systems in the skin participate in blood pressure regulation via the baroreflex. A decrease in perfusion pressure can be caused by systemic hypotension or by a proximal arterial obstruction. Raynaud’s phenomenon has been associated with obstructive vascular disorders, such as cervical ribs\textsuperscript{46} and thromboses. Subjects with entrapment in the carpal tunnel exhibit increased prevalence of RP.\textsuperscript{42} Thenar- and hypothenar hammer syndrome are disorders with reduced blood flow and may appear similar in their manifestation to RP. The baseline cutaneous blood flow of healthy females is lower than that in males and may in part explain the higher prevalence of RP in women.

### Dysregulation and Abnormalities of the Luminal Radius

The regulation of the luminal radius is balanced by vasoconstrictor and vasodilator systems. The neural vasoconstrictor system is tonically active in thermoneutral environments. Sympathetic vasoconstrictor nerves release norepinephrine, which interact with postsynaptic a1- and a2-receptors on cutaneous arterioles and arteriovenous anastomoses. Noradrenergic vasoconstrictor nerves also release neuropeptide-y and adenosine triphosphate. Cold augments smooth muscle a2-adrenoreceptor function. Adrenoreceptor (AR) dysfunction among VWF cases causes weakened a1-receptor-mediated response and predominance of a2-receptor function. Cold-induced vasoconstriction is usually a protective response to prevent heat loss and is mediated by a reflex increase in sympathetic nerve activity. The a2-adrenoreceptors comprise three subtypes and only the a2C AR seems to be sensitive to cold. Results from rat-tail models indicate that vibration can augment sympathetic vasoconstriction by selectively increasing a2 AR reactivity.\textsuperscript{43} Cooling activates a2C AR.
Intraneural swelling occurred in the rat model when the skin temperature was below 15°C. In addition to the neural regulation, there are endothelium-produced vasoconstrictors and vasodilators. The most potent vasoconstrictor is endothelin-1. Patients with VWF seem to exhibit lower endothelin-1 levels than primary RP in response to cold provocation tests, but more advanced cases of VWF show an exaggerated response compared to normal subjects. Cutaneous injection of endothelin-1 results in a large area with vasospasm, but a reduced vasodilator response which indicates a local axon-reflex deficit, with abnormality in unmyelinated 'C-fibres' and thinly myelinated A-delta fibres. Nerves supplying blood vessels produce several vasodilatory substances. Temperature increase normally causes vasodilation by stimulating local release of neuropeptides from sensory nerves, such as calcitonin gene-related peptide (CGRP), substance P (SP) and neurokinin-A (NKA). It also stimulates release of endothelin-related nitric oxide (NO).

Immunohistochemical studies have shown a reduction in the number of sensory-motor nerves containing the vasodilator CGRP in finger skin biopsies of patients with hand–arm vibration syndrome. There was also a reduction in the pan-neuronal marker protein gene product 9.5, suggesting that the CGRP depletion might be a consequence of damage with neuronal loss.

Biopsies from patients with VWF reveal thickening of the muscular layers of the artery walls, with hypertrophy of individual muscle cells without intimal fibrosis.

**INTRAVASCULAR DYSFUNCTION**

Changes in leukocytes, erythrocytes and the intima have been reported in long-term exposure to vibration. Where reduced blood viscosity has been found, it has been interpreted as a compensatory mechanism in reaction to tissue ischaemia.

**Pathogenesis of carpal tunnel syndrome**

Recent studies have demonstrated neuropathies proximal to the hand among vibration-exposed workers or at multifocal levels. Structural changes found just proximal to the wrist may be involved in the development of carpal tunnel syndrome in vibration-exposed workers. Histological findings in the wrist of post-mortem specimens showed synovial membrane hyperplasia, endothelial reduplication and increased epineural density inside the carpal tunnel. The findings are interpreted as steps in the pathogenetic path based mainly on pressure produced by forces and displacement of tendons. This mechanical factor in the aetiogenesis of carpal tunnel syndrome (CTS) has later been modified and extended by supporters of an additional vascular pathogenesis for CTS. The pathophysiology of the microcirculation and the subsequent neuropathy varies with the various stages of the CTS lesion. In the early stages, there is evidence for oedema formation and vascular insufficiency manifested as nocturnal paraesthesia, while in the advanced stage, there is severe injury with severe nerve fibre lesions of neuropractic and axonotomotic type. Evidence from meta-analysis of studies on CTS and work supports and extends previous conclusions that there is a relation to vibration and to certain hand activities.

**Pathogenesis of Dupuytren’s disease**

Dupuytren’s disease (DD) is characterized by thickening, nodule formation and contracture of the palmar fascia, resulting in flexion deformity of the fingers. Heredity, alcohol abuse, epilepsy, diabetes and smoking have been associated with DD. When reviewing studies focusing on the relation between intensive manual work, trauma, vibration exposure and the development of DD, Liss and Stock concluded that there was good support for an association between vibration and DD. However, a recent study including almost 100 000 subjects failed to show this association. Biomolecular advancements at gene and cellular level have brought new insights to the pathogenesis of DD. Studies of gene expression using DNA microarray technology revealed that several genes were upregulated, while at the same time others were downregulated in tissue samples of DD. Contractile myofibroblasts are involved in contracture deformity. Histologically, the cords of DD consist of a dense collagenous matrix with fibroblasts. The cause of myofibroblast proliferation on the cellular level in DD is unknown. One hypothesis is that reduced peripheral blood flow causes ischaemia and the generation of free radicals, which damage the surrounding tissue and cause fibroblast proliferation. Initially, in the pathogenesis, there is a proliferative stage characterized by an increase in myofibroblasts. In the subsequent involutional stage, the microvessels within this tissue are considerably narrowed. It has been suggested that the pathogenesis of DD is a result of vessel narrowing causing local hypoxia and chronic ischaemia, activating the xanthine oxidase pathway, releasing free radicals that stimulate fibroblasts to proliferate.

**Pathogenesis of vibration-associated muscular disease**

Reduction of neuromuscular function and strength may occur following long-term exposure to work with vibrating machines. Farkkila and co-workers reported loss of extrinsic hand muscle strength among lumberjacks with hand–arm vibration syndrome. More recent studies have confirmed reduction in both extrinsic and intrinsic hand muscle strength. The results of Necking et al. demonstrate thenar muscle strength loss in subjects with long-term exposure to hand-held vibrating machines. The morphological assessments demonstrated centrally located
myonuclei with fibre type grouping, angulated muscle fibres, ring fibres, regenerating fibres and fibrosis. The observed muscle necrosis, fibrosis and the structural disorganization were all interpreted as suggestive of direct muscle damage, whereas the angulated fibres and fibre type grouping suggests muscle denervation and reinnervation.59 These findings are in accordance with those observed in short-term vibration in animal models.60 Several theories regarding the pathogenesis have been suggested, including vibration, tonic vibration reflex with continuous elevation of muscle tone, blood flow reduction, and mechanical and metabolic changes. The evidence suggests that working with vibrating machines may cause both damage to the muscle units within the contractile muscle fibres and nerves.

CLINICAL FEATURES

Sensorineural hand–arm vibration syndrome

In the natural history of the condition, neurological (sensorineural) symptoms tend to occur first. Most surveys record them as twice as common as vascular symptoms and generally causing greater disability. The latent period for sensorineural symptoms varies from a few months to many years.

SIGNS AND SYMPTOMS

Use of vibratory tools causes transient paraesthesia in the fingers of most users. This usually passes off within 20 minutes. Often, the first abnormal symptoms are an extension of this time. Tingling or numbness usually starts at the fingertips, but can affect all, or the whole, of the fingers. With continuing exposure, these symptoms may become persistent lasting for hours or even all day. Although aggravated by coldness, the tingling and numbness can occur in a warm environment, causing considerable distress. The sensory loss causes workers to describe their fingers as feeling thick or ‘like bananas’ in many instances.

There is a loss of feeling, of temperature appreciation and of pain sensation. In severe cases, workers can experience clumsiness and loss of manual dexterity, with poor finger coordination causing inability to do fine work.

Assessing a case of suspected neurological HAVS requires details of vibration exposure, past medical history and a clinical history of date of onset of symptoms, site of paraesthesia, time of occurrence and duration of symptoms. Nocturnal symptoms may occur, but are less frequent than in cases of carpal tunnel syndrome.

Before reaching a diagnosis of sensorineural HAVS, all other causes of peripheral neuropathy must be considered (see under Diagnosis, p. 505).

There are no visible signs of neurological damage. This makes the use of tests all the more important before advice can be given to the worker on the severity of the condition and implications of further exposure to vibration.

As there is no gold standard to diagnose sensorineural HAVS, and no single test with sufficient specificity or sensitivity, researchers have recommended the use of a battery of tests.51,61

The appreciation of touch, vibration, temperature, joint position and motion are transmitted by nociceptors, thermoreceptors, mechanoreceptors and nerve fibres. Tests have been designed to detect abnormalities in these receptors and transmission pathways. Their main value is in assessing the severity of sensory loss.

Simple tests, such as cotton wool and moving two-point aesthesiometry, can demonstrate a loss of sensation, but are limited by inter-observer error, and generally will only pick up the later stages of sensory loss. These clinical findings have no normative data available for comparison. Semmes–Weinstein monofilaments have been used to grade such loss and are considered a better validated example of these types of test.52

Other psychophysical or quantitative sensorineural tests (QST) with a sound anatomical and physiological basis have been developed. As all these tests have a subjective input, they are not truly objective and are often referred to as ‘standardized tests’.

These tests derive from the work on mechanoreceptors by Mountcastle.63 Vibration stimulates mechanoreceptors, end organs and nerve fibres. The superficial Meissner corpuscles or fast adapting 1 (FA1) respond to frequencies between 5 and 60 Hz, while the deep Pacinian corpuscles or fast adapting 11 (FA11) react to frequencies between 50 and 400 Hz. These signals are transmitted by the large myelinated A-alpha and A-beta fibres. There are also cold and warm receptors in the fingertips. Messages from the cold receptors are transmitted by small myelinated A-delta fibres, while those from warm receptors use unmyelinated C fibres.

The vibrotactile threshold test (VTT)64,65 and thermal aesthesiometry test (TA)66 have had their integrity investigated.67–69 These tests must be performed in a temperature-controlled environment. As they are psychophysical tests, a random element should be built in to eliminate any deliberate exaggeration. In both tests, the flexor surface of the distal phalanx of the index and little fingers is tested to assess the median and ulnar innervation. The VTT requires a constant downward pressure of 1 Newton. Thresholds are generally measured at 31.5 Hz (Meissner corpuscles) and 125 Hz (Pacinian corpuscles), although some equipment includes a broader range of frequencies.

Change of the temperature in TA is 1°C per second. The ‘pulse method’ should be used.70 The zone in which change in temperature cannot be felt is known as the temperature neutral zone (TNZ), and is calculated by subtracting the cold threshold from the warm threshold.

A test, such as the Purdue pegboard test (PPT), may demonstrate loss of dexterity against age-related normative data.71,72 As an isolated test, it is of little discriminatory value.
As the mechanism and proportion of damage is unclear, the VTT and TA should be given equal weighting. A scoring system can be used to record the extent of this damage (see Table 47.2).59

The first attempt to grade the stages of vibration damage was the Taylor/Pelmear classification in 1967. Unfortunately, the only neurological category was the earliest stage 0N (numbness) or 0T (tingling). Once the importance of the neurological damage was recognized this neurological grading became inadequate and was replaced by the sensorineural component of SWS (see Table 47.1).4

A very large contract examining more than 100,000 miners with the use of VTT and TA gave the opportunity to recommend refinements to the sensorineural staging of the SWS.6 As tingling was thought to be as important as numbness, the wording ‘with or without tingling’ was changed to ‘numbness and/or tingling’. Stage 2SN was thought to cover a very wide range of neurological damage from patients with relatively minor handicap to those with severe sensory loss, but without a dexterity problem in a warm environment. For this reason, the combined VTT and TA score was used to divide this stage into 2SN early and 2SN late (see Table 47.3).

True 3SN cases have severe persistent neurological damage. For a grading of stage 3SN, there had to be a loss of dexterity in a warm environment, VTT and TA score of equal to or greater than 9, and an abnormal Purdue pegboard test. As the maximum single test score per hand was 8, a score of ≥9 was required to show evidence of damage in both tests. When these criteria were met, 10 was added to the combined VTT and TA score.

In the United Kingdom, the use of these tests, scoring system and modified sensorineural staging has been accepted by the Health and Safety Executive in their Guidance on Health Surveillance for Occupational Health Professionals 2005.22

### Vascular clinical features

The vascular component is one of arterial vasospasm, and the clinical features are indistinguishable from Raynaud’s phenomenon. Raynaud’s phenomenon is a very common condition in the community manifested by cold-induced episodic attacks of digital arterial vasospasm, causing ‘whiteness’ of the affected parts of the fingers. It is more common in colder climates. Overall, it affects up to about 15 per cent of the community with a female preponderance of approximately 3:1 compared with males. In temperate European countries, a prevalence of about 5 per cent for males and 30 per cent for females would be expected. In warm countries, fewer manifestations of Raynaud’s phenomenon have been reported.

Raynaud’s description in 1862 included a variety of conditions, but as time has passed, the condition has become much more clearly described and primary and secondary Raynaud’s conditions are now recognized.

Primary Raynaud’s phenomenon is otherwise known as Raynaud’s disease. This condition affects younger people, mostly under the age of 40 years, and usually females. Individuals suffer episodic attacks of whiteness of the fingers and/or toes occurring in response to cold. Fingertips are affected first and, as the condition progresses, the entire fingers are affected in late cases. Although some or all of the digits can be affected, the extent of the blanching is usually variable from attack to attack and is diffuse.

The extensive use of vibrating powered tools in industrial processes is responsible for most cases of secondary Raynaud’s phenomenon. However, there are other well-recognized diseases (many under the heading of collagen

</table>
vascular disorder, for example, systemic sclerosis and CREST syndrome). These are all associated with digital artery vasospasm occurring in response to cold. In these conditions, the symptoms can come on at any age and may be rapidly progressive leading to ischaemia of the fingers and toes necessitating amputation. Investigations will normally show antibodies in the blood enabling the diagnosis to be made, and although these may be absent initially, they frequently emerge with time and may be some years after first presentation of the disease that they become detectable. Severe Raynaud’s disease is often said to be an autoimmune secondary Raynaud’s phenomenon without the antibodies, yet being identifiable. It is rare for Raynaud’s disease or Raynaud’s phenomenon secondary to vibration to be as severe in its effect as secondary Raynaud’s phenomenon arising in association with autoimmune vascular disease. A systematic review found evidence that vascular symptoms could occur in the lower limbs in those diagnosed with HAVS, providing symptoms were apparent in the hands.9

Vibration-induced Raynaud’s phenomenon is graded on the Stockholm scale according to the severity of the symptoms and the extent of the blanching. In stages 0, 1, 2 and 3, there is a transition from vibration exposed, but no blanching to extensive blanching affecting all of the fingers in their entirety. A stage 4 category is reserved for those individuals who have trophic or ischaemic changes evident in the fingers: while it is true that some vibration-exposed workers will show trophic changes in the fingertips, it is the experience of the authors that all of these cases have another reason for the trophic change to be present. Almost certainly, stage 4 HAVS does not exist and if a case is seen in which stage 4 seems a likely diagnosis, full blood investigations for autoimmune vascular disease should be instigated, and repeated if the results are initially negative.

The onset of HAVS is dependent on two factors. The first is the susceptibility of the individual using vibrating tools to the harmful effects of vibration, and the second is the vibration dose received: higher dose leads to an earlier onset. Some individuals develop symptoms early in their careers, yet others may never develop symptoms or have the onset of symptoms delayed for many years. The first symptom or sign of digital arterial vasospasm is the onset of blanching affecting the tips of one or more fingers and occurring in response to cold. Gradually, the extent of the blanching increases until the full length of each finger may be affected. The thumbs tend to be spared, but they can be affected particularly in more severe cases of HAVS, or when the thumb is particularly exposed to vibration. The blanching of the fingers may just extend on to the most distal aspect of the palms. The blanching is circumferential and sometimes obliquely so, affecting the territory of one digital artery, but not both.

A typical attack lasts for between 20 and 30 minutes, although it can last longer for up to an hour or so. Longer-duration attacks are highly unusual and a regularly experienced ‘attack’ lasting more than two hours is more likely to be a description of a natural physiological response to the cold. Recovery can be hastened by warming of the hands, although this may be painful. True digital artery vasospasm is accompanied by numbness in the fingers due to the transient ischaemia of the digital nerves. The area of blanching is normally sharply demarcated from the surrounding normal skin.

In the recovery phase, the circulation is restored to the digit from the base towards the tip, and there is usually a reactive hyperaemia, reflecting the acidosis or acidemia that will have developed in the digit during the period of ischaemia. The finger often appears a prominent red colour as recovery proceeds, with ultimately a normal pink hue being resumed. Many individuals describe this phase as being one of hot aches, and a comparison is often made with the sensation in the hands remembered from childhood after playing in the snow. In some people, the red discolouration does not occur, but a cyanotic colour is present instead. In addition, some people give a description of arterio-venous vasospasm without whiteness, only cyanosis of the fingers. This is likely to be compatible with a diagnosis of HAVS.

Blotchiness of the fingers may be a complaint. This is not normally considered to be Raynaud’s phenomenon, which causes a uniform blanching. Mottling is a common normal skin appearance.

Another common complaint is of cold fingers or cold sensitivity. In isolation, this is not Raynaud’s phenomenon, nor does it necessarily reflect any underlying vascular pathology, although some consider it to be to a presymptomatic phase.

Some individuals describe a whiteness of the skin that is simply a normal appearance or a physiological response to cold. Some drug therapy is associated with the potential side effect of cold extremities (for example β-blockers) that around 3 per cent of patients experienced troublesome vasospastic phenomena of the periphery. The symptoms occurred within two months of starting the treatment and usually affected the extremities of all four limbs. At about the same time, Marshall and colleagues74 published higher figures for the development of Raynaud’s phenomenon, although the diagnosis was based only on the results of a questionnaire. Fifty-nine per cent of patients on propranolol had Raynaud’s phenomenon compared with 35 per cent on atenolol. Overall, patient numbers were small; however, this study is important for it found that all patients with Raynaud’s phenomenon attributable to β-blockers had developed it in both the hands and feet simultaneously.
These factors relating to the vasospastic phenomena of HAVS are probably of greater importance in the litigation arena than in the occupational health environment. It is suggested below that the management of the individual exposed to vibration, who has arterial vasospastic symptoms and signs, is based on the presence of the Raynaud’s phenomenon, and not on whether β-blockers or other factors might be causing the symptoms.

People affected by HAVS present in either the occupational health setting or in the medicolegal arena. In the former, the symptoms may be under-reported, for there may be a genuine concern about continuing employment, but in the latter the symptoms may be exaggerated to try and increase the financial compensation. Much time and effort has been expended in trying to identify a test that might be useful in this respect (e.g. cold water provocations). Attempts to do this are confounded by the fugitive nature of the disease itself. There currently is no objective assessment of a sufficiently high sensitivity, specificity and positive predictive value to enable decisions to be made at an individual level regarding the presence, absence or severity of the disease.

While vibration causes the underlying disease to be present, it is cold which provokes an attack of arterial vasospasm. The affected person knows the circumstances that might lead to an attack occurring, but whether an attack will occur in those circumstances cannot be predicted. The attacks tend to be random. There are a number of variables that can confound the application of these tests. These include core body temperature, recent smoking and alcohol intake, recent vibration exposure, anxiety, drug therapies and the state of the arterial tree.

The nature of Raynaud’s phenomenon means the response to cold in any individual varies from day to day. The sufferer knows the circumstances which may provoke an attack of blanching and also knows that an attack may or may not occur under those circumstances. The response is unpredictable. Despite these caveats, a number of these tests have been studied. These have included uncontrolled cold provocation tests, in which the worker’s hands are plunged into ice or iced water for a variable period of time. The response is observed without any criteria having been established against which the results of the challenge can be assessed. In this situation, ‘objective’ means that the test cannot be manipulated either by the observer or the subject. The test involves cooling the fingers for a defined time and then measuring, by means of thermocouples, the rewarming time. The application of this test on over 40,000 miners was assessed in the UK miners’ compensation scheme established by the Department of Trade and Industry. The results showed that the test employed was of little or no value in assessing these miners. The Health and Safety Laboratory of the HSE reported similar findings. An alternative to measurement of finger skin temperature using a thermocouple is to use a thermographic measurement of the digital rewarming, but the principle remains the same.

Other techniques have included the measurement of finger systolic blood pressure after controlled cooling of the fingers. This test is technically difficult to perform in the field setting, but is suited to an occupational health laboratory. However, considerable overlap of results has been documented in a study of dockyard workers with and without symptoms of HAVS. Some researchers have suggested that the sensitivity and specificity of these tests might be improved after body cooling. Others suggest that a cooling test, with measurement of changes in the recovery phase, does offer a test of high sensitivity, specificity and positive predictive value. Despite this, the Faculty of Occupational Medicine evidence review concluded ‘no current vascular test has been shown to accurately stage the extent of an abnormality in an individual as defined by the Stockholm Workshop Scale’.

There is no test or process which will enable a decision to be taken with absolute certainty as to whether Raynaud’s phenomenon is secondary to vibration or is simply due to Raynaud’s disease. The main potential causes, when considering the differential diagnosis, are presented in Table 47.4 (see under Diagnosis, p. 505).

**CARPAL TUNNEL SYNDROME**

Carpal tunnel syndrome (pressure on the median nerve at the wrist) has a high prevalence in the adult community. Episodes of intermittent mild numbness in the median innervated fingers will not necessarily take a person to their primary care physician for investigation or treatment. Two studies in the 1990s sought to identify the prevalence of carpal tunnel syndrome in the community by patient questionnaire and nerve conduction studies. De-Krom et al. identified a prevalence of 3.4 per cent of adult females with known carpal tunnel syndrome, but an additional 5.8 per cent of females where the diagnosis had been previously undetected. The figures for men range from 0.6 to 8 per cent depending on the criteria used. Ferry et al. felt the prevalence estimate lay between 7 and 18 per cent of the adult population (and was similar for male and female populations).

Patients complain of pain and paraesthesia in the distribution of the median nerve, with numbness in the fingers especially at night, and aggravation of symptoms when using the hand. There may be wasting of abductor pollicis brevis in long-standing cases. Provocation tests may be useful in diagnosing carpal tunnel syndrome; Phalen’s test increases the pressure on the median nerve, as the wrist is moved from neutral dorsopalmar flexion to maximum

This list is not a complete list, but it does cover some of the more common potential causes of doubt in the diagnosis. Inclusion here does not necessarily mean the second pathology or the presence of drugs is the cause of symptoms. Only a very small number of people on β-blocker therapy will develop Raynaud’s-like symptoms; only a very small number of diabetic patients will have a peripheral neuropathy.

Carpal tunnel syndrome in workers exposed to vibration

A variety of papers have identified a high prevalence of carpal tunnel syndrome in vibration-exposed workers (Table 47.5). The studies mentioned are composed of relatively small numbers of workers. Stromberg et al. reviewed 100 vibration-exposed workers and noted that 48 per cent had isolated neurosensory symptoms, 20 per cent isolated vasospastic problems and 32 per cent combined neurosensory and vascular problems. Twenty-two per cent of the cases were also considered to have carpal tunnel syndrome. The Industrial Injuries Advisory Council in the United Kingdom has accepted carpal tunnel syndrome as a prescribed industrial disease, having reviewed the evidence and concluded a doubling of relative risk in vibration-exposed workers. The council did not consider there was sufficient evidence to offer an opinion on qualifying exposure, but would expect the symptoms to begin during employment when hand-held vibrating tools were used.

The relationship between carpal tunnel syndrome and hand–arm vibration is unclear. If there is an association, its pathological process is not known. Those exposed to vibration commonly use their hands for high force, high repetition activities, which Silverstein et al. consider a potent cause of higher prevalence of carpal tunnel syndrome. Lundborg et al. believe that vibration creates oedema by adjustments of working height, and the use of appropriately designed tools with suitably sized handles. Repetitive and forceful activities should, if possible, be shared through the entire working day, to minimize the prospect of difficulties. An ergonomic programme outlined by Eversman reduced a workforce incidence of carpal tunnel syndrome by 60 per cent. Nerve and tendon gliding exercises have been shown to be of benefit in reducing the need for carpal tunnel decompression. Wrist splints can also be extremely helpful in the earliest stages of the disease. The volume of the carpal tunnel is maximal in the neutral flexion extension range and the wrist splint should be applied in this position for maximal benefit.
within the nerve and swelling of the synovial linings, creating increased pressure within the carpal tunnel. Stromberg, a co-worker, took biopsies of the posterior interosseous nerve in vibration-exposed workers and controls.99 The posterior interosseous nerve lies on the dorsal surface of the wrist. There was evidence of myelin breakdown and intraneural fibrosis in those exposed to vibration, confirming that vibration damage can occur to nerves at wrist level.

The diagnosis of carpal tunnel syndrome in vibration-exposed workers with neurosensory impairment is difficult. Tinel’s and Phalen’s tests are helpful in classical cases of carpal tunnel syndrome,100 but the specificity and sensitivity of these tests has not been evaluated in a vibration-exposed group. Stromberg et al.101 assessed the value of nerve conduction studies and concluded that they did not discriminate between carpal tunnel syndrome and vibration-induced neurosensory impairment. Numbness and tingling in the median innervated fingers that wakes a patient at night, or is present on awakening in the morning, may be the most helpful clinical sign, confirming a diagnosis of carpal tunnel syndrome in vibration-exposed workers. Burke et al.102 reported the assessments of 26,000 miners seeking compensation for hand–arm vibration syndrome. The doctors assessing the claimants observed 38 per cent to have nocturnal awakening, 15 per cent had a positive Tinel’s test and 20 per cent a positive Phalen’s test. The doctors assessing the claimants considered 15 per cent of the claimants to have carpal tunnel syndrome.

Carpal tunnel decompression in patients not exposed to vibration produces a very satisfactory outcome in most cases.103 Decompression in vibration-exposed workers is effective at relieving night pain and intermittent numbness within the median nerve distribution.104 Hagberg et al.105 considered carpal tunnel decompression slightly less effective in vibration-exposed patients, but the majority still had a satisfactory outcome from surgery.

In conclusion, the Industrial Injuries Advisory Council considers there is a doubling of risk of carpal tunnel syndrome in vibration-exposed workers. However, the prevalence of carpal tunnel syndrome in the community is high, with many patients not seeking treatment for their complaints. Vibration exposure may be an aetiological risk factor for carpal tunnel syndrome, or alternatively a risk factor for provocation of symptoms of carpal tunnel syndrome. However, the relationship between carpal tunnel syndrome and hand–arm vibration remains uncertain.106

**DUPUYTREN’S DISEASE**

Dupuytren’s disease commonly affects mature males in Northern Europe. The prevalence there varies between countries, with Gudmundsson et al.107 noting very considerable variations in prevalence between communities in the United Kingdom, Norway, Sweden and Iceland.

The prevalence of Dupuytren’s disease rises steeply with age. Hueston108 noted 4 per cent prevalence in working male Australians if they were under the age of 40 years, but a 30 per cent prevalence in those older than 60 years. A genetic predisposition is noted in most cases, with a particularly high prevalence observed in diabetics.109 An increased prevalence has also been noted in those with a high consumption of alcohol,110 and in those who smoke tobacco.111

The condition manifests itself with the development of thickening in the palmar fascia, producing nodules, bands and pits. The ulnar border of the hand is most commonly involved, extending into the ring and little fingers, but all digits may be affected, including the thumb and first web space. Those with a strong Dupuytren diathesis will have deposits of Dupuytren tissue on the dorsal surface of the proximal interphalangeal (PIP) joint (Garrods pads), and there may be involvement of the plantar fascia (Ledderhose disease) or the penis (Peyronie’s disease). Nodules may be tender at the outset, but the discomfort usually settles as the nodules mature, with shortening that can produce contracture to the metacarpophalangeal (MP) and PIP joints, particularly to the ulnar border of the hand. The distal interphalangeal joints are rarely involved in primary unoperated cases. Excision of the foreshortened fascia in the palm or fingers is effective at releasing contractures, but recurrence is common, particularly in younger patients.

The effect of heavy manual work on the prevalence of Dupuytren’s disease has been debated for many years. Dupuytren112 considered there was an association between manual work and the condition which bears his name. Hueston113 was not supportive of an association. Mikkelsen114 did consider there was a relationship and postulated that heavy manual work gives rise to rupture of the fibres in the palmar fascia initiating an unregulated fibrotic response creating nodules and contractures.

The subject was reviewed in 2004 by Khan et al.115 who compared the incidence of Dupuytren’s disease across social classes in England and Wales, using data from the National Morbidity Survey. They reviewed the incidence rates of first ever consultations for Dupuytren’s disease with general practitioners in a 500,000 population. They reviewed the prevalence of attendances with Dupuytren’s
Disease combining skilled manual, partly skilled manual and unskilled manual workers as a group and compared them with a group of professional, managerial and technical and skilled non-manual workers. Accumulative standardized incidence of Dupuytren’s disease rose in a similar way with increasing age until normal retirement age (65 years), but a divergence then occurred between the manual and non-manual groups. The non-manual group were found to have a higher incidence than manual workers. Their findings are in conflict with those of Mikklesen,114 who found a higher incidence in retired manual workers in an epidemiological study involving 16000 citizens of a small Norwegian town. Khan et al.115 concluded that manual occupations were not associated with an increased incidence of Dupuytren’s disease. Ross116 reviewing the available literature considered that most authors believed there was no association between occupation and the risk of developing Dupuytren’s disease.

The effect of a single traumatic event on the development of Dupuytren’s disease has been investigated. Stewart et al.117 studied patients who had sustained a Colles fracture and observed that 11 per cent of the 235 patients developed features of Dupuytren’s disease between three and six months from injury. Contractures were mild and were not progressive when reassessed at a later date.

**Dupuytren’s disease in vibration-exposed workers**

Some studies of vibration-exposed workers have revealed an increased prevalence of Dupuytren’s disease. Liss and Stock118 reviewed the literature and felt that there were three papers which offered reasonable evidence of an association. Cocco et al.119 matched 180 cases of Dupuytren’s disease against controls with age matching ± five years. They found a statistically significant increase in the risk of Dupuytren’s contracture in vibration-exposed workers, and there appeared to be a dose–response relationship. Bovenzi et al.119 reviewed 570 quarry workers who had been exposed to vibration, using stone workers as controls. They considered the odds ratio for developing Dupuytren’s contracture was 2.6, although no dose response was identified. Thomas and Clarke120 identified a prevalence of Dupuytren’s disease of almost 20 per cent in vibration-exposed workers (double the prevalence in the controls). They found no correlation between the Taylor Pelmar stagings for hand–arm vibration and the prevalence of Dupuytren’s disease. The sample size of the three studies is relatively small and age matching relatively loose.

However, age does have a major effect on the prevalence of Dupuytren’s disease. A review of over 97000 miners seeking compensation for hand–arm vibration syndrome, revealed a Dupuytren’s disease prevalence of 1.7 per cent in claimants in the 35–39 year age group.121 The prevalence in 80–84 year olds was 19.6 per cent. Age was found to be the prime determinant of the prevalence of Dupuytren’s disease in this study. An accurate assessment of vibration exposure throughout previous employment cannot usually be obtained, and employees who may overestimate time spent holding the vibrating tool (the ‘anger time’ or ‘trigger time’) by as much as a factor of four.121 However, the vibration exposure in years (in all industries) was known for this large group of miners. There was no statistically significant correlation between the years of exposure to vibration and the prevalence of Dupuytren’s disease (controlling for age).

Stockholm vascular and neurosensory grading and thermal aesthesiometry and vibrotactile threshold scores (when corrected for age) were found not to be predictors of Dupuytren’s disease. This study does not support Liss and Stock’s view that there is an association between vibration exposure and the development of Dupuytren’s disease.

The prime determinant for the prevalence of Dupuytren’s disease is age, and any study of a possible association between Dupuytren’s disease and occupation must be tightly controlled for age. On the available evidence, Dupuytren’s disease is unlikely to occur more frequently in manual workers and is probably not more common in vibration-exposed workers.

**HAND–ARM VIBRATION AND MUSCLE WEAKNESS**

Normative data for grip are available from the United States122,123 and in the United Kingdom.124 All three studies used a Jamar dynamometer on the second grip setting, with a mean of three grips in standard positioning. Mathiowetz et al. obtained values from 310 males,122 Hanten et al. 533 males123 and Gilbertson and Barber-Lomax 130 males.124 The Hanten series, and Gilbertson and Barber-Lomax are broadly supportive of Mathiowetz’s male grip normative values. Grip reaches a maximum in the late 20s and early 30s and halves in old age. Males are noted to be almost 50 per cent stronger than females in comparable age bands. There was a slight preponderance to the right hand being stronger than the left, and minimal difference in the power of grip between dominant and non-dominant hands. Seven per cent of Mathiowetz’s males and 11 per cent of Hanten’s study were left-handed. Bohannon125 reviewed ten studies and concluded that in all but one study, strength was greater to the dominant right hand. For dominant left-handers the results were equivocal.

Patients suffering from HAVS are frequently noted to suffer from weakness of grip.68 Farkkila et al.126 noted muscle forces to be significantly diminished among workers reporting numbness in the hands. Weakness was not found in forestry workers who had been exposed to less than 5000 hours of sawing. Farkkila et al.58 explored the matter further, reassessing grip after a two-year interval. Lumberjacks with HAVS (described as white finger) lost 21 per cent of grip over the two years, while lumberjacks not suffering from HAVS only lost 5 per cent of grip. The numbers in the study are small. The HAVS group comprised 11 subjects.
with a mean age of 45 ± 8 years. The mean age of the 44 subjects considered to have normal grip and no HAVS was 39 (±10) years. Mirbod et al.127 performed a similar study over a four-year interval. Fifty-three grinders were assessed for grip over a four-year interval. None were considered to have HAVS at the first assessment, two at the second assessment. The average diminution of grip was 7.4 per cent over the four-year interval. The mean age rose from 42.3 years (range, 37–59) to 46.3 years (range, 41–63).

Sorensson and Burstrom128 assessed the translation of vibration to different parts of the arms (knuckle, wrist and elbow). They confirm that energy transmission decreases with increasing distance from the source. There is progressive dampening more proximally in the limb. If vibration causes nerve or muscle injury, the parts most at risk would be the intrinsic muscles of the hand, rather than the long flexor and extensor muscles of the forearm. Necking et al.129 explored the effects of vibration on the intrinsic and extrinsic muscles of the arm in 81 workers exposed to vibration and 45 controls. They noted a 7 per cent reduction in extrinsic muscle power in vibration-exposed patients and a 19 per cent reduction in intrinsic muscle power compared to controls. Their study supports the view that the principle cause of weakness of grip in vibration-exposed workers relates to intrinsic muscle dysfunction in the hand rather than the forearm, where energy transmission is less.

Intrinsic muscle mass may be considered relatively small compared with the forearm muscles, but the intrinsic contribution to grip is significant. Kozin et al.130 explored the contribution of extrinsic and intrinsic muscles to grip in 21 volunteers, who were subjected to low median and low ulnar nerve blocks. A low nerve block to the ulnar intrinsics reduced grip by 38 per cent and a low nerve block to the median innervated intrinsics reduced grip by 32 per cent. Blocks to both median and ulnar innervated intrinsics reduced grip from pre-injection levels by 49 per cent.

A series of studies from Malmo in Sweden have indicated that chronic vibration exposure can damage nerves at the level of the wrist. Stromberg et al.131 biopsied the posterior intersosseous nerve at the level of the wrist in ten patients who had been chronically exposed to vibration. A variety of pathological changes to the nerve was noted (including myelin breakdown and intraneural fibrosis). These features were not found in a similar number of cadaver controls that had not been exposed to vibration.

Necking and co-workers60 in the same research institute, explored the short-term effects of vibration exposure to the hind paws of rats (five hours daily for two days). Exposure was noted to expand muscle fibres, and nuclei took on a more central position within the fibre. In a more recent study, the same group biopsied abductor pollicis brevis in 20 patients known to be suffering from HAVS.132 A variety of abnormalities were noted (centrally located myonuclei, angulated muscle fibres, ring fibres, regenerating fibres and fibrosis). Most of these changes are indicative of direct muscle injury, but angulated fibres were considered to likely arise from muscle denervation and re-innervation, suggesting not only direct muscle damage, but additional injury to the motor nerve fibres.

In a separate study, Necking observed reduced index abduction power in patients suffering from hand–arm vibration syndrome.59

Grip strength assessments in 97 581 miners seeking compensation for hand–arm vibration syndrome revealed weakness of grip in two-thirds of cases.133 Figure 47.1 compares the miner’s grip, by age band, to UK and US normative values. The effect of vibration exposure on grip was not dose-related and was small when corrected for age (Figure 47.2). The Stockholm neurological and vascular stagings had little correlation with grip, except those with a 3SN rating. Thermal aesthesiometry and vibrotactile threshold staging also had little correlation with grip, when corrected for age. The claimants’ low grip values in all age bands, when compared to normative data were not explained. An early vibration effect on grip during the first five years of exposure was not identified.

Workers exposed to the use of vibrating tools frequently complain of weakness of grip and research studies have shown that vibration can cause damage to the small muscles of the hand and the nerves that supply them. The onset

---

**Figure 47.1 Mean grip by age band:** The miners compared to United Kingdom and United States normative data.
of weakness requires further investigation to identify any possible dose response. This will allow development of guidelines for working practice. All studies concerning grip strength need to be tightly controlled for age.

HAND–ARM VIBRATION AND BONE AND JOINT DISORDERS

Gemne and Saraste\textsuperscript{134} reported a low frequency of bone and joint disorders with the use of percussive tools. These disorders take the form of bone cysts or osteoarthritis to elbow or wrist. Other authors have found cysts to be present in the carpal bones as frequently in controls as in those exposed to vibration. Local attitudes are to an extent moulded by variations in national compensation schemes. Most countries do not consider that the available evidence justifies compensation for bone and joint disorders routinely.

DIAGNOSIS AND TERTIARY CASE ASSESSMENT

Examination models for the diagnostic work up of subjects with possible injury from work with vibrating tools and equipment vary with the purpose of the assessment. These models range from questions about symptoms, signs, the possible association between exposure and injury; to questions on fitness for work, disability; through to the evaluation for medicolegal assessment and workers’ compensation. In those instances where the purpose of the clinical examination is to confirm a possible association between vibration exposure at work and injury, the assessment may include the following aspects:

- evaluation and judgement of symptoms and signs, and grading of severity;
- exposure assessments that include both vibration and ergonomic aspects;
- excluding other potential differential diagnoses.

Scientific reviews on the diagnosis of HAVS are collected in the supplementary issues of the \textit{International Archives of Occupational and Environmental Medicine}\textsuperscript{135} which report the First International Workshop on Diagnosis of Injuries 2000 and from the corresponding second workshop held in Göteborg, 2006.\textsuperscript{136} The Faculty of Occupational Medicine has reviewed the evidence on clinical testing and management of individuals exposed to hand–arm vibration.\textsuperscript{9} A number of textbooks,\textsuperscript{137} websites (for example, www.humanvibration.com) and articles present guidance in the diagnostic process for investigating subjects with suspected HAVS.

The level of diagnostic precision required is determined by the outcome required. Screening in the workplace for disease needs to be simple and easy to carry out, yet alert the professional to the possible presence of disease. When disease is suspected more sophisticated diagnosis will be required especially when outcomes may be expensive, such as workers’ compensation claims or when deciding on ongoing fitness for work, or in terms of future harm occurring to the individual. The clinical picture of severe cases presenting to a tertiary care setting will be different from those manifesting early signs in a surveillance setting.

Neurological symptoms are usually the first manifestation of HAVS. Finger blanching, although visible, is almost invariably the second symptom or sign. Sensory symptoms can be classified as positive (paraesthesia, dyseaesthesiae or pain), negative (motor or sensory loss) or provocable. Symptom disturbance in early cases of HAVS usually presents with tingling or numbness. Symptoms following immediately after vibration exposure (temporary threshold shift) are physiologically normal if they disappear within 20 minutes. Workers may refer to a reduced ability to withstand cold and damp conditions (cold sensitivity). For some susceptible individuals, symptoms may result in early incapacity and reduced workability, while others just have discomfort. Some cases may present with nothing more than a loss of sensitivity in the fingertips. As the
condition progresses, more severe symptoms including a reduction in finger precision, manual dexterity, grip force or an increase in extent and frequency of finger blanching lead to a progressive reduction in hand function and resistance to cold.

In the occupational health setting, the medical interview is currently widely accepted as the best available method of diagnosing ‘white fingers’ (Raynaud’s phenomenon). The medical interview should include information on symptoms, distribution, time and duration of blanching. The course, pattern and symptom distribution should ideally be specified pictorially on an upper limb or hand manikin or diagram. Identification of ‘white fingers’ by comparison with a standardized colour chart has long since been advocated. The medical history should entail assessment of other diseases, injuries or medication that might be related to neuropathy or those related to Raynaud’s phenomenon, such as autoimmune diseases, endocrine disorders, blood and vessel abnormalities, malignant diseases and infections (see Table 47.4).

Several drugs used to treat hypertension, asthma and cancer are also vasoactive. Medications such as beta-blockers (see under Vascular clinical features, p. 495), ergotamine, clonidine, metysergide, bleomycin, vinblastine, lithium and methylamphetamine may be relevant. Enquire about potentially relevant occupational exposures – rarely specific organic solvents and heavy metals can cause neuropathy and chemicals, such as arsenic, vinyl chloride and lead, are likely to influence the occurrence of Raynaud’s phenomenon. Exposure to stress and tobacco consumption may add to the interpretation of the medical history.

A history of exposure to a significant degree of vibration is required when diagnosing a presentation of Raynaud’s phenomenon as VWF, or a sensory neuropathy as a vibration-associated neuropathy. An understanding of the level of vibration magnitude and its limitations is an essential stage in reaching a diagnosis. Mean frequency, intensity level, trigger times and overall duration are all important. The amount of vibration transmitted to the hand is modified by ergonomic factors such as grip and push forces and if possible an inspection of the job may provide valuable information especially where symptoms are asymmetric. Work organization and work technique may influence the amount of exposure indirectly.

**Physical examination**

Guided by a differential diagnosis from the history, a careful examination should be performed. Both upper and lower extremities should be examined in order to exclude possible signs of neuropathy, upper limb pain or other systemic disease. (This examination will assist in interpreting abnormal findings in subsequent quantitative sensory threshold (QST) and electrodiagnostic testing.) The examiner inspects the appearance of the distal parts of the hands and fingers for signs such as scarring, callosities, trophic changes, nail abnormality or Dupuytren’s contracture.

Tinel’s and Phalen’s tests should be performed if carpal tunnel syndrome is suspected. Grip strength can be assessed by Jamar dynamometer and dexterity by Purdue pegboard test and compared to age-related normative data. These along with Semmes–Weinstein monofilaments can be used for assessment in an office environment.

The assessment should include an assessment of upper limb circulation, including blood pressure in each arm, auscultation of the major vessels at the base of the neck and upper arm for bruits indicating possible presence of atheromatous disease and thoracic outlet syndrome (TOS). Roos test and Adson’s manoeuvre can be useful if TOS is suspected by symptoms presenting on shoulder abduction. These clinical tests for TOS are of low discriminatory value.

Allen’s test assesses the patency of the radial and ulnar arteries supplying the hands. It has always been of doubtful significance for it cannot distinguish between the normal, abnormal and simple anatomical variations that are of no clinical relevance. However, an 8–mHz hand-held Doppler probe is a more informative method for assessing arterial patency in the hands. The Doppler wave-form or laser Doppler may show evidence of conditions such as occlusive vascular disease and hypothenar hammer syndrome. Capillary recirculation time (Lewis–Prusik test) is of very limited diagnostic use.

If, after history and examination, there is no or low suspicion of an underlying disease, then there is no need for further specialized testing. If there is a suspicion that the patient has secondary RP, then further evaluation is needed. The musculoskeletal examination should follow standard clinical orthopaedic examination, specifically looking for signs of carpal tunnel syndrome, Dupuytren’s contracture and osteoarthritis (Figure 47.3).

**Laboratory tests**

**BLOOD TESTS**

For subjects with a suspected neuropathy, blood tests will include blood count, sedimentation rate, blood glucose determination, serum protein electrophoresis, thyroid studies and vitamin B12 level. Although where a peripheral neuropathy exists it is unlikely that blood tests will reveal an unknown pathology.

If secondary RP is suspected, blood tests should also include renal and liver function, rheumatoid factor, cold agglutinins, complement (C3 and C4) and ANA (if positive, tests for antitopoisomerase I and anticientromere antibodies are indicated). Although country-specific medical custom will determine who carries out these tests, it is recommended that they are performed in the tertiary specialist setting.
Figure 47.3 Equipment for the physical examination of subjects exposed to hand–arm vibration. *Motor function:* (a) Jamar grip test. *Sensory function:* (b) monofilaments, (c) vibrotactile thresholds, (d) thermal thresholds. *Dexterity:* (e) Purdue pegboard.
FINGER SYSTOLIC BLOOD PRESSURE

Raynaud’s phenomenon can often be diagnosed on the basis of a medical interview, a questionnaire and by identification of white fingers on a colour chart. In some countries, medicolegal demands are for objective support despite ongoing uncertainty about sensitivity and specificity (see under Vascular clinical features, p. 495). This may justify finger systolic blood pressure measurement (comparing distal systolic blood pressure before and after cooling).

QUANTITATIVE SENSORY TESTING

QST provides modality-specific assessment of altered perception thresholds for both large (vibration perception threshold) and small (thermal perception thresholds) fibres. Vibrotactile threshold and thermal thresholds assist in staging severity (see under Sensorineural hand–arm vibration syndrome, p. 494). It should be remembered that upper extremity pain might influence the results from subsequent QST measurements.143

ELECTRODIAGNOSTIC TESTING

Electrodiagnostics are useful in cases where there is clinical uncertainty about whether weakness is neurogenic or myogenic, whether the neuropathy is axonal or demyelinating, or where the clinical localization of a nerve lesion is difficult.144

BIOPSY

Nerve and skin biopsies should never be performed in the occupational health setting and are rarely ever indicated in the specialist laboratory because of the risk of causing secondary injury or neurona. However, biopsies have been performed to categorize injury in patients with symptoms that suggest involvement primarily of small fibres.145 Symptoms of small fibre sensory neuropathy may entail paraesthesia, altered thermal sensation and pain.

RADIOGRAPHY AND MAGNETIC RESONANCE IMAGING

If osteoarthritis is suspected, radiographics are helpful to illustrate the severity and degree of the disorder, more rarely magnetic resonance imaging will reveal cases of nerve entrapment.

DIAGNOSIS

There is currently no established algorithm that unambiguously identifies the specific diagnosis of HAVS. A history of increase of tingling and/or numbness suggests possible sensorineural abnormalities requiring further investigation. A clinical description comprising cold-induced whitening of the skin of the distal phalanges, with a clear demarcation from the normal proximal skin, constitutes a minimum criterion for the diagnosis of Raynaud’s phenomenon. For RP to be diagnosed as being secondary to vibration, then the exposure to hand–arm vibration must precede the appearance of the vasospastic episodes. Other probable cause of the Raynaud’s phenomenon must also be excluded. To be active, these episodes of finger blanching have to have occurred within the last two years (when exposed to cold).

Staging is carried out in accordance with the Stockholm Workshop Scale (Table 47.1) with grading made separately for vascular and sensorineural components and for each hand.

The diagnosis of carpal tunnel syndrome rests on clinical and electrodiagnostic findings.

The diagnosis of HAVS rests largely on symptoms, signs and test results that rule out other conditions that might form a differential diagnosis, leaving vibration, on the balance of probability, as the cause.

WORKPLACE HEALTH SURVEILLANCE

Workplace health surveillance is primarily for the detection of adverse health effects at an early stage. It can also be used as a means of identifying and protecting susceptible individuals at increased risk from the effects of hand–arm vibration. In addition, it can provide feedback on the adequacy of risk assessment, and as a check on the effectiveness of control measures that have been introduced, and also to prevent the progression of HAVS to the more severe and disabling stages.22 At the outset, it is critical to ensure that the company or industry concerned agrees a comprehensive policy, including identification, assessment, case management, information, instruction and training, and exposure control.146 Full discussion with employee representatives and company legal advisers is essential.147 A programme of health surveillance can only be introduced when these policies have been agreed. Decisions should be agreed on continuing exposure to vibration and at what point cessation of exposure or redeployment should be considered. The policy should include details of how risk assessments should be carried out and whether these should include vibration magnitude measurement and the level of health surveillance required. This may range from the use of a self-administered questionnaire to a fully validated questionnaire administered by a suitably trained occupational health professional. In Europe, the Physical Agents Vibration Directive mandates that health surveillance should be provided.17 In effect, this means those who are:

- likely to be regularly exposed above the action level of 2.5 m/s (A8); or
- likely to be exposed occasionally above the action value and where the risk assessment identifies that the frequency and severity of exposure may pose a risk to health; or
- have a diagnosis of HAVS (even when exposed below the action value).
The application of this directive in six European countries has been reviewed and several countries, such as Italy, Sweden and Germany, have adopted local guidelines with differing approaches.\textsuperscript{11}

The Control of Vibration at Work Regulations 2005 implemented in July 2005 in the United Kingdom describes a five-step tiered approach to health surveillance.\textsuperscript{22} This includes a pre-employment or pre-placement baseline check by a qualified person, and annual review by either a qualified person or a responsible person. A positive result is referred to tier 3 for health assessment by a qualified person, normally a suitably trained occupational health nurse. A tentative diagnosis of HAVS should lead to referral to tier 4 which involves a formal diagnosis carried out by a suitably trained doctor qualified in occupational health, who can advise on fitness for work. An optional tier 5 involves referral to a specialist centre for standardized vascular and sensorineural tests.

**MANAGEMENT OF CASES**

**Management of individual cases**

The approach to managing individual cases of HAVS is limited by our understanding of the natural history and prognosis of the condition. Objective evidence of reversibility in HAVS is weak. Reversibility is greater for vascular symptoms than sensorineural symptoms, but unlikely in those with stage 3 symptoms.\textsuperscript{148}

Regardless of the stage the condition has reached, there are a number of generic recommendations that may reduce the chance of progression. These include reduction in exposure and advice on maintaining general body warmth, avoiding cold damp conditions and specifically smoking cessation.\textsuperscript{149,150} In practice, the progression in an individual case very much depends on intangible variables including whether the employer has a policy, individual susceptibility and inadequate exposure–response models.\textsuperscript{146}

The Physical Agents Vibration Directive exposure action value (EAV) for the introduction of health surveillance effectively accepts a likely prevalence of 10 per cent finger blanching after nine years of exposure.\textsuperscript{17} The apparently pragmatic recommendation to reduce exposure may not be practicable for the employee’s patterns of work. The effective vibration dose can depend on intermittency of exposure, the magnitude and direction of applied grip forces and adopted body postures. Vibration magnitudes from the same tools can vary greatly depending on the background tool maintenance programmes.

International Organization for Standardization dose–response models suggest no observed effect levels at exposures of less than 1 m/s\(^2\), although this cannot be regarded as a ‘safe level’ (ISO 5349, Annex C 2001).\textsuperscript{16} The latent interval can vary from six months to 20 or more years between first exposure and onset of vascular symptoms. Some workers are peculiarly resistant to the effects of vibration.

Accepting differing national regulatory frameworks, it would seem reasonable that HAVS cases diagnosed at stage 1 on the SWS should be allowed to continue with exposure, unless there has been a particularly short latent interval or rapid progression of symptoms. Stage 1 cases should be reviewed annually with recommendations for reduction in exposure along with a review of control measures to reduce exposure as far as possible and ideally not exceed an $A(8)$ value of 1.0 m/s\(^2\).

For later stages, consensus statements and evidence reviews have recommended exposure cessation that prevents the development of either stage 3 vascular or stage 3 sensorineural on the Stockholm Workshop Scale.\textsuperscript{21,151} At the onset of stage 2, there should be closer monitoring, say six monthly, and a similar review of exposure and control measures. Follow-up of existing cases after cessation of exposure should continue until they are free of symptoms. A more recent recommendation from the Health and Safety Executive (HSE) in the United Kingdom is to prevent HAVS stage 3 developing, as this represents a more severe form of disease with associated loss of function and disability.\textsuperscript{22} The National Institute of Occupational Safety and Health recommends the removal from exposure at neurosensory or vascular Stockholm stage 2 or above.\textsuperscript{19} Stage 2, however, ranges from minimal neurosensory symptoms, through to imminent functional disability. Lawson and McGeech divided stage 2 into an early and late stage.\textsuperscript{6} The progression to late stage 2 then becomes a stronger criterion for recommending cessation of exposure. The ultimate decision for removing an employee from exposure is between the employer and the employee. The employer’s duty of care needs to be offset by the rights of the employee to have an informed acceptance of risk. The tipping point in favour of the employer’s duty of care to accept a recommendation of removal from exposure is at late stage 2. Terms ‘intermittent’, ‘persistent’ and ‘constant’ have been suggested as a way of separating ‘2 early’ from ‘2 late’ in a screening environment.\textsuperscript{22} The HSE subsequently went on to recommend that an employee will only be declared unfit when the disease has reached ‘a late stage 2’. They qualify this for older employees, closer to retirement, who fully understand the ongoing risks. They may continue work with limited exposure and regular surveillance.

In many respects, the ideal management of someone affected by HAVS is to remove them from vibration exposure altogether. Continuing exposure is a compromise between the ideal and the practical. Medically, however, it makes little sense to continue to expose someone to a physical agent which has already caused harm. From follow-up studies, once established sensorineural-only HAVS shows
no sign of reversibility or regression, so preventive measures should be the main focus.

**Treatment of the individual with HAVS**

There is no active drug treatment for the neurological symptoms. The treatment of the vascular phenomena is the same as the treatment of Raynaud’s disease. In general, measures are aimed at the prevention of the signs and symptoms. The worker should specifically keep the hands warm, as well as the body. Simply wearing gloves is not enough if the body is cold. Working in a warm environment is the ideal, but often not feasible. Drug treatment is often of little benefit and the side effects of medication usually preclude its use. Alpha-adrenergic blockers will cause vasodilatation, but are associated with tachycardia, hypotension and a stuffy nose.

Calcium-channel blockers, such as nifedipine, may be used with some success, but the beneficial effects are often not sustained in the long term with side effects such as hypotension, tachycardia and flushing.

Other agents, such as endothelin receptor antagonists, have been tried in the management of severe Raynaud’s phenomenon (for example, systemic sclerosis). These have no part in the management of Raynaud’s phenomenon in the vibration exposed. Similarly, interventions, such as cervicodorsal sympathectomy, are not indicated.

**Key points**

- The diagnosis of the vascular component of hand–arm vibration syndrome, a secondary Raynaud’s phenomenon, relies on a description of diffuse, circumferential, well-defined finger blanching that occurs in response to cold. Cold-water provocation testing does not assist either diagnosis or staging severity.
- The diagnosis of the sensorineural component of HAVS relies on the presence of appropriate peripheral symptoms. Selective psychophysical tests can assist in staging severity.
- Identification of nocturnal paraesthesia (not involving the little finger) facilitates the diagnosis of carpal tunnel syndrome from the sensorineural component of HAVS.
- There is no association between the development of Dupuytren’s disease and exposure to the use of vibrating tools.
- In managing an individual case, advice on continuing exposure to hand–arm vibration should aim to avoid anyone progressing past late stage 2.

Whole body vibration

MASSIMO BOVENZI AND KEITH PALMER

INTRODUCTION

The nature of whole body vibration and its assessment

Mechanical vibration arises from a wide variety of processes and operations performed in manufacturing industry, mining, construction, transport and haulage, forestry and agriculture, and the public utilities. Whole body vibration (WBV) occurs when the human body is supported on a surface that is vibrating.

Vibration is an oscillatory motion characterized in terms of the frequency of the oscillatory cycle, its magnitude and its direction. The magnitude of vibration can be quantified by its displacement (m), its velocity (ms\(^{-1}\)) or its acceleration (ms\(^{-2}\)). However, it is usually expressed in terms of an average measure of the motion’s acceleration (to give the root mean square (rms) value in ms\(^{-2}\) rms) so that a complex time-varying pattern is not unduly influenced by a few unrepresentative peaks. The rms magnitude can be related to the energy imparted and hence to the injury potential.

The frequency of vibration is expressed in cycles per second (Hertz, Hz). Biodynamic investigations have shown that the response of the human body to vibration is frequency dependent. The adverse health effects of WBV seem to be related mainly to exposures in the low frequency range (from 0.5 to 80 Hz), although frequencies below 0.5 Hz can cause motion sickness. Thus, to account for differences of response, current standards for exposure evaluation recommend weighting the frequencies of measured vibration according to the assumed deleterious effects of each frequency. Frequency weightings are applied to measurements taken in three orthogonal directions (x-, y- and z-axes) at the interfaces between the body and the vibration.

The evaluation of exposure is based on the vibration total value \(a_v\), a quantity defined as the square root of the sum of the squares of the frequency-weighted acceleration values \(a_w\) determined on the three orthogonal axes x, y, z. For a seated or standing worker, the \(a_v\) for whole body vibration is calculated as

\[
a_v = (k_x^2a_{wx}^2 + k_y^2a_{wy}^2 + k_z^2a_{wz}^2)^{1/2},
\]

where

\[
k_x = 1.4 \text{ for } x- \text{ and } y-\text{axes and } k_z = 1 \text{ for } z-\text{axis}.
\]

The health effects of WBV may also be influenced by shocks or vibration peaks. To allow for this, international standard ISO 2631-1 recommends the fourth power vibration dose as the basis for averaging, rather than the second power of the acceleration time history (i.e. rms). The fourth power vibration dose value (VDV) is expressed in the unusual units of metres per second to the power of 1.75 (i.e. ms\(^{-1.75}\)).

According to European Directive 2002/44/EC, the assessment of exposure to WBV is based on the calculation of daily exposure \(A(8)\) expressed as continuous equivalent acceleration over an eight-hour period, calculated as the highest (rms) value, or the highest vibration dose value (VDV) of the frequency-weighted accelerations, determined on three orthogonal axes \((1.4a_{wx}, 1.4a_{wy}, a_{wz})\) in accordance with the international standard ISO 2631-1.

EU Directive 2002/44/EC establishes daily exposure action values and daily exposure limit values for WBV, above which administrative, technical and medical measures have to be implemented (as described below).
Exposure to WBV arises in workers who operate tractors, excavators, bulldozers, forklift trucks, armoured vehicles, buses, lorries and many other vehicles and machines. Such exposures are common in the working population. Palmer et al. conducted a national survey of exposures in the United Kingdom in 1998 and estimated that 7.2 million men and 1.8 million women were exposed to WBV at work in a one-week period. The most common sources of occupational exposure to WBV as estimated by the survey were cars, vans, forklift trucks, lorries, tractors, buses and loaders. In another large UK community survey, 7 per cent of respondents reported having been drivers of trucks, tractors, diggers and other industrial vehicles, while in a third UK survey of self-reported working conditions in 1995, 12 per cent of men (95 per cent CI, 9–14) and 1 per cent of women (95 per cent CI, 0.5–2) reported their job sometimes involving sitting or standing on a vibrating machine or vehicle, the exposure prevalence being highest in farming, fishing and forestry, and in road transport. A recent European survey on working conditions from the same period estimated that 24 per cent of respondents were exposed to mechanical vibration for at least a quarter of the time in EU workplaces, with craft workers, machine operators, agricultural workers and members of the armed forces having notable exposures to WBV. Elsewhere, it has been estimated that 4–7 per cent of all employees in the United States, Canada and some European countries are exposed to potentially harmful WBV. Vibration, a population-based investigation, the estimated VDV exceeded a proposed British Standard action level of 15 ms\(^{-1.75}\) in more than 374,000 men and 9,000 women (Figure 48.1). Occupations in which the estimated exposures most often exceeded 15 ms\(^{-1.75}\) included forklift truck and mechanical truck drivers, farm owners and managers, farm workers and drivers of road goods vehicles (Figure 48.2). The highest estimated median occupational eVDVs were found in forklift truck drivers, drivers of road goods vehicles, bus and coach drivers, and technical and wholesale sales representatives, among whom a greater contribution to total dose was received from occupational exposures than from non-occupational ones; but in many other occupations the reverse applied. Leisure time and commuting exposures are also very common.

Other measurements of vibration magnitude (vibration total value or vector sum) of the frequency-weighted rms accelerations have been made in industrial surveys covering specific vehicles, with reported values varying from 0.25 to 0.67 ms\(^{-2}\) in cranes, 0.36 to 0.56 ms\(^{-2}\) in buses, 0.35 to 1.45 ms\(^{-2}\) in tractors, and 0.79 to 1.04 ms\(^{-2}\) in forklift trucks and freight-container tractors.

**COMMON SOURCES OF EXPOSURE**

Exposure to WBV arises in workers who operate tractors, excavators, bulldozers, forklift trucks, armoured vehicles, buses, lorries and many other vehicles and machines.

**HEALTH EFFECTS**

The best-recognized health effect of WBV relates to the outcome of low-back pain (LBP). LBP is a symptom rather than a diagnosis, and consequently case definitions of outcome in research studies have varied in relation to anatomical distribution symptoms and in relation to their frequency, intensity and impact in terms of disability, medical consultation and sickness absence. Other common research end points have included radiating leg pain and sciatica. Some investigators have focused on lumbar disc degeneration, as assessed by imaging or presumed on clinical grounds (although degeneration is common in the absence of symptoms and only weakly correlated with LBP). In addition, a few have studied surgically confirmed symptomatic prolapsed intervertebral disc.

Other suggested effects of WBV include neck–shoulder pain or cervical disc degeneration, autonomic disturbance, disorders of balance and digestion, and effects on menstruation and perhaps labour. However, evidence in many of these areas is very weak and we focus this account on back pain.

**Back disorders and WBV: Epidemiological evidence**

The effects of WBV on the low back have been the focus of many studies, variously set in the workplace, in hospitals and in the general community. Findings have also been summarized and discussed in several detailed reviews.

In general, these support the idea of a causal association between WBV and back problems defined in a range of ways.
Thus, for example, a systematic review by the US National Institute for Occupational Safety and Health (NIOSH) described evidence on the association with LBP as ‘strong’ (15 of 19 studies positive), while a review by Bovenzi and Hulshof reached similar conclusions and offers a model of the generally available evidence. In a systematic search using several databases and a broad definition of outcome, these authors retrieved 45 articles. The quality of each study was evaluated in terms of methodology and the care taken in assessing vibration exposure and health effects; then a meta-analysis was conducted to combine the results of independent studies of sufficient quality. Altogether, 17 articles reporting the occurrence of back disorders in 22 WBV-exposed occupational groups, met the inclusion criteria. Most of these studies were cross-sectional in design (13 occupational groups), but in four groups longitudinal data were available. The main reasons for exclusion of studies were insufficient quantitative information on exposures to WBV, lack of control information and a failure to consider important confounders. Typically, the qualifying studies focused on crane operators, bus drivers, tractor drivers and forklift truck drivers with administrative or manual workers as controls. Vibration measurements on the vehicles were performed according to ISO 2631-1, and vibration total value or vector sum of the frequency-weighted rms acceleration ranged from 0.25 to 1.45 m/s². Outcome assessment focused mostly on symptoms reported at medical interview or in response to the standardized Nordic questionnaire on musculoskeletal symptoms, but medical records and radiological investigations were sometimes also available.

Table 48.1 presents meta-analyses for four outcomes where results could be combined – 12-month and acute LBP, sciatic pain and herniated disc – all based on self-reports in the original cross-sectional surveys. It may be seen that summary prevalence odds ratios (POR) are raised for all outcomes and by up to two-fold. A recent further meta-analysis, carried out by the first author, of cross-sectional studies published between 1986 and 2006, confirms previous findings, with a summary POR of 2.4 (95 per cent CI, 2.0–2.8) for 12-month LBP in 16 driver groups (Figure 48.3). On the basis of such evidence, WBV is considered one of the best-established risk factors for LBP.

However, longitudinal data are still relatively sparse and cross-sectional studies suffer some well-known limitations. These include the potential for affected workers to be selected out of exposure (healthy worker effect), with underestimation of risks, or (less likely) the selection of workers with back pain into driving jobs as an alternative to, say, heavy manual work, with overestimation of risks. Cross-sectional studies are also limited by inaccuracies in the assessment of prior exposures. In addition, a problem of interpretation arises in that prevalence depends not only on incidence but also on duration, and could be higher through prolongation of, rather than initiation of, symptoms. Thus, to strengthen the evidence base and to define safe working limits of exposure, interest has focused on
Whole body vibration longitudinal studies and on evidence on exposure–response relations.

Current information in these areas comes largely from a series of studies commissioned by the Dutch Ministry of Social Services and Employment, in the 1980s. Retrospective cohort studies in crane operators, tractor drivers and other transportation workers examined risks for prolonged sick leave and disability pensioning, as demonstrated by social insurance and medical records. Findings were supplemented with in-fill cross-sectional surveys in other exposure groups. A complex picture emerged. In one survey, a relation was found between intervertebral disc disorder and working for more than five years as a crane operator: the age-adjusted risk ratio for disability pension was raised almost three-fold and increased with years of driving experience, while age-adjusted rates of prolonged sickness absence were also somewhat higher. However, prolonged sickness absence was somewhat less common for non-specific LBP and back disorders overall. Similarly, in tractor drivers, an increasing trend of sick leave with increasing dose was found for disc complaints, but not for non-specific LBP – using a Cox model, estimated RRs were 2.47 and 0.94, respectively, for a dose increase of five years m²/s⁴.

Figure 48.3 Prevalence odds ratios (POR) and 95 per cent confidence intervals (CI) for 12-month low-back pain in 16 driving occupations with exposure to whole body vibration compared to control groups. The POR of each study is adjusted for several confounders (individual characteristics, ergonomic risk factors and/or psychosocial variables). The area of each box is inversely proportional to the estimated variance in the study. Random effects estimation of the combined POR and 95 per cent CI is shown.
of wheel loaders, for example, back pain was somewhat less common in those from the low exposure band and somewhat more common in those from the high band, but in lift-truck and freight-container tractor drivers, back pain lasting several weeks was marginally less common in the high exposure group. Back pain was more common than in non-driver referents, but within the exposed group was more common at younger ages, related largely to dose within the short term (the five years preceding back pain onset). In a cross-sectional survey of helicopter pilots, much higher odds ratios were reported than in other surveys involving higher levels of exposure to WBV. LBP and lumbago were more prevalent in pilots from the least and most exposed bands, defined by dose and cumulative duration of flying (a U-shaped relationship), whereas these outcomes increased with hours of daily flight time, as did back pain lasting more than two weeks. Prevalence of sciatica showed a monotonic relationship to estimated vibration dose, but peaked with intermediate durations of lifetime and daily flight time.

Such differences may reflect real differences in the risks of different outcomes (e.g. LBP versus prolapsed disc) in relation to different metrics of exposure (e.g. short versus long term). However, they may also reflect a combination of measurement errors, selection effects and uncontrolled confounding. The high rates of back pain in helicopter pilots, for example, have been attributed partly to the cramped space of cockpits as a source of transient discomfort. Other potential confounders common among professional drivers include heavy lifting (e.g. loading and unloading of delivery vehicles by hand), and twisting with a non-neutral trunk position (e.g. looking behind when manoeuvring a forklift truck).

In a growing number of surveys, special effort has been made to control for confounding by known causes of back disorders. A cross-sectional study of tractor drivers by Bovenzi and Betta provides one example. In an epidemiological survey of 1155 tractor drivers and 220 controls unexposed to WBV, cumulative vibration exposure and postural load were found to be independently associated with chronic LBP, defined as daily experience of LBP or several episodes of LBP lasting more than 30 days in the previous 12 months (Table 48.2). A significant trend was found with higher levels of both vibration dose and postural load, such that tractor drivers with high exposure to both factors had a more than three-fold elevated risk of chronic LBP relative to subjects who scored low on these counts (Table 48.3). The analysis also took account of other risk factors for LBP such as age, body mass index, smoking, education, sport activity, car driving, marital status, mental stress, climatic conditions and previous back trauma.

However, even with great care in execution, a problem exists in disentangling the separate risks of sitting and WBV. Intradiscal pressure is higher when sitting, and so prolonged sitting is a biologically plausible confounder, especially given that both exposures are almost always present together. Estimates of dose often incorporate an allowance for time as well as vibration magnitude, so

With reference to controls exposed to mild postural load and unexposed to vibration.

**Cumulative vibration exposure was estimated as in Table 48.2. Odds ratios were adjusted for age, body mass index, smoking, education, sport activity, car driving, marital status, mental stress, climatic conditions and previous back trauma.
dose–response patterns do not necessarily implicate vibration or exonerate sitting, while higher vibration magnitudes themselves may be correlated with sitting (as the vehicles that generate such exposures tend to be operated by professional drivers). The ideal study design might compare drivers with people who sit equally long in blue-collar jobs that do not involve driving, or might take as a focus a controlled intervention to reduce vibration magnitude without reducing driving time. Some surveys have used office workers as controls, but intervention studies have rarely been reported. Driving of vehicles with relatively low vibration magnitudes has been linked with an excess of prolapsed intervertebral disc and new onset simple LBP, pointing to a possible role for posture rather than WBV; but, on the other hand, sitting in the absence of vibration (work in other sedentary occupations) does not seem to carry a very high or consistent risk of LBP.42

Vibration dose is a composite of vibration magnitude and time. Thus, in principle, the relative importance of sitting time and vibration could be assessed in exposed populations receiving doses held to be equivalent, but in which these subcomponents vary (high sitting time–low vibration versus low sitting time–high vibration). Few data of this kind are available at present. However, some studies offer risk estimates by cumulative vibration dose, vibration magnitude and duration of exposure separately, and these seem to suggest that duration of exposure (driving years) is associated with LBP disorders more than vibration magnitude alone (ms–2). In another recent survey, LBP, high pain intensity in the lower back and disability from LBP (based on the Roland–Morris scale) were all significantly associated with total driving hours, but not with A(8).

Assuming that the health effect arises from WBV, and taking risk estimates from careful cross-sectional investigations, some elements of an exposure–response relationship may be tentatively offered. Thus, for example, two large epidemiological studies of tractor drivers used the same methods to measure WBV in the workplace and to assess cumulative vibration dose according to the equal energy principle. The two tractor driver groups differed with respect to mean duration of exposure (10 versus 21 years) and vibration magnitude (0.7 versus 1.1 ms–2 rms). LBP symptoms were collected with a similar questionnaire and the influence of a wide range of potential confounders, including postural load, was taken into account in the study design and data analysis. Figure 48.4 displays the estimated prevalence odds ratio for LBP as a function of the lifetime cumulative WBV dose, and suggests a trend of increasing risk with increasing exposure to WBV.

As may be judged from the foregoing discussion, a number of uncertainties in the knowledge base prompt continuing research interest in the field. Recently, these have encouraged a European research consortium (VIBRISKS) to mount several cross-European prospective cohort studies, the pooled analyses from which are awaited (see www.vibrisks.soton.ac.uk).

We summarize current epidemiological knowledge as follows:

- Consistent associations have been shown between various measures of LBP and professional driving in many cross-sectional and a small number of longitudinal and case–control studies. In keeping with this consistency, meta-analyses support a relationship.
- Such a pattern is unlikely to be due to chance. If attributable to confounding, then the most plausible confounder is sitting. However, most authorities assume the association is causal.
- Some evidence exists of an exposure–response pattern, but there is a substantial agreement that firm conclusions on the relationship between WBV exposure and LBP disorders cannot be drawn from available epidemiological data.

**Pathophysiological mechanisms**

While research continues apace, the role of WBV in the pathogenesis of LBP remains uncertain. A popular working hypothesis is that vibration causes mechanical overloading which leads to premature degeneration of the lumbar spine. Biodynamic and physiological experiments suggest the possibility of several interacting mechanisms, e.g. muscle fatigue, reduced disc height and bending of the spine jointly leading to high strain on the vertebral column. Direct mechanical effect – fatigue failure and impaired nutrition of the disc – may ensue.

However, mechanical injury to the spine appears to be neither a necessary nor sufficient cause of LBP in general.
(pain can occur in the absence of demonstrable pathology, disc changes are common even in people without LBP, and symptoms come and go without a change in imaging status), and the same may be true of LBP associated with professional driving. Symptoms can arise from local soft tissue injury, or be moderated, reinforced or perpetuated by higher level inputs from the central nervous system. Reflecting this, experience of LBP is common across all jobs and influenced importantly by psychological factors, including illness beliefs and mental health. Nociception, pain, suffering, pain behaviour and disability are only partially correlated.

Local injury may be an initiating event, but a question arises as to whether high peak of exposures matter most (acute injury) or long-term steady exposures with insufficient recovery (chronic wear and tear). Some epidemiological studies have found a greater risk of back symptoms and referred pain with more years of driving, but this does not necessarily favour a long time course of pathogenesis – more time could simply give more opportunity for acute injury – and other studies have reported raised risks within quite short intervals of driving (e.g., in a study by Boshuizen et al., ORs were raised by five-fold for frequent or long-lasting LBP or prolapsed disc in tractor drivers with as little as 0–5 years of exposure) and at young ages.

Animal experiments have demonstrated that excessive mechanical overload can result in structural injury and degeneration of the tissues of bones and joints. Repeated impact loading can lead to cumulative microdamage and metabolic changes in bone and cartilage of the rabbit tibia; and there is evidence that heavy vibration loads and repetitive mechanical shocks can cause stress damage in porcine intervertebral discs. Animal experiments, however, have seldom been undertaken to explore mechanisms and the impact of different controlled patterns of vibration exposure.

**CONTROL STANDARDS**

Reflecting current uncertainty, the distinction between shocks and steady continuous exposures is glossed over in current control standards. Table 48.4 sets out exposure standards for WBV according to the European Directive 2002/44/EC, defined in terms of an exposure action value (EAV) – the daily amount above which employers must act to control exposure, and an exposure limit value (ELV) – the maximum amount an employee may be exposed to on any given day. (Regulations in member countries permit a transitional period until July 2010 for work equipment in use before July 2007.) EAVs and ELVs are expressed either in terms of A(8) (rms), an averaging method, or VDV, a dose measure that accumulates exposures in accord with a fourth power time dependency. However, as Griffin points out, these methods are not equivalent and show a large internal inconsistency for short duration exposures to WBV. Specifically, high short-term peaks (shocks) can be offset under the averaging method by periods of low vibration, whereas this does not reduce VDV. Griffin suggests that the Directive does rule out 'extraordinarily high' vibration of short duration if assessed by the rms method – severe enough to be intolerable to those exposed to vibration. He suggests it would be prudent to base actions on qualitative guidance, to reduce risks to a minimum, rather than relying on this quantitative guidance.

Uncertainty is compounded because the thresholds chosen are not rooted in a clear understanding of the exposure–response relationship.

**Table 48.4** Daily exposure action values and daily exposure limit values for whole body vibration (WBV) according to the European Directive 2002/44/EC on mechanical vibration.

A(8) is the daily vibration exposure value normalized to an eight-hour reference period and VDV is the Vibration Dose Value (see text for definitions).

**FACTORS AFFECTING EXPOSURES AND CONTROL MEASURES**

In addition to the magnitude, duration and pattern of WBV, several other factors may relate to the injury potential, including individual susceptibility to injury, the dynamic response of the human body (mechanical impedance, vibration transmissibility, absorbed energy), body posture and health status. Dose may be related to the design of the vehicle, the cabin seating, the suspension, the road conditions, the road speed and ultimately the behaviour and training of the driver.

Consistent with these notions, Article 4 of Directive 2002/44/EC requires the employer to assess and, if necessary, measure the levels of WBV to which workers are exposed, giving particular attention to such items as:

a. the level, type and duration of exposure, including any exposure to intermittent vibration or repeated shocks;
b. the Exposure Limit Values and the Exposure Action Values laid down in Article 3 of the Directive;
c. workers specially sensitive to risks;
d. any indirect effects on worker safety resulting from interactions between mechanical vibration and the workplace or other work equipment;
e. information provided by the manufacturers of work equipment in accordance with the relevant Community Directives;
f. the existence of replacement equipment designed to reduce the levels of exposure to mechanical vibration;
g. the extension of exposure to WBV beyond normal working hours under the employer’s responsibility;
h. specific working conditions such as low temperatures;
i. and appropriate information obtained from health surveillance, including published information.

Where exposures exceed the EAV, employers must eliminate or reduce risks as far as reasonably practicable and exposures should not exceed the ELV (Article 5).

The prevention of ill health and injury requires administrative, technical and medical responses, many of which are specified in or supported by the Directive. Administrative measures include adequate information and advice to employers and employees (Articles 6 and 7), organizational changes in the work, and training to instruct the operators of vibrating machinery in safe and correct work practices. Work schedules should be arranged to include rest periods.

Technical measures include the choice of vehicles with the lowest vibration and best ergonomic designs. An EC Directive concerning the safety of machinery [89/392/EEC] obliges manufacturers to state whether the frequency-weighted acceleration of WBV exceeds 0.5 ms\(^{-2}\) rms, to facilitate informed choice.

Within the United Kingdom, where the Directive is implemented as the Control of Vibration at Work Regulations 2005, the Health and Safety Executive\(^{53}\) advises on several preventive precautions: drivers should adjust their seating, avoid rough, poor or uneven surfaces, and moderate their speed to suit road conditions; vehicle suspensions should be maintained as should site roadways, ‘safer systems of work’ should be encouraged with sufficient rest breaks and care should be taken in the choice of seating.

HEALTH SURVEILLANCE

The Directive also requires health surveillance, assuming a reasonable likelihood of health problems arising, a valid means of detection and sensible options for response. According to article 8, para 1: ‘health surveillance, the results of which are taken into account in the application of preventive measures at a specific workplace, shall be intended to prevent and diagnose rapidly any disorder linked with exposure to mechanical vibration. Such surveillance shall be appropriate where:

- the exposure of workers to vibration is such that a link can be established between that exposure and an identifiable illness or harmful effects on health;
- it is probable that the illness or the effects occur in a worker’s particular working conditions;
- there are tested techniques for the detection of the illness or the harmful effects on health.

In any event, workers exposed to mechanical vibration in excess of the values stated in Article 3(1)(b) and 2(b) [the daily Exposure Action Values] shall be entitled to appropriate health surveillance.’

Implementation is problematic however, in that LBP is so common in the general population as to be expected in many workers, drivers and non-drivers alike, while there are differing views on the added value of physician’s examination over screening questionnaires (the HSE recommends a simple system of health monitoring for workers at greater risk).\(^{53}\) Surveillance implies pre-employment and regular periodic inquiry, but back pain episodes may come and go in-between inquiries, and the immediate management of cases will mostly be dictated by severity of symptoms and incapacity in the acute phase, extremes of which normally lead to consultation independent of regular inquiry. Thus, the main virtues of health monitoring may lie in identifying extremes of unacceptable exposure, in ensuring systematic coverage, and in gaining a group level impression of the success in controlling health problems. Where surveillance is undertaken, it should be managed by certified occupational health personnel.

Key points

- Whole body vibration is a very common component of the working environment, especially when account is taken of the many professional drivers with low-level exposures in delivery and transport duties.
- Substantial industrial exposures are less common, but many workers still approach the exposure standards set in European legislation and many contribute additionally to total dose during leisure-time travels and commuting.
- Exposure to WBV is generally thought to be a cause of work-related back pain and a great deal of epidemiological evidence supports this, while not excluding a role for other concurrent risk factors, such as posture and prolonged sitting.
- Knowledge of the exposure–response relation is incomplete and the current control standards are to an important extent arbitrary.
- In spite of this uncertainty, many practical steps can be taken to mitigate risks of ill health which can be supported, to a greater or lesser extent, as sensible occupational health and safety practice.
- Control by engineering means is preferable to measures aimed at changing behaviour. Both, however, offer scope for intervention.

Heat and cold
Heat and cold

E HOWARD N OAKLEY

INTRODUCTION

Humans live and work in the widest range of thermal environments of any single species, and the strategies they have developed to support relatively normal activities in the face of extreme heat and cold have been crucial to the survival and success of the species.

Historically, techniques for surviving thermal challenges have extended and supported the underlying physiological responses by changing behaviour and the establishment of a favourable local microclimate within clothing. Nomadic hunter-gatherers and traders in hot, arid lands have developed activity patterns that minimize exposure to heat stress, wearing loose garments that isolate the skin from high solar radiation load, and move cooler air around an internal microclimate as the clothing moves. Others living in very cold areas have herded and hunted animals to supply the fur that humans lack, then fashioned those skins into layered garments to maintain a near-tropical microclimate at the skin.

Shelters have developed from small and temporary structures permitting the hands to be exposed for manual tasks and exclusion of wind and precipitation to allow a limited range of other activities, to massive fixed structures consuming huge amounts of power to condition the internal environment regardless of external conditions. However, many workers continue to spend much of their working day outdoors, away from the comfort of shelters. Others are involved in processes such as the filleting and preparation of fish that have to be performed in cold and wet conditions, or at the opposite extreme with molten metals at very high temperatures.

The twentieth century saw substantial improvements in mechanical handling that have reduced the number of workers who have to operate plant in extreme heat or cold. The frozen food industry, for example, has moved from largely manual handling within stores to highly mechanized warehouses in which products can be even better preserved by reducing atmospheric oxygen levels. There are still workers who need to enter modern cold stores, but they are mainly maintenance engineers who may have to carry out prolonged tasks that require tactile sensation and dexterity: great challenges in temperatures below −30°C and at an equivalent altitude to half-way up Mont Blanc.

The future is increasingly uncertain, perhaps even bleak. Despite innovative efforts to reduce the carbon footprint of conditioned buildings, it is much less efficient to chill or heat the entire working environment than it is to cool or insulate the individual worker. With rising average temperatures, many buildings in previously temperate climates will prove costly and inefficient to chill during hotter summers. The only option may be for office and other workers to have to cope with hotter, and less comfortable, conditions for much of the year. Rising sea levels and more frequent heavy precipitation will increase the risks of flooding, particularly in densely populated coastal areas. Rescue workers who seldom had to cope with floods are more likely to have to work in floodwater, with its thermal and other challenges.

So far from being problems afflicting less industrialized societies, heat and cold are likely to become increasingly important as employment patterns and climate change in the future.

Throughout this chapter, careful distinction will be made between the terms ‘stress’ and ‘strain’. In accordance with their engineering origins, these will be used rigorously: ‘stress’ is the force applied to an object (in a thermal context, the thermal load to which the body is subjected), while ‘strain’ is the response within that object to the
applied stress (thermally, the physiological and behavioural responses that result from thermal load). The usefulness of this distinction should not be underestimated: for example, the measurement of stress is useful in predicting the safe exposure for groups, while measurement of strain can assess how well a given individual is coping with a certain stress, and thus whether or not that person should be withdrawn or treated.

This chapter reviews the fundamental factors in human heat exchange, describes the reactions to thermal stress and their adverse consequences, and outlines approaches to the modification of both stress and strain. Although coverage includes discussion of local cold injury, such as frostbite, thermal burns are omitted in deference to authoritative accounts elsewhere.

**PHYSICAL AND PHYSIOLOGICAL PRINCIPLES**

Overall, the human body is subject to the law of conservation of energy, succinctly expressed in the equation:

\[
M + (R + C + K - E) = S
\]

where \(M\) is the heat generated by metabolism (always positive); \(R\) is the net radiant heat exchange with the environment (negative for loss from the body); \(C\) is the convective heat exchange with the surrounding fluid (negative for loss); \(K\) is the conductive heat exchange with any contacting solid (negative for loss); \(E\) is the evaporative heat loss resulting from the evaporation of liquid from the body or its clothing (almost always positive for a loss from the body, or zero); and \(S\) is the heat stored (positive) or lost.

**Box 49.1 Examples of thermal balance**

1. Sedentary, in balance. In sedentary work, \(M\) will be approximately 100 W. For \(S = 0\), thermal equilibrium, most of that 100 W will be lost in \(C\), with a small loss in \(E\) as a result of 'insensible perspiration'.

   \[
   M = 100 \quad S = 0
   \]

2. Exercising, in balance. When \(M\) rises to 250 W or more, thermal equilibrium can only be maintained by overt sweating to increase \(E\) substantially, to 200 W or more, as \(C\) will not increase much. This requires the effective evaporation of upwards of 300 mL of sweat per hour, comfortably within human capability.

   \[
   M > 250 \quad S = 0
   \]

3. Exercising in occlusive clothing. Workers who are required to perform physical work inside occlusive clothing can find that \(R, C, K\) and \(E\) all fall close to 0 W, so that all the heat that they generate, perhaps 200 W or more, will be stored at \(S\). This results in a rapid rise in body temperature, perhaps as high as 10°C per hour, and rapid onset of heat illness.

   \[
   M = 100 \quad S = -700
   \]

4. Cooling when wearing wet clothing. Inadequate protective clothing can result in excessive evaporative loss too. With a sedentary \(M\) of about 100 W, someone whose clothing is soaked might evaporate as much as a litre of water every hour, which would make \(E\) become about 700 W. \(S\) then becomes very negative and their body cools in spite of shivering attempting to increase \(M\). They will become hypothermic unless their evaporative loss is stopped, perhaps by surrounding them with a plastic bag to act as a water vapour barrier.

   \[
   M = 250 \quad S = 250
   \]
Basal metabolic heat generation remains relatively constant in health, but is diminished in hypothermia, endocrine disorders such as hypothyroidism, certain drug intoxications, and other disorders. It rises following a meal (the 'specific dynamic effect'), and in some endocrine and other disorders. However, the greatest variation in metabolism is seen in the additional heat generation resulting from physical activity. Depending on the intensity of that activity, total metabolic heat production can vary from less than 80 W when asleep, to over 500 W during short-duration intense exercise by a trained athlete.

The four modes of heat exchange ($R, C, K$ and $E$ defined above) are each governed by physical laws that, in theory at least, allow their precise computation. In practice though, information is seldom sufficiently complete, and more empirical relationships have to be used. Most popular are lumped equations analogous to Ohm’s law:

$$q = t/h$$

where $q$ is the heat flux by that route, $t$ is the thermal differential driving that mode of heat exchange, typically the difference between the surface and ambient temperatures, but notably the difference between fourth powers of temperatures in the case of radiant heat transfer ($R$), and $h$ is the coefficient of resistance to that mode of heat exchange.

Although empirical, such equations are valuable in demonstrating the crucial importance of temperature gradients in determining the direction and size of heat flows. Heat cannot flow against a temperature gradient.

The magnitude of each mode of heat exchange is thus set by a combination of environmental conditions, including ambient radiation, air movement, temperature and water content, together with skin temperature and clothing worn. For example, some industrial environments impose a high radiant heat load ($R$) from hot machinery, molten metals and flame; this can be usefully attenuated by garments coated with an outer metallized reflective layer. However, this may in turn render the garments impermeable to water vapour transfer, resulting in evaporative heat loss ($E$) falling to zero. Another major factor that affects thermal resistance is the difference in physical properties of fluids: convective exchange with water is much greater than that with air.

A common error in the application of physics to human thermoregulation is to assume that the body can be treated as a single inert and undifferentiated entity. Regulatory mechanisms respond to central (or 'core') temperatures quite differently from those in the periphery. When someone is hyperthermic immerses their hands in cold water, peripheral vasodilatation is maintained and they can lose substantial amounts of heat into the water; euthermic or hypothermic subjects will not only vasoconstrict on (cold) hand immersion, but may not be able to vasodilate even if the hands are immersed in warm water.

Should heat production not match heat loss, heat will either be gained or lost from the body, according to the sign of $S$ defined above, and it is this which results in a change in body temperature. The over-simplistic single-element model of the body then fails to show the change in internal thermal gradients that occurs. If excessive heat is being lost from the skin, the peripheries will cool first and there will be little effect on the 'core' other than its shrinking in effective volume; this strategy of 'sacrificing' the homeostasis of the peripheries in order to preserve the core environment is important in paving the way for local cold injury. Insufficient heat loss and a rising 'core' temperature tends to externalize the core by reducing thermal gradients with the peripheries, and increasing the volume of the body at core temperature.

### Responses to cold

The primary physiological responses to cold exposure are peripheral vasoconstriction, piloerection, and the increase in metabolic heat production by shivering. Skin temperature falls first, a result of local cooling without a corresponding increase in the delivery of heat to the skin by the flow of blood. This fall in skin temperature stimulates peripheral cold receptors and leads to both locally mediated and centrally regulated vasconstriction, which in turn allows a further fall in skin temperature. If the rest of the body is sufficiently warm, cyclical cold vasodilatation ('cold induced vasodilatation' or the 'hunting reaction') may ensue, with skin temperatures falling below 12°C, rising with the vasodilatation, and then falling again. The mechanism responsible for this phenomenon remains controversial, but extensive experimentation has shown that it is very variable between and within individuals, and absent if the rest of the body is cold. Sustained peripheral vasoconstriction may be accompanied by fluid shifts resulting in a reduction in plasma volume. Shivering first appears as short bursts in a few groups of muscles, becoming continuous and generalized as a rectal temperature of about 35°C is reached. Further cooling or exhaustion results in shivering gradually tailing off, until it is replaced by generalized rigidity and finally the flaccidity of imminent death.

### Responses to heat

Under heat stress, changes in blood flow to the periphery are again the earliest response, followed by an increase in evaporative heat loss by sweating. The normally low nutrient skin capillary flow is augmented by the opening of arteriovenous anastomoses in the skin, which allow high rates of heat transfer from the deeper body to its surface without altering capillary exchange. This increases skin temperature, driving higher rates of heat loss as long as the ambient temperature is lower than that of the skin. When this temperature difference becomes too small to support adequate
heat loss or is actually reversed, the only significant means by which the body can lose heat is by the evaporation of sweat, which also makes high demands on peripheral blood flow.

These responses conflict with the requirement to perfuse working muscle during exercise, which may of course be the cause of the thermal stress. Fluid loss in sweat also threatens plasma volume, which is in turn essential to the maintenance of peripheral vasodilatation and sweating. A further problem is that thermally effective sweating requires evaporation from the skin (or, less effectively, the outermost layers of clothing); sweat which drips from the body makes no contribution to the loss of heat, while remaining a drain on fluid reserves. Failure of evaporation in humid conditions, with little air movement or impermeable clothing, explains many cases of heat illness in relatively moderate dry bulb temperatures.

COLD STRESS

Assessment of cold stress

The dominant components of cold stress are the temperature and nature (air or water) of the fluid surrounding the body. Wind speed, and to a lesser extent water movement, can also be important. A simple thermometer and a wind speed indicator are the main measuring instruments needed. Anemometers need not be complex: one of the cup type is best for outside use, whilst vane and hot wire systems are preferred in enclosed spaces. Inexpensive hand-held anemometers are popular in outdoor leisure activities and generally sufficiently accurate for these purposes. However, they often present derived measures such as ‘wind chill equivalent temperature’ that should be treated with suspicion. The measurement of radiant heat exchange is more difficult to measure accurately, although it is generally small except under a clear night sky.

Evaporative loss is even harder to assess and is small in cold-dry systems. However, if the clothing is wet, evaporative losses alone can exceed 700 W, exceeding the total of other modes of heat loss; simple techniques such as repeated weighing to estimate water loss can then only give a crude overestimate. Although convective losses in water are much greater than in air of the same temperature, partial immersion presents a particularly complex situation. Subtle differences in behaviour and conditions can result in large changes in heat loss, as the body switches from convective cooling in water, through evaporative cooling of wet surfaces in air, to dry convective cooling. The delayed evaporative cooling of sweat-soaked garments after exercise is also difficult to quantify, but of potentially great significance in those working hard in cold conditions.

Siple and Passell were the first to attempt to incorporate dry bulb air temperature and wind speed into a single figure, now commonly referred to as ‘wind chill equivalent temperature’ (Table 49.1). Models for this vary and none is universally applicable, despite considerable efforts to improve on the original work by Steadman and others in North America; for example, the cooling effect of wind depends greatly on whether the individual is wearing windproof clothing. Another crucial factor is that wind-chill to freeze fingers is acting over very different physical dimensions to that chilling clothed bodies, and it is not possible to derive a single index capable of expressing such disparate risks. However, these models usually give a useful first approximation of cold stress.

Assessment of cold strain

Any fall in core temperature below 35°C, the accepted threshold for hypothermia, is the best guide to a serious degree of general cold strain. Rectal measurement, at least 10 cm and preferably 15 cm beyond the anal sphincter, is the most reliable in cold conditions, though tympanic, oesophageal, gastric, vaginal, deep arterial and deep venous sites can each be used in different circumstances; detailed discussion is given in ISO 9886. All require careful calibration of probes and measures to prevent the transmission of infections, such as HIV. Oral temperature is never reliable in
the cold, as it is depressed by cold saliva, and infrared tympanic techniques are likely to be dangerously misleading.³

Skin temperatures can give warning of lesser degrees of general cold strain, and are necessary measures of local cold strain, particularly when there is a risk of cold injury. Techniques are based on thermistors or thermocouples, or infrared emission measurement systems for uncovered skin. Repeated efforts have been made to estimate core temperature from measurements of skin temperature taken under insulation. In cold environments at least, these are doomed to failure because of the great variation in subcutaneous insulation. In cold environments at least, these are doomed to failure because of the great variation in subcutaneous insulation and local skin blood flow. Electromyography (EMG) and oxygen uptake can be used to assess shivering insulation and local skin blood flow. Adaptation of more sustained responses has been seen to be more variable and difficult to demonstrate, although they may play a part in the physiology peculiar to long-distance sea swimmers,⁶ and in the reduced response to cold by aboriginal peoples in Australia and Ama divers. It may be that this ‘hypothermic’ adaptation has an advantage in increasing comfort during cold exposure, in particular permitting sleep, though it could be hazardous in cold exposure of longer duration. Many other attempts to demonstrate central adaptation or acclimatization to prolonged cold have failed to provide clear or consistent effects. The signal exception to this is earlier and more marked cold vasodilatation, which may be a result of reduced vasoconstriction, described in occupational groups subjected to repeated peripheral cold exposure, such as fish filleters.⁷

### Freezing cold injury

Local freezing of tissues, the most rapid and dramatic form of cold injury, may occur when people are exposed to temperatures below 0°C without adequate protection or opportunities to return to warm environments when the extremities become chilled.

The areas most commonly affected include fingers and toes, followed by nose, cheeks and ears, and occasionally the male genitalia. The last can occur in association with local or general trauma.⁹ Although most commonly seen in wartime and the military, freezing cold injury is also seen in those undertaking winter sports and in outdoor workers in cold climates, sometimes when the air temperature is not particularly low.¹⁰ Cases can occur in those working in cold stores and other processing plants. Those who now appear most vulnerable are maintenance engineers, who may need to work with limited hand protection, and lubricants may contaminate their clothing and reduce the effectiveness of its insulation. The damage is mainly caused by high concentrations of electrolytes left in tissue fluids when most of the water turns to ice. While frozen, the skin is white and hard; on thawing, there is first hyperaemia and then, in severe cases, pallor and a woody feel to the skin as local blood vessels become occluded by red cells.

Derived from the work of Siple and Passell,² applicable to naked exposed fingers. The equivalent temperature indicated in the main body of the table for a given combination of wind speed (at the left) and dry bulb temperature (at the top) is claimed to be that at which there is an equal rate of heat loss, given a wind speed of 0 m/s. For example, at a wind speed of 15 kt and a dry bulb air temperature of −12°C, the wind chill equivalent temperature is indicated to be −32°C, i.e. the risk of cold injury is the same as that for a wind speed of 0 kt and a dry bulb temperature of −32°C.
FROSTNIP

‘Frostnip’ is popularly used to describe mild freezing cold injury in which the superficial tissues (that are the only layer affected) recover completely within 30 minutes of starting rewarming; such recovery must include the return of normal sensation. Classically, it involves any combination of the loss of peripheral sensation and the slight freezing of superficial tissues. Typically, one or more finger or toe tips are blanched, the skin is leathery to the touch, but not of wooden feel (which usually indicates deeper freezing) and anaesthetic. The immediate and diagnostic treatment is to rewarm the affected periphery against the warm skin of an understanding colleague; hands and feet may conveniently be placed in an axilla or groin, whilst portions of the nose, cheeks or ears are best warmed by firm contact with a hand or fur patch on the back of a mitten. Rubbing, massage and direct heat should be avoided. Provided that recovery is complete within the 30-minute period, no further treatment is necessary. However, those who have not returned to normal should then be treated for superficial frostbite.\textsuperscript{11} Thereby hangs the dilemma in that this diagnosis is dependent on the outcome to field treatment; an adverse outcome has serious consequences in terms of further management. Anyone who suffers recurrent episodes of frostnip should be suspected of having a more significant problem and withdrawn from further cold exposure.

SUPERFICIAL FROSTBITE

More severe freezing injury that would not recover so rapidly is usually termed ‘frostbite’. If confined to the skin and most peripheral layers of tissue, it can usefully be qualified as being ‘superficial’. Initial appearances may be indistinguishable from frostnip, but in the hours and days following thawing, gross discoloration may occur, with haemorrhagic patches and blisters with fluid varying from clear serous exudate to the frankly haemorrhagic. Later still, small and superficial areas of dry gangrene may develop, with skin peeling and nail loss.

The standard treatment for superficial frostbite remains conservative. Rapid rewarming in a stirred waterbath at 38–41°C should be prolonged and thorough, with good analgesic cover.\textsuperscript{12} Care must be taken to ensure that patches do not remain partially defrosted on removal from the waterbath. For some, rewarming is an exquisitely painful process that may even merit titration with intravenous morphine, but non-narcotic analgesics normally suffice. Although objective evidence of other beneficial effects is still needed, moderate quantities of alcohol can reduce the requirement for analgesia and improve general well-being, and a twice daily ‘tot’ is recommended. Infection must be prevented with liberal use of topical anti-bacterials, such as those based on chlorhexidine gluconate, preferably in combination with twice daily ‘whirlpool’ baths at 40°C. Tetanus prophylaxis is also required in most cases, although systemic antibiotics are normally only considered when there is active infection or deeper tissues are involved. Unfortunately, those with substantial areas of necrotic tissue are at risk of developing antibiotic-resistant hospital infections: the advice of a specialist in infection control is recommended at an early stage in management.

Blisters should not be burst or aspirated because of the risk of infection, unless a high standard of asepsis can be maintained. Their resolution will be aided by the elevation of the injured part, which should be kept comfortably warm, but not too hot. Early physiotherapy to restore functional movement is very important, particularly when hands are affected, as is the restraining of overenthusiastic surgeons; in the absence of any other threat to the injured tissues, surgery should be avoided for at least four and preferably six months. Careful conservative management will normally result in the loss of much less tissue than might originally be expected from appearances in the first few weeks after injury. One decisive factor is the avoidance of premature or incomplete rewarming. In spite of the diagnostic definition of frostnip, rewarming should never be attempted until it is certain that further freezing cannot occur and that the affected part will not be used or further damaged. For this reason, rewarming is generally best avoided in remote areas, unless the casualty can be evacuated by stretcher and in guaranteed warmth.

An almost complete lack of good clinical trials of adjuvant drugs makes it impossible to recommend pharmacological intervention. Different groups have advocated colloidal infusions, various vasodilators, even derivatives of snake venoms. To date, the only addition to the conservative regimen that might hold promise is the use of aloe vera-derived inhibitors of thromboxane, but few are licensed and evidence remains scant.\textsuperscript{12}

DEEP AND COMPLICATED FROSTBITE

Freezing of muscles and other deeper tissues, including their blood vessels, is much rarer and more serious. Almost unseen in ordinary working situations, it is mainly a product of wartime and occasionally in mountaineering accidents. Whole limbs may freeze solid and victims are invariably hypothermic. Rapid rewarming should only be attempted in hospital under full biochemical control, as massive release of potassium from damaged cells can otherwise cause sudden death. Surgical decompression of tissue spaces may be needed before rewarming, to limit the rise of tissue pressures which results from the volume expansion accompanying the melting of ice crystals. The amount of tissue likely to be dead or dying demands the utmost care in preventing tetanus, gas gangrene and resistant infections.\textsuperscript{13} Even so, proper conservative management may result in the salvage of much of the limb.\textsuperscript{14} Cyclic freezing, thawing and refreezing is even more destructive of cells, and can result in the very worst end result. Early and radical amputation, at two to three months following injury, may be preferred in these cases, as it might in established infections.\textsuperscript{12}
LONG-TERM SEQUELAE OF FREEZING COLD INJURY

Military campaigns and civil disaster, such as an earthquake in winter, may leave swathes of the population recovering from the acute effects of freezing cold injury. Although often not as severe as the long-term consequences of non-freezing cold injury, those resulting from freezing injuries may be just as frequent. Reviews of veterans as long as 45 years after their original injuries reveal many suffering from chronic problems as a result.

The most common sequelae include cold sensitization (which is more usually associated with non-freezing cold injury, see below), chronic pain, residual neurological defects that rarely may involve loss of proprioception rather than touch, joint pain and stiffness, hyperhidrosis, skin and nail abnormalities. Radiographic examination may reveal characteristic appearances of ‘frostbite arthritis’, but long-term changes in gait may be more commonly responsible for overuse injuries in more proximal joints, particularly in the lower limb. Although hyperhidrosis may lead to chronic fungal infection, the skin is often dry and scaly, and may crack painfully; topical application of lanolin cream, or preparations intended for the care of cows’ udders, can alleviate this. Fungal infections of the nails may respond little to treatment and, together with disturbances of nail growth, can result in thickening and frank onychogryphosis, making a high standard of podiatry essential if mobility is to be maintained.

More unusual sequelae include recurrent ulceration and breakdown of old scars, which may in turn lead to an increased risk of local skin cancers. It is not clear whether this is specifically related to the frostbite or is common to other causes of recurrent ulceration. Although rare, complete local loss of proprioception is a neurological abnormality that is characteristic of old cold injury. In the hands, this can make dressing very hard, while in the feet it may threaten mobility.

Non-freezing cold injury

Longer exposures to less severe temperatures, particularly when coupled with other conditions liable to cause circulatory stasis, can result in injuries that appear generally mild in comparison with frostbite. A wide variety of terms have been applied to non-freezing cold injury (NFCI) since it was first described in the eighteenth century, including trench foot, immersion foot, shelter limb and Flanders foot, depending on the circumstances in which the variant was described. It often coexists with freezing injury, but in spite of its apparent innocence during the acute phase, NFCI frequently results in more severe long-term sequelae. In common with freezing injuries, NFCI is overtly more frequent in certain ethnic groups, most notably Africans and Caribbeans, even when their antecedents migrated to colder areas, such as northern Europe. However, most recent studies in the British army have shown that previously reported relative incidences of up to five times those of Caucasian groups, found with freezing injuries, may be underestimates: African and Caribbean groups were found to have a relative incidence of NFCI of 30 compared to Caucasians, and they appeared to suffer more severe injuries too.

The great majority of cases of NFCI affect the feet alone, although recent series in the UK claim that a quarter of cases are found to have suffered NFCI of the hands as well as the feet. Apart from military personnel in cold wet climates, the main groups affected by classical NFCI are survivors in the water, in liferafts, or during flooding. Immersion of a hand for as little as 45 minutes in water at 0°C may produce mild NFCI, but three hours are needed to result in overt injury. Because seawater freezes at a temperature below 0°C (normally around −1.9°C), tissues immersed in very cold seawater may sustain freezing rather than non-freezing injury. Although circumstantial evidence points to dependence on a function of duration of exposure and low temperature, variation between individuals may obscure this. In the same person, the same injury might result from a short period at a low temperature, or a longer period exposed to a milder temperature. There also appear to be relationships with other similar conditions: long immersion in lake-warm water results in ‘paddy foot’, which is clinically indistinguishable from NFCI. The pathogenesis of these conditions remains obscure; factors that have been proposed include the direct effect of cooling on nerves, prolonged ischaemia during cold exposure and the liberation of reactive oxygen compounds during reperfusion. Some or all of these may be important in the evolution of vibration injuries, complex regional pain syndromes (formerly known as reflex sympathetic dystrophy) and other similar syndromes.

PRESENTATION AND MANAGEMENT

Clinical appearances have been divided into four stages:

1. Injury: in which the foot is very cold, ischaemic and numb.
2. Rewarming: in which the foot becomes mottled blue-pink and exquisitely painful.
3. Hyperaemia: in which the pulses are full and bounding, but there is slow capillary refill, there is marked swelling, some degree of anaesthesia and paraesthesia, and severe pain (primarily nocturnal).
4. Recovery: in which the foot gradually returns towards normal, with residual sequelae including cold sensitization.

Stage 1 is seen throughout the period in which the injury is actually occurring, ranging from minutes to days in duration. It is therefore usually only witnessed by the patient, who may provide the diagnostic description of numbness or other sensory impairment. Stage 2 is seen fleetingly during rewarming, typically lasting just a few minutes. The great majority of cases present in stage 3, which lasts for several days or weeks. Stage 4 may then supervene for months, years, possibly lifelong.
Although NFCI is best managed using similar conservative principles to those for freezing injury, it has been established that rapid rewarming in a waterbath exacerbates both damage and pain. Slow (or ‘passive’) rewarming is therefore preferred. The management of early pain can be fraught: bedclothes should be cradled over the feet at night and conventional analgesics are invariably ineffective. Although it has never undergone formal trialling, and in most countries is beyond the normal licensed indications, the standard approach is to give a single daily dose of morphine does not affect the pain but the patient no longer cares about the discomfort, while regional analgesia is highly effective but short-lived. Patients who do not obtain good relief from amitriptyline (25–150 mg) in the evening, much as is used for the treatment of other types of neuropathic pain. Amitriptyline and conventional analgesics are invariably ineffective.

The cause of cold sensitization remains ill understood. It was originally supposed that it resulted from a sympathetic denervation supersensitivity, but most recent assessment of other sympathetic nerve function in sensitized feet has shown this not to be the case. The cause may lie in a vascular endothelial abnormality (and NFCI is known to result in endothelial injury) or the devascularization which is known to arise when local blood flow is chronically reduced. No effective treatment is known, although exposure to heat may be ameliorative. This can be accomplished by living in a tropical country for some years, or possibly by bathing the affected parts in water at 40°C for at least 30 minutes every day; again trials are needed. Severe cases may enjoy slow and slight benefit from sustained release nifedipine, but it is hard to achieve therapeutic benefit without troubling side effects. Other long-term sequelae are common and include those mentioned for freezing cold injury above. Because of the risk of long-term alteration in gait and resulting overuse injury, early and expert assessment of gait should be considered in those who have sustained NFCI of the feet.

### Hypothermia on land

Taken across the working population as a whole, hypothermia is comparatively rare without immersion, and as a cause of death it is quite unusual. Even in social groups deemed to be at particular risk, notably the very young and very old in poorer circumstances, hypothermia is considerably less common than is usually portrayed. In those of working age, cases tend to occur in clusters when groups involved in military or leisure activities are exposed to particularly harsh conditions, frequently in association with inadequate planning and preparation.

On land, its onset is usually gradual, over a period of hours, when heat loss is greatly increased by evaporation from precipitation, previous immersion or accumulated sweat, but heat production is falling due to physical exhaustion. In many cases, victims have been maintaining thermal balance by hard physical exertion and then start to tire; as their fatigue causes them to reduce the rate of work, heat loss starts to exceed heat production and core temperature falls. Inadequate replenishment of energy and fluid, insufficient physical fitness, and previous alcohol intake (which can produce sustained hypoglycaemia) are all common predisposing factors.

Detailed clinical descriptions of hypothermia and its management are given elsewhere. In the field, actions should be directed at reducing further heat loss and evacuating the casualty. Although the risks associated with rough handling are thought to be lower on land than following immersion, evacuation should be careful and considered rather than rushed. Those providing assistance should not neglect the risk of others in the party succumbing to hypothermia: it may be necessary for them to be placed in shelter, or for their evacuation after that of the immediate casualties. Issues relating to rewarming are discussed below.

### Immersion hypothermia and ‘cold shock’

Immersion poses more threats beyond hypothermia alone. Many of those who die in the water do so because of drowning, although even then this simple diagnosis obscures a complex causal sequence. Golden and Hervey have divided up the hazards of cold immersion into four phases according to the time since entry into the water.

Sudden immersion in cold water produces dramatic physiological responses that have been reviewed by Tipton. In the great majority of adults, any tendency to the potentially protective effects of the ‘diving response’ is usually overwhelmed by an inspiratory gasp followed by hyperventilation, tachycardia and peripheral vasoconstriction. If trapped in a ditched helicopter, flooding building or capsized vessel, useful breath-hold time diminishes almost to zero, making underwater escape almost impossible; underwater breathing apparatus (particularly if not based on pressurized gas, with its concomitant risk of
arterial gas embolism) can be invaluable in enabling successful escape. Hyperventilation not only makes the inhalation of water, thus primary drowning, more likely, but its effects on blood chemistry can be disabling. Cardiovascular responses may be dramatic, such as the sudden onset of lethal cardiac arrhythmia, and combine to produce a sharp rise in blood pressure, which may be sufficient to burst arterial aneurysms.

Those who survive the first 2–3 minutes of cold water immersion and thus suffer ‘cold shock’, may drown in the ensuing 10–15 minutes, apparently failing to swim even though they may be close to safety. Such ‘swimming failure’ is largely independent of warm water swimming ability and appears related to the direct cooling of peripheral nerves (making muscular control harder), failure to synchronize breathing with swim-stroke and other subtle effects. It is only when the casualty has been immersed for more than about 20 minutes that immersion hypothermia becomes a serious threat, and even then it may lead to dis-ablement and thus drowning long before core temperatures reach lethal levels below about 28°C.

Divers have been claimed to be prone to two forms of hypothermia that may occur with minimal physiological responses. One may affect saturation divers who are dependent on careful control of breathing gas temperature and their hot water suits to maintain thermal balance. If their inspired gas is slightly too cool, large amounts of heat could be lost from the core, while skin temperatures are held high. In the absence of stimulus to the peripheral cold receptors, the body may make little or no physiological response to the falling core temperature. The other form of insidious hypothermia may affect slightly underdressed free-swimming divers in water temperatures between about 20 and 25°C. Although cold enough to result in falling core temperature, such water may not elicit any sensation of cold, and once again peripheral vasoconstriction and shivering may not occur. These conditions remain controversial, and extensive review of thermal aspects of diving is sceptical of their occurrence in real life.

The hazards of immersion do not stop when rescue starts. As high as 20 per cent of all those conscious, but thought to be hypothermic at the time of rescue, die during the following minutes. Golden et al. have reviewed the causes, which are related to the mode of rescue and subsequent treatment. Because the ailing circulation receives substantial hydrostatic support during immersion, during which the margin for cardiac compensation is being eroded, vertical modes of recovery can result in sudden loss of venous return and complete circulatory collapse. The adoption of horizontal modes of rescue, such as double rescue streps, can reduce this risk, provided that they do not compromise the chances of successful recovery.

Another risk following rescue is that of rewarming collapse, which appears to be the result of peripheral vasodilatation during rewarming. For this reason, casualties should not be left unattended nor rewarmed in an upright position, for example in a shower. Hot baths are often the method of choice for those who are cold, but not clinically hypothermic. Aggressive or active rewarming techniques should be avoided unless they are applied in sophisticated medical facilities, such as intensive therapy units; they may hasten complex and life-threatening problems during rewarming, and good evidence that they improve outcome is still lacking. Another pitfall is the decision to start external cardiac massage (ECM) should it be thought that cardiac output is insufficient in the hypothermic. Because this is likely to precipitate ventricular fibrillation (if still alive), and the cold heart cannot be defibrillated, starting ECM commits the first-aider to maintaining it – effectively – until the casualty is delivered to a place of definitive care. If this will only take 30 minutes, ECM may prove life-saving; if evacuation could take many hours or even days, it is probably wisest to avoid starting ECM for this reason.

Those who have inhaled insufficient water to cause primary drowning may exhibit signs of adult respiratory distress during the first one to three days after immersion; this is secondary drowning and requires immediate aggressive intensive therapy. All those who have become immersed and could have aspirated water, and thus could be at risk of secondary drowning, should be cautioned of the unlikely chance of the condition, and the need to seek medical aid as a matter of urgency.

The ideal protection from cold immersion is an integrated survival system, consisting of personal protective equipment to provide appropriate buoyancy and thermal protection, if necessary with underwater escape supported by a breathing system. Those who may need to hold their breath to permit escape to the surface can have their initial responses attenuated by cold habituation, for example a daily cold shower, or even psychological skills training. It would appear that surfers, kayakers and others who submerge themselves out of choice have already learned their own techniques for coping with cold shock, including habituation and breath-hold training.

For longer-term survival, as when abandoning a ship in the ocean, dry-shod entry into a seaworthy and thermally effective liferaft should be the goal.

The prediction of survival during immersion is very important in determining how long search and rescue efforts should be maintained. As immersion incidents commonly happen when sea and weather conditions are most threatening to those engaged in searching, accurate prediction not only determines the cost of expensive assets such as helicopters, but also the risk to which the rescuers are exposed. National coastguard manuals include aids for the prediction of survival during immersion, and these should improve considerably in the coming years with the ongoing analysis of a large survey of immersion incidents in UK waters. Traditional approaches to survival prediction generally work best in colder water temperatures, below 20°C. In warmer waters, in particular, there are many survivors’ accounts of very long periods of complete or partial immersion that imply that several days could be the norm. However, the strong currents associated with movement of
peripheral cooling, while the metabolic cost of submaximal exertion and protective clothing can be particularly dangerous, as rest periods may result in rapid and severe impairment of performance is commonly a result of many factors. The combination of cold, physical exertion and protective clothing worn to prevent cooling. Where studies have been able to show significant effects on dexterity, they are usually related to both local and central cooling. In actual occupational settings, impairment of performance is commonly a result of many factors. The combination of cold, physical exertion and protective clothing can be particularly dangerous, as rest periods may result in rapid and severe peripheral cooling, while the metabolic cost of submaximal work increases and maximal aerobic performance falls.

Observations that accident rates increase during cold periods of the year are too crude to permit conclusions to be drawn about the influence of moderate cold on higher mental functions. However, a particularly disturbing study by Coleshaw et al. demonstrated that even slight levels of body cooling (above those diagnosed as hypothermia) can have dramatic effects on simple measures of mental function, such as memory registration and the speed of reasoning.

## HEAT STRESS

### Assessment of heat stress

Because of the greater capacity for warm air to contain water vapour and the importance of evaporative heat loss in higher temperatures, the simple dry measures made in cold environments are insufficient to assess warmer conditions quantitatively. The one exception to this is when personnel are clad almost entirely in impermeable clothing, as they might be when working in toxic or radioactive environments, for instance. Then the exclusion of evaporative heat transfer permits simplification of the measurements detailed below.

Most measures of heat stress therefore attempt to combine weighted values of dry bulb temperature with some estimate of humidity, together with radiant heat load and sometimes other variables. Although different indices come into vogue at different times and for different purposes, that with perhaps the best all-round record is the wet bulb globe temperature (WBGT) index, which also has the advantage of being simple to compute and easily measured with compact instruments. More detailed work may require a psychrometric chart on which the relationship between air temperature, moisture content and relative humidity is shown. Body heat production is again important, and can be measured in the field by expired gas analysis using a portable respiratory system, or more crudely estimated from activity levels against standard scales. Methods for doing this are given in ISO 8996.

### WET BULB GLOBE TEMPERATURE INDEX

ISO 7243 prescribes a standard method for the estimation of heat stress using three temperature measurements: those of a standard dry bulb, a wet bulb and one inside a blackened globe of 150-mm diameter. The three temperatures are combined into the WBGT index using the following equation:

\[
\text{WBGT} = 0.7T_{\text{wet bulb}} + 0.2T_{\text{globe}} + 0.1T_{\text{dry bulb}}
\]

Under this ISO standard, it is permissible to ignore the dry bulb temperature if there is little difference between it and that of the globe (e.g. indoors with little radiant heat load), in which case the equation becomes:

\[
\text{Indoor WBGT} = 0.7T_{\text{wet bulb}} + 0.3T_{\text{globe}}
\]

The standard provides a set of reference index values for five levels of metabolic rate for both acclimatized and unacclimatized people, which may be of value in assessing the relative stress. For example, on a warm summer’s day in a temperate climate the dry bulb temperature may rise as high as 34°C. When the relative humidity remains low, at 40 per cent, the wet bulb will remain low at 24°C. In full shade, the globe temperature should be close to that of the dry bulb, giving a WBGT index of 27, the threshold for sustaining moderate exercise in acclimatized individuals. If the air is wetter, with a higher relative humidity, the wet bulb will be higher, hence the WBGT index will exceed that threshold and make it impossible to exercise for long. In the full radiant heat load of the sun, the globe temperature will soar, with similar effects on WBGT index and exercise.

Related indices can be derived for environments in which formal measurement of the WBGT index are not possible. For example, Nunneley and Stiblery developed a ‘fighter index of thermal stress’ (FITS) for the cockpit of aircraft at low altitude, but using measurements taken at ground level on clear days:

\[
\text{FITS} = 0.83T_{\text{psychrometric wet bulb}} + 0.35T_{\text{dry bulb}} + 5.08
\]

Unfortunately, none of the temperatures used to derive the WBGT index is routinely measured in standard...
Heat stress

meteorological practice, nor can normal meteorological forecast variables be substituted into the WBGT equation. However, work has been undertaken to permit estimation of the three input temperatures from normal forecast variables, and it is likely that some meteorological centres will produce WBGT forecasts in the future. It remains to be seen whether this becomes commonplace as average temperatures rise.

PSYCHROMETRIC CHARTS

In many situations, radiant heat loads are fairly small in comparison to the heat exchange by convection and evaporation. The psychrometric chart (ironically derived from the Greek *psychron* meaning cold), reproduced in Figure 49.1, is a clear graphical way of understanding the effect of changing humidity and temperatures alone. Use of the chart requires a measurement of the water content of the air (e.g. by some form of psychrometer capable of yielding relative or absolute humidity values) and the dry bulb temperature. Limits may be defined on the chart appropriate to a given group of individuals for specified activities and clothing, thus allowing the user to make recommendations as to how their physiological requirements may be met. The chart may also be used to understand the relative effects of lowering air temperature and humidity when trying to control an environment.

OTHER INDICES

Although the WBGT index is simple to measure quite accurately, it is only indirectly linked with heat strain. In most circumstances, operators prefer to employ measures that can give a more direct assessment of heat strain, and to this end many alternatives have been proposed. These have been compared by Parsons and more formally in ISO 11399. A potentially very attractive approach to the assessment of heat stress is to attempt to relate it to the amount of evaporative heat loss required for thermal balance; this was originally incorporated into a ‘predicted 4-hour sweat rate’ (P4SR), but has more recently evolved into the required sweat rate and ‘predicted heat strain’, as defined in ISO 7933. Measurement essentially consists of a semi-empirical solution of the equation of heat balance, to arrive at an estimate of the sweat rate required for the maintenance of thermal equilibrium. It is thus considerably more complex than the WBGT index and more suited to experimental investigations rather than routine monitoring. The latest studies have confirmed its efficacy in predicting averages and limits to exposure, although modifications have been required to the calculation of the evaporative efficiency of sweating.

More moderate thermal stress may need to be assessed by more complex methods than the simple WBGT index, as the transfer of heat by each physical mode is usually more sensitive to subtle changes. Detailed accounts of the

Figure 49.1 A psychrometric chart. The grid is laid over a graph of water vapour pressure against dry bulb air temperature. On this, curves of equal percentage relative to humidity are superimposed, as are lines of equal wet bulb temperature. Thus, the graph may be entered using any pair of dry bulb air temperature, water vapour pressure, relative humidity or wet bulb temperature. For a given garment assembly and work rate, it is possible to plot a straight line which determines the upper limit of the exposure envelope, marked as the ‘linear portion’ in this figure. Those conditions to the left of and below this line are acceptable. However, there are two additional linear segments which are also shown: at higher relative humidities, the small vapour pressure gradient from clothing to ambient limits tolerance, whilst at low relative humidities sweating endurance is limited and thus restricts the envelope.
'predicted mean vote' (PMV) and predicted percentage of dissatisfied (PPD) indices are given in ISO 7730,40 based on measurements of air temperature, mean radiant temperature, humidity, air velocity, metabolic rate and clothing insulation. Indeed, in any situation in which clothed individuals are being assessed, reference will need to be made to the estimation of the thermal insulation and resistance to evaporative heat loss imposed by clothing; ISO 992041 provides a sound practical basis for this.

Assessment of heat strain

The principal measurement of heat strain, like that of cold, is core body temperature. However, core temperature can rise rapidly in the heat and the fact that rectal temperature changes later and more slowly than other sites makes it less suitable for safety purposes. Accordingly, it is more common to estimate deep body temperature in the heat from a tympanic membrane or auditory canal reading; this has the added advantage that this site should usually be a good indicator of the temperature of the brain, which is not only the central temperature controller, but is also one of the more critical organs in heat illness. Unfortunately, the otherwise convenient infrared tympanic membrane thermometers that have become so popular in general clinical practice are again a potential source of error, and should not be trusted: a thermistor or thermocouple needs to be placed just short of the tympanic membrane, and the auditory meatus occluded and carefully insulated if the temperature recorded is to be a reliable estimate of core temperature.

Three other variables are commonly recorded in heat studies: heart rate is the simplest of all to measure, loss of body mass due to sweating is also very easily determined, whilst skin temperatures are sometimes of value if judiciously interpreted.

Heart rate is well correlated with heat strain, provided that changes due to exercise are taken into consideration. It is often used, in conjunction with aural temperature, in establishing criteria for the withdrawal of people exposed to heat loads. The simple estimate of body weight loss is a useful measure of fluid loss in laboratory conditions. Skin temperatures can prove misleading, as they fall if there is good evaporation from the skin, but climb close to core if evaporation is limited or absent. These methods are described in ISO 9886.3

Acclimatization

Temperate residents cannot perform as well under heat stress as those used to living in the tropics. Careful studies during the middle of the twentieth century demonstrated that unacclimatized temperate residents show significant acclimatization after only two weeks of exposure to heat.42 This can be produced by prolonged exposure to an environmental heat load (e.g. by living in the tropics or working in hot conditions) or by repeatedly raising the body temperature by undertaking sustained physical exercise, or by a combination of both. Pure fitness training produces similar changes to heat acclimatization and so improves tolerance to heat stress.

During the first week of acclimatization, the ability of the body to sweat is increased, so that thermal sweating occurs more rapidly under heat stress, and the amount of sweat produced is increased. Cardiovascular changes sustain peripheral vasodilatation and the blood flow required by active sweat glands. Salt is retained by the kidneys and salt content of the sweat declines, so that increased sweating does not result in severe hyponatraemia. Consequently, some individuals may need to increase dietary salt intake slightly during the first week of acclimatization, but seldom after that. It should be noted that required water intake may actually be increased in those who are acclimatized: popular belief that those conditioned to living in the tropics are also able to do without water, or even worse to substitute alcohol, is completely erroneous.

The process of acclimatization continues more gradually over the remainder of the first three months or so spent in the tropics, at the end of which the temperate-born individual is almost physiologically indistinct from those who have spent their entire lives under a heat stress. However, behavioural adaptation, in which dress and habits are changed to those most appropriate in the heat, may never occur.

De-acclimatization can occur surprisingly rapidly, after just a few days of withdrawal from heat stress. Those who spend a period working in air-conditioned comfort, or who return to more temperate climates for a holiday, therefore need to undergo supervised re-acclimatization on their return to heat exposure. This introduces a dilemma in choosing optimal living and working conditions in hot climates: while many find it more comfortable and sleep better in conditioned accommodation, more constant exposure to heat stress will maintain a better level of acclimatization.

Immediate consequences of heat strain

The continuing popularity of prolonged physical exercise in temperate climates, such as marathons and triathlons in the populous countries of the northern hemisphere, reinforces the need to move away from the traditional classification of heat illness. The latter, evolved during British Imperial days, endeavoured to distinguish acute, subacute and chronic disorders involving overheating, and water and electrolyte losses in a complex and probably misleading terminology. Setting aside a few discrete disorders, such as prickly heat and salt and water deficiencies, true heat illness can be spread along a continuum from heat exhaustion to heat stroke.43 At the one extreme, this consists of little change in body temperature and overt hyperventilation, and at the other, a core temperature in excess of 41°C, absence of sweating and complete circulatory collapse. Patients can move rapidly from minor heat exhaustion to
life-threatening heat stroke; so no matter how mild the symptoms may appear to be, anyone suffering from a heat illness should be considered to be in incipient heat stroke and thus in imminent danger of death.

HEAT EXHAUSTION

Heat exhaustion is typified by the moderately well-trained athlete competing in a marathon during the warmer months in a temperate country. It may also be seen in military personnel during fitness training in similar conditions and in groups of manual workers with moderate environmental heat loads. The first sign of impending heat exhaustion is usually hyperventilation, in someone who appears ill at ease with the exercise that they are performing.43

Classic signs and symptoms from the disturbance of the body's acid-base balance and the calcium–phosphate ratio in the blood follow, with dizziness, nausea, paraesthesiae in the peripheries and around the mouth, progressing to confusion, collapse, vomiting and even seizures. Core temperature at this stage is below 40°C, and usually between 37° and 39°C. Early cases respond rapidly to rest in a recumbent position, rebreathing from a paper bag to restore end-tidal CO₂ levels and simple cooling. Fluids may also be beneficial and should always be given by appropriate means. If these patients are allowed or even encouraged to continue exercising, they may rapidly develop frank heat stroke.

HEAT STROKE

Those working in very hot surroundings, particularly when evaporative cooling is ineffective due to high humidity, may undergo a rapid rise in core temperature, to the point at which thermoregulation fails.44 The classic victim of heat stroke has stopped sweating and is dry to the touch. They may still maintain peripheral circulation and thus be red, or may have undergone circulatory collapse, in which case their skin colour is not diagnostic. They are very hot, semiconscious or comatose, and prone to convulsions, cardiac and respiratory arrest. The onset of this dramatic illness may have been very rapid, although many will have shown evidence of earlier heat exhaustion.

Cooling is best achieved in the field by stripping the patient in the shade, drenching with tepid water and fanning if there is little natural wind. Cold water or ice is less useful in adults because of the intense vasoconstriction which it can precipitate, which limits heat transfer from the core to the skin; however, there are recent claims that ice-water baths may still produce the most rapid fall in core temperature even in adults, as they do in infants with their much greater surface area to volume ratio. Alternating litres of isotonic dextrose and saline intravenously are the best means of fluid administration, but cannot be a substitute for immediate and effective cooling. The precise quantity given may be based on an estimate of fluid loss, but in unconscious cases it is probably best to give the first litre over 15 minutes or less, thereafter reducing the rate of infusion according to clinical indications and the perceived risk of hypervolaemia leading to pulmonary oedema. Such fluids should not be warmed, but neither should they be cooled below 15°C. Elevation of the legs to assist venous return, administration of oxygen and possibly sedatives, are of value. However, vasodilators and platelet inhibitors, such as aspirin, should be avoided. Rapid but careful evacuation to an intensive care unit is essential, where urinary output, blood biochemistry and direct measurement of the central venous pressure can be monitored closely. Cooling is normally discontinued when the rectal or aural temperature has reached 38°C, lest it overshoot. A useful if empirical guide to prognosis is the area under a curve of core temperature against time, during which core temperature exceeds 39°C: the greater the duration and elevation above that temperature, the poorer the likely outcome.

Unfortunately, the outcome of true heat stroke is not good. If core temperature rises to around 45°C, irreversible heat denaturation of proteins causes multiple organ failure or disseminated intravascular coagulation. If this is not immediately fatal, renal dialysis may be necessary during recovery. Heat illness, associated with exercise, can produce subacute rhabdomyolysis (necrosis of muscle) that can in turn lead to late renal failure. Follow up of military personnel who made complete recoveries from an initial episode of heat illness have suggested that subsequent episodes are more common than among those who have not suffered heat illness.45 However, numbers were small and further work is merited. At least two national armed forces have now introduced work-in-heat testing of those who have suffered an episode of heat illness during military training. Although experience is limited and the optimal test protocol remains controversial, these have enabled the identification of individuals with metabolic disorders related to malignant hyperthermia, cases of anhidrosis and other conditions that predispose to further heat illness.

HYPONATRAEMIA

For much of the nineteenth and twentieth centuries, an important task in preventing heat illness among athletes, service personnel and workers in hot environments has been to encourage the replacement of body fluid lost by sweating with sufficient quantities of aqueous fluid. For a surprisingly long period in history, athletes and others consumed very little in the way of fluid, and the drinks used were often physiologically unsuitable, such as beer or even spirits. In the early decades of professional cycle racing, for instance, some competitors consumed at least a bottle of brandy a day when taking part in arduous stage races, while foundry workers were at one time notorious for drinking many pints of beer during their working day. Recent years have seen a dramatic change, in which fluids are thrust at athletes in particular in considerable quantities, to the point where many are now at risk of becoming hyponaemic, which can cause collapse, death and severe neurological disturbances in those who survive.46
The aim of drinking during exposure to heat stress should be to replace fluid and electrolyte losses in sweat. Even when acclimatized and fit, few humans are capable of losing more than 2 litres an hour in sweat, so drinking should never exceed that rate. Over a typical extended working day, a ceiling of 10–12 litres of fluid intake is advisable. Most western diets provide ample daily sodium intake, but it is common for meals to be lightened or skipped when exercising in the heat. If a normal diet of three meals per day is not maintained, careful consideration needs to be given to supplementation with fluids containing electrolytes so that proper balance can be maintained. This is potentially very complex, and the margins for error can be narrow: injudicious consumption of sports gels and fluids can be as dangerous as inadequate intake of salt. It is far simpler to maintain a normal diet and balanced fluid intake.

OTHER CONDITIONS

Classic salt depletion, due to salt loss in sweat while on a low salt diet, with adequate water intake, is now rarely seen. The classic accompaniment of cramp (e.g. miner’s cramp) only occurs in association with hard exercise and is now very unusual. Plasma sodium only falls in more severe cases, with milder cases showing a fall in extracellular fluid volume with normal plasma sodium. In the worst cases, vigorous treatment with oral or intravenous saline may be required. Subacute and other variants of this condition, sometimes attributed to different combinations of water and electrolyte depletion and ‘disacclimatization’, are similarly uncommon. They are best treated by cooling, rest, rehydration and the restoration of a normal diet. Those whose appetite has been suppressed and who have overindulged in alcohol, should recover quickly in this way. The blind administration of salt, even with the copious quantities of fluid that are required, is potentially dangerous and should be avoided.

One possible danger is that of hyperkalaemia; many young people often rehydrate following exercise in the heat using some form of orange juice, or a ‘sports rehydration’ fluid, which may be high in potassium. They should be advised to ensure that their rehydration fluid is well diluted with water.

Perhaps the most common of the ‘mild’ heat disorders is prickly heat or miliaria rubra, which results from blocking of the orifices of sweat glands. Because of the blockage, the glands rupture their ducts, raising a weal within an erythematous area, which is intensely itchy. Removal from the heat both abolishes sweating and prevents the body overheating as a result of its impaired ability to sweat. Other less well-understood conditions which may appear during heat stress include a transient ankle oedema (which may result from the thermal attenuation of the veno-arteriolar reflex) and mild muscular cramps. Some individuals experience dizziness and fainting that may have a common aetiology.

The effect of heat on performance

Reconciling the subjective and objective is no easier for the possible effects of heat than were noted above for cold. Ramsey47 has reviewed more than 150 studies that attempted to find differences in ‘perceptual motor performance’ in the heat and commented on the remarkable lack of objective evidence of dominant effects. It appears that there is no significant detectable impairment in the performance of the great majority of tasks until the level of heat stress reaches a WBGT index of approximately 30°C. This is broadly in accordance with the criteria originally laid down by NIOSH in their original recommended exposure limit (REL).48 Paradoxically, when revised 14 years later, NIOSH omitted this REL because of lack of supporting evidence.49

A few studies cast interesting and potentially different light on the area. There is much stronger support for adverse effects in circumstances in which core temperature has risen; when core temperature is 38°C or greater, a prominent effect is an increase in irritability independent of the rise in subjective discomfort.50 Critics of studies which have used more artificial and perhaps oversimplified measures of performance may find some comfort in the work of Wyon et al.,51 who examined the effect of moderate heat stress on driving performance. While they observed a heat-related increase in overt driving errors, it was found to occur only in women.

Perhaps the most useful tool (beyond tenuous attempts to relate accident statistics to heat stress or strain) in the practical examination of performance effects is the expression of subjective judgement scales. ISO 1055152 lays down a standard approach to these, which allows inclusion of comfort, acceptability and tolerance in the assessment of thermal environments.

PRINCIPLES OF THE REDUCTION OF THERMAL STRAIN

Given that there are many industrial processes and situations that could lead to injury or illness resulting from cold or heat, and the potential consequences of such injuries or illnesses, the importance of prevention cannot be overemphasized. In addition to specific remarks in previous sections, the following provides general principles to form the basis of systematic plans for prevention. There are already a number of good examples of codes of practice that illustrate how preventive measures can be implemented.53–57

The worker

Working in particularly cold or hot environments makes many demands of the individual. The body and mind may be taken to the limits, something that is often viewed as an attraction for those who voluntarily expose themselves to thermal extremes in their leisure-time pursuits.
Any condition that impairs the physiological mechanisms responsible for compensating for heat or cold stress risks the safety of the individual and thus is contraindicated in workers exposed. Margins for such compensation generally decline with age, although experience in coping behaviourally increases with maturity, and the very young may be limited on both counts. The additional metabolic and cardiovascular demands of pregnancy make exposure to heat stress inadvisable for women during those times. Any form of concurrent illness, especially if febrile, increases risks whether the worker is exposed to heat or cold. The consumption of alcohol or drugs of abuse, even in small quantities, or of most medications, can compromise some or all of the physiological mechanisms; in the case of medication, it needs to be ascertained from recognized pharmacological authorities that the treatment in question is not likely to do this. On the other hand, general physical fitness of a cardiorespiratory or endurance nature is usually a great benefit.

If called upon to assess the fitness of an individual to undergo thermal stress, detailed knowledge of the environment, activities and clothing to be worn are essential. For those undertaking work in the cold, obesity is actually highly undesirable, as it impairs the mobility of someone required to wear already bulky protective clothing, and increases the likelihood of their being subject to heat stress when wearing that clothing. The level of physical fitness required is at least that of a person undertaking the same activity in more comfortable temperatures, while carrying the whole protective clothing ensemble.

Sedentary work in the heat, particularly following acclimatization, is not normally too physically demanding. However, those who have to wear restrictive protective clothing, breathing apparatus, and then have to perform arduous physical work, need to be physically very fit. For example, in both laboratory and field studies of firemen,

\[58\] it is more usual that their ability to carry out work is limited by physical exhaustion than by dangerous elevation of body temperature; factors of particular importance include the duration of work and the use of breathing apparatus. In the face of these demands, firemen should have good pulmonary and cardiovascular function, and significant pathology such as myocardial ischaemia or lung disease should contraindicate further exposure. Formal tests of physical fitness, such as step tests and even the measurement of maximal oxygen uptake, are only guides in the overall assessment of individuals. In all cases, the examining doctor should ask the question as to whether the person presenting for examination is capable of undertaking the specific tasks in the given environment in reasonable safety, and not whether they have achieved an arbitrary standard in an artificial test.

Good progressive training, coupled with conditioning or acclimatization, is very valuable in preparing the individual for work in stressful environments. In the case of heat, every effort should be made to allow personnel to acclimatize before they are required to carry out any exercise in the heat. Once they do start, the period for which they work should be carefully controlled according to the heat stress and strain, making due allowance for accidents and emergencies which might happen. For example, firefighting teams wearing breathing apparatus are limited in duration by the air supply which they carry with them; this supply should not encourage them to stay so long in the full heat of the fire that they suffer from heat illness, but at the same time it must allow for delays in withdrawing once their anticipated working time is over. The total number of teams should allow for a reasonable number of entries to be made, with adequate cooling and rest periods in between. In some cases, three teams will be needed to provide these breaks, but each team may then be limited in the number of entries that it can make. It should be borne in mind that, in these circumstances, cooling down takes longer than heating up.

In environments in which all other methods have failed and personnel are required to work hard physically, the only solution may be to plan that they undertake only brief periods of work, interspersed with rest periods in which they may cool. Although many factors have to be taken into consideration, guideline WBGT indices above which this may be required are 29–33°C for the sedentary, 24–28°C for those working moderately hard, and 20–26°C for those performing heavy exercise. Those who have acclimatized to the heat can generally tolerate higher temperatures for longer periods (provided that they are both kept well hydrated and are able to sweat effectively), and at higher work rates increased air movement may also reduce heat stress at a given WBGT index. In extremely hot environments, such as coke ovens, it may be necessary to restrict exposure to a very short period, which must be strictly enforced.

Although there is little physiological advantage to progressive training in the cold, it is psychologically and behaviourally of great benefit. Circumstantial evidence suggests that the experienced individual develops many small but very effective techniques for minimizing their cold stress, such as an ability to don and doff clothing quickly and with minimum cooling. The naive person in a cold environment can quickly run into trouble, particularly when things start going wrong or there is an accident or emergency. On the other hand, those who have had adverse effects, such as previous cold injury or any other evidence of cold intolerance, should be prevented from further cold exposure. This includes a small number of people with conditions which predispose to local cold injury, including those with vibration white finger, any form of Raynaud’s disease, impaired circulation, skin grafts or other cold sensitivity (whether resulting in excessive vasoconstriction or allergic responses as in cold urticaria). Similarly, those with a history of previous heat illness should only be re-exposed under careful supervision, as further episodes are likely, and anyone with a skin disorder should avoid heat stress, as most will impair thermally effective sweating.

Care also needs to be taken in considering the nature of work to be performed, with regard to the effects of its impairment. In spite of the equivocal results from experimental
work discussed above, those operating plant and machinery, in particular vehicle drivers, should only ever be permitted to be exposed to very mild heat or cold stress. An extreme example of this is in aircrew, in whom even very subtle psychological impairment resulting from thermal stress may have disastrous consequences. Careful consideration should always be given to the potential role of thermal stress and its consequences in the investigation of all incidents and accidents.

Traditionally, it has been assumed that those exposed to challenging thermal environments will be fully fit and healthy and have no form of disability, but this is increasingly inaccurate, as endurance sports become popular among even severely disabled athletes, and a greater proportion of the disabled population expects to pursue a full range of working and leisure activities. Detailed understanding of the sometimes severe thermoregulatory problems in certain types of spinal injury, for example, can help tackle the problems that individuals may face, but there are no general solutions. Even in those working in the relative shelter of conditioned office environments, achieving thermal comfort needs careful attention to the individual.59

<thead>
<tr>
<th>Box 49.3 The office worker</th>
</tr>
</thead>
<tbody>
<tr>
<td>Traditionally, legislative requirements for sedentary workers, particularly those in offices, have set a minimum temperature for their environment, but no maximum. It is not hard to arrive at a reasonable minimum temperature based on acceptable dress and the need to keep hands warm enough to undertake typical tasks. However, healthy sedentary workers arephysiologically capable of dissipating their metabolic heat output over a wide range of thermal environments. Whether or not an employer deems it acceptable for office workers to have to sweat 2 litres or more over the course of their working day, as long as they maintain adequate hydration and are fit and healthy (and preferably acclimatized to the heat), they should thermoregulate and there should be no danger to their health.</td>
</tr>
</tbody>
</table>

In climates with seasonal differences in environmental heat stress, office environments can follow these changes, to exploit seasonal acclimatization in workers. In the winter, the tendency to wear warmer clothing can be used to lower office temperatures by a couple of degrees below their annual average. Once warmer summer temperatures have become established, office temperatures can be allowed to rise a couple of degrees above annual average. Allowing approximately two weeks lag in these changes of office environment should suffice to allow for changes in clothing and acclimatization.

Careful consideration also needs to be taken of the effects on human performance, social interaction and psychology. In times of austerity, workers have been motivated to try to press on even when wearing multiple layers of heavy clothing and gloves, but current social attitudes would not tolerate that now. Those working under mental rather than physical pressure may deliver their best when their thermal expectations are met, or at least they perceive that they are. Uneven heating or cooling is as likely to result in discomfort and complaints as more uniform discomfort. Consideration must also be given to those whose health is not perfect, or are pregnant, growing old, or have a disability; it is usually necessary to reduce the potential thermal stress posed by an environment to ensure sufficient margin of comfort for those individuals.

<table>
<thead>
<tr>
<th>Box 49.4 Disabilities and thermal stress</th>
</tr>
</thead>
<tbody>
<tr>
<td>Although other types of disability may have subtle thermal implications, the most prominent considerations need to be given to those with generally impaired mobility, and disabilities that specifically impair thermoregulation. Mobility impairment usually results in lower average metabolic rates and lower peripheral perfusion, making individuals more susceptible to whole body and peripheral cooling when they are exposed to cold environments with the same thermal protection provided to more mobile workers. This requires consideration in workplace assessment, potentially the provision of more efficient personal protective equipment and shortened periods of exposure to compensate.</td>
</tr>
</tbody>
</table>

The most common disabilities that result in dramatic alteration in thermoregulation are spinal injuries. From the approximate level of the injury distally, normal peripheral vasoconstriction and vasodilatation may be impaired or completely absent. Deprived of these fundamental defences against thermal stress, those with spinal injuries can quickly cool or heat up in environments that others may find perfectly comfortable. Assessment may need consultation with their neurologist to establish the nature of an individual's problems, followed by thorough planning of the workplace to accommodate their needs. Contingency plans may also be needed to protect them in the event of failure of environmental conditioning.

<tr>
<th>Personal protective equipment</th>
</tr>
</thead>
</table>
| Hot or cold working environments are often those in which there are more serious thermal hazards (e.g. in the steel industry or firefighting) or other serious threats (e.g. chemical or radioactive contamination) and personal protective equipment (PPE) is frequently required to counter the thermal and other hazards. The use of PPE in the heat is a more serious problem, as almost all PPE adds to the heat stress. Garments that are worn necessarily increase the resistance to heat loss from the body and may, of course, abolish all effective evaporative
transfer; equipment that is carried increases the amount of work performed for a given task, and thus it increases the metabolic heat generated. In some cases, workers who require to wear effective PPE to protect them from a high radiant heat load, flame and contact burns, such as firefighters, find that this PPE imposes considerable heat stress on them (Figure 49.2). Apart from the impaired performance which results, there is the real risk that workers will not use the PPE completely or correctly, in an effort to increase their comfort, and there is the constant danger that their discomfort will detract from performance in an emergency, resulting in an accident.

There are no easy solutions to these problems. Active cooling systems still require substantial chilling plants and power, and may not always work with the body; a liquid-conditioned garment, for example, may be cooled with water so cold that it induces vasoconstriction in the skin and thus slows cooling, or with tepid water which must have a very high flow rate to remove sufficient heat. Workers who need to be mobile can often only carry the cooling plant with them, which may make matters still worse. A promising approach currently introduced into some industries is the use of regional cooling, for example periodic immersion of the hands in cold water, which does not result in vasoconstriction but may lead to substantial heat loss. Phase-change packs, consisting of crystalline gels that freeze at a physiologically valuable temperature, sealed in plastic bags, appear promising, but packs need to be replenished periodically, and are heavy and bulky.

Another useful advance is in the availability of vapour-permeable materials, such as Goretx® which can sometimes replace impermeable protective layers, yet allowing evaporative cooling to occur through them. Garments using vapour-permeable materials are becoming very popular in many circumstances, for example in affording firemen a water-impermeable and chemical-resistant layer. However, consideration still needs to be given to the essential function of the garment, as failure to achieve that cannot be excused by the improvement of thermal comfort.

Selecting protective clothing for cold environments is also fraught with difficulty. The amount of thermal insulation provided by clothing is approximately proportional to its thickness (actually, it is more accurate to refer to the thickness of air trapped within), so the greater the insulation, the more cumbersome the garments. As the body sweats, so water may condense within these layers and reduce insulation. This is worst if the individual overdresses when working, leading to extensive wetting of their clothing, and then stops to rest; they may then become cold surprisingly rapidly. Workers who enter very cold environments only intermittently, such as those in cold stores, should always doff their protective clothing as soon as they return to warmer conditions, or they will quickly start to saturate the garments with sweat. Water may also mist or ice up eye protection, causing the wearer to remove it (Figure 49.3).

The most intractable problems in PPE for cold conditions are in protecting the hands and feet. Any form of glove reduces manual dexterity, while trying to work without in even cool conditions is just as deleterious to performance. As temperatures fall below 0°C, gloves cannot provide sufficient insulation to keep the fingers warm, and mittens must be worn, very severely impairing work requiring tactile sensation and dexterity. Some of those working in cold conditions have additional protective requirements of their handwear, such as those preparing meat in cold rooms. Although metallic elements may be incorporated into their gloves, to reduce the risk of injury from knives and other cutting equipment, it must be remembered that metal is also an excellent conductor of heat and will reduce the thermal protection of such clothing. The situation with regard to the protection of the feet has been reviewed by Oakley, albeit in a military setting, but the same considerations are needed when choosing footwear for workers (see Figure 49.4).

Using tables of thermal insulation and evaporative resistance for garments such as those in ISO 9920, and the required values for the environment and physical
activity (e.g. IREQ, the calculated clothing ‘Insulation REQuired’), it is possible to make provisional choices as to suitable clothing ensembles. However, careful trials and experience in use are required before firm decisions can be made, owing to the extreme complexity of the situation. For example, the efficacy of closures such as zips and cuffs may be critical in a cold environment, and those with physical limitations or disabilities may need bespoke tailoring of clothing to allow it to be donned and doffed readily. Although aided by national and international standards, the selection of PPE remains a difficult task, which requires detailed knowledge, possibly careful trials, and is often only a rough compromise.

**Control of the environment**

In an ideal world, of course, all working environments would be thermally neutral, and all the preceding material irrelevant. While it is often impossible to achieve this, most situations are capable of improvement to the extent that the untenable may become at least temporarily acceptable, or the uncomfortable become not unpleasant. A range of standards for different occupational settings has been offered by the leading national and international standards organizations. Careful application of the equation of heat balance given at the start of this chapter can be of great value. For example, if ambient air temperature and humidity cannot be controlled, then forced ventilation can increase cooling markedly; thus, in enclosed machinery spaces, a very effective way of providing ‘cooling off stances’ is to force ventilate air into a number of places. Then, workers can stand in a draft to cool down intermittently and significantly extend their effective working time in the compartment. The provision of shade for those working exposed to the sun and the wetting of surfaces and even clothing in dry heat, are other examples. However, such an approach in a cold storage facility is much more difficult to implement, as deliberately warming several areas would add greatly to the problem of refrigerating the rest. A parallel in cold environments might be to heat small shelters in a cold and windy outdoor setting, allowing workers as much time as possible within them, out of the high wind chill.

The involvement of a good heating and refrigeration engineer can also save much wasted effort. Simple physical facts, such as the rising of warmed air, can be harnessed and turned to advantage, rather than negating that which is being attempted; expert advice at the earliest stage can anticipate such problems. Indeed, the appalling environments often found in working places that have no real intrinsically severe thermal problems (modern electronic share-dealing rooms, for example) usually arise because this has been neglected. For while heat and cold may be among man’s oldest environmental enemies, there is a wealth of new and old technology available to control them.

**Figure 49.3** This worker in an experimental refrigerated wind tunnel requires good facial protection, but he has had to remove his goggles because of icing (Crown copyright).

**Figure 49.4** A complete mukluk assembly, consisting of a canvas outer boot, insulative insoles and a double felt inner boot, which has been used successfully in temperatures below −40°C (Crown copyright).
Key points

- Illness and injury arising from hot or cold exposures remain relatively common in some occupations.
- Local cold injury may be non-freezing, leading to cold sensitivity and pain in peripheries that have undergone only modest cold exposure.
- Cold immersion can result in rapid death long before the onset of hypothermia; life jackets and protective clothing are key prevention.
- Heat illness is a life-threatening emergency that can largely be prevented by acclimatization and wise exposure policies, and is often exacerbated by the wearing of personal protective equipment.
- Cooling the hot and warming the cold remain therapeutic challenges.

OVERVIEW OF THE NEED FOR DIVING AND TUNNELLING AND THE HAZARDS

The history of mankind is inextricably linked with the sea. The sea and inland lakes and waterways have been vital as sources of food and for exploration and travel. As a result, numerous food stuffs and items of value have been sought from beneath the sea surface throughout the history of man. These driving forces, enhanced by military requirements, have resulted in enormous efforts to explore the subsea environment for profit, military advantage, scientific research and for pleasure. The history of diving begins with simple breath-hold diving as is still practised for gathering pearls and by recreational snorkellers, and moves through the development of breathing apparatus to modern saturation diving methods. Practical solutions have been found for many of the problems encountered in exploration of the subsea environment which now allow man to conduct a wide range of work activities underwater. However, the underwater environment remains alien to man and is always hazardous.

Within the last 200 years, the technological advances have also been applied in civil engineering situations where excavation beneath a water table results in ingress of water. By enclosing the excavation and applying increased pressure, the ingress of water can be prevented allowing continued excavation in a dry environment. These enclosures are called ‘caissons’ and have been extensively used in the building of bridge piers, tunnels and other civil engineering works. Workers in caissons do not dive, but do share exposure to increased pressure with divers, and hence many of the same problems and hazards. In the last 20 years, due to increasing health concerns, several of the techniques previously developed in military and commercial diving are now used within tunnelling operations involving compressed air work.

This chapter deals with the occupational health issues of both diving and compressed air work.

THE INCREASED PRESSURE ENVIRONMENT

On the surface of the Earth at sea level, we live in an air environment where the air pressure results from the mass of the air in the atmosphere above and the effect of the Earth’s gravitational field. On ascent to altitude on mountains or in aircraft, the mass of air above is less and hence the pressure is also lower. On descent underwater, the environmental pressure results from both the mass of air above and the mass of water. Since water is many times denser than air, there is a very rapid increase in pressure with progressive descent underwater and pressure changes occur when compressed air is used in engineering works. This change in pressure is the most critical environmental factor in both diving and compressed air work.

Pressure can be measured in many alternative units which are in everyday use. The pressure on the Earth’s
surface at sea level has been defined as 1 bar (=1000 millibar). (Fluctuations in pressure reported in millibar form an important measurement in weather forecasting.) One standard atmosphere absolute (ata) is almost equivalent to 1 bar. Other measures in regular use are torr and millimetres of mercury (mmHg), pounds per square inch (psi), kilogram force per square centimetre (Kgf.cm⁻²), meters of seawater (msw), feet of seawater (fsw) and pascals (Pa). Many of these will be familiar in everyday medical or scientific use. Table 50.1 provides equivalent values.

Pressure is most usefully measured in absolute terms where zero equals an absolute vacuum, but is often measured relative to surface air pressure (called gauge pressure) which introduces confusion in physical calculations. Although scientifically it is most appropriate to use SI units (Pa), the units in most common use in the diving and compressed air industry have been retained in this chapter. Care should be taken when comparing different pressure units to avoid mistakes and confusion, particularly where pressure is measured either as absolute or total pressure or gauge pressure (where the pressure above ambient is recorded).

Gases are compressible, so become denser as pressure increases. As a result on ascent to altitude, air density reduces with ascent and so the pressure reduction is not linear with height. Water is not compressible and hence underwater the pressure rises linearly with depth by 1 atmosphere for every 10 m additional depth. The absolute pressure underwater in ata can simply be calculated from the water depth in meters divided by 10 and adding 1 for surface air pressure. Hence, pressure at 50 m depth is 50/10 + 1 = 6 ata. In compressed air work, 1 bar (gage) is equivalent to 2 bar absolute pressure (i.e. 1 bar atmospheric pressure + 1 bar gauge pressure).

Both divers and compressed air workers operate in an environment where the ambient pressure is raised. Historically, compressed air work has rarely involved pressures above 3–4 ata, but in recent years the development of tunnel boring machines used in modern tunnel excavation has led to much higher pressures being required. Diving is regularly undertaken at pressures of up to 35 ata and the world record exceeds 70 ata.

Divers and compressed air workers also share other environmental problems. Both commonly require to use compression chambers and hence work in an enclosed space and while divers inevitably require breathing apparatus, compressed air workers may also need to use breathing apparatus for breathing alternative gases or protection in potentially contaminated environments.

### PHYSICS OF THE PRESSURE ENVIRONMENT

The physical properties of the environment are defined by the gas laws. The following are of critical importance in understanding the pressure environment.

Boyle’s law states that for a fixed mass of gas at constant temperature the volume is inversely proportional to the absolute pressure. Hence, if pressure is doubled, the volume is halved.

Charles’ law states that for a fixed mass of gas at constant pressure, the volume is proportional to the absolute temperature.

Dalton’s law states that ‘in a mixture of gases, the pressure exerted by each of the constituent gases is the same as it would exert if it alone occupied the same volume’. The pressure exerted by each constituent is called a partial pressure. The total pressure in a gas mixture is the sum of the partial pressures of the constituents, and these partial pressures can be calculated from the total pressure and the fractional concentrations of the constituents. Hence, in air at sea level where oxygen forms 20.9 per cent of the gas mixture, the partial pressure of oxygen is 20.9 per cent of 1 ata or 760 mmHg, i.e. 0.209 ata, 159 mmHg.
